In the circumstances of *severe global ischemia with prolonged loss of consciousness*, the clinical effects can be quite variable. Following cardiac arrest, for example, consciousness is lost within seconds, but recovery will be complete if breathing, oxygenation of blood, and cardiac action are restored within 3 to 5 min. Beyond 5 min there is usually permanent injury. As shown in experimental models, one of the reasons for the irreversibility of the lesion may be swelling of the endothelium and blockage of circulation into the ischemic cerebral tissues, the so-called no-reflow phenomenon described by Ames and colleagues. Clinically, however, it is often difficult to judge the precise degree and duration of ischemia, since slight heart action or an imperceptible blood pressure may have served to maintain the circulation to some extent. Hence some individuals have made an excellent recovery after cerebral ischemia that apparently lasted 8 to 10 min or longer. Subnormal body temperatures, as might occur when the body is immersed in ice-cold water, greatly prolong the tolerable period of hypoxia. This has led to the successful application of moderate cooling after cardiac arrest as a technique to limit cerebral damage (see further on).

Generally speaking, anoxic patients who demonstrate intact brainstem function—as indicated by normal pupillary light and ciliospinal responses, “doll’s-head” eye movements, and oculovestibular reflexes—have a more favorable outlook for recovery of consciousness and perhaps all of their faculties. Conversely, the absence of these brainstem reflexes even after circulation and oxygenation have been restored, particularly pupils that are unchanged to light, implies a grave outlook in most circumstances, as elaborated further on. If the damage is almost total, coma persists, decerebrate postures may be present spontaneously or in response to painful stimuli, and bilateral Babinski signs can be

evoked. In the first 24 to 48 h, death may terminate this state in a setting of rising temperature, deepening coma, and circulatory collapse, or the syndrome of brain death intervenes, as discussed below.

Most patients who have suffered *severe but lesser degrees of hypoxia* will have stabilized their breathing and cardiac activity by the time they are first examined; yet they may be comatose, with the eyes slightly divergent and motionless but with reactive pupils, the limbs inert and flaccid or intensely rigid, and the tendon reflexes diminished. Within a few minutes after cardiac action and breathing have been restored, generalized convulsions and isolated or grouped myoclonic twitches of muscles may supervene. The seizures, if severe and recurrent, double or treble the oxygen need of cerebral tissues. With severe degrees of injury, the cerebral and cerebellar cortices and parts of the thalamus are partly or completely destroyed but the brainstem-spinal structures survive. Tragically, the individual may survive for an indefinite period in a state that is variously referred to as cortical death, irreversible coma, or *persistent vegetative state* (see page 304).

Some patients remain mute, unresponsive, and unaware of their environment for weeks, months, or years. Long survival is usually attended by some degree of improvement, but the patient appears to know nothing of his present situation and to have lost all past memories, power of reasoning, and capacity for meaningful social interaction and independent existence (a so-called minimally responsive state, actually a severe dementia, page 305). One has only to observe such patients and their families to appreciate the gravity of the problem, the family’s anguish, and the tremendous expense of medical care. The only person who does not appear to suffer is the patient.

With *lesser degrees of anoxic-ischemic injury*, the patient improves after a period of coma lasting hours or less. Some of these patients quickly pass through this acute posthypoxic phase and proceed to make a full recovery; others are left with varying degrees of permanent disability.

The findings on imaging studies vary. The most common early change in cases of severe injury is a loss of the distinction between the cerebral gray and white matter (Fig. 40-1); both ischemia and hypoxia are usually involved. Patient with this finding are invariably comatose and few awaken with a good neurologic outcome. With less severe and predominantly hypotensive-ischemic events such as cardiac arrest, watershed infarctions become evident in the border zones between the anterior, middle, and posterior cerebral arteries (Fig. 40-2). The clinical syndromes associated with watershed infarction are discussed below.

Brain Death Syndrome (See Chap. 17) This represents the most severe degree of oxygen lack, usually caused by circulatory arrest; it is manifest by a state of complete unawareness and unresponsiveness with abolition of all brainstem reflexes. Natural respiration cannot be sustained; only cardiac action and blood pressure are maintained. No electrical activity is seen in the EEG (it is isoelectric). At autopsy one finds that most if not all the gray matter of cerebral, cerebellar, and brainstem structures—and in some instances even the upper cervical spinal cord—has been severely damaged.

One must always exercise caution in concluding that a patient has this form of irreversible brain damage, because anesthesia, intoxication with certain drugs, and hypothermia may also cause deep coma and an isoelectric EEG but permit recovery. Therefore it is often advisable to repeat the clinical and laboratory tests after an interval of a day or so, during which time the results of toxic screen-

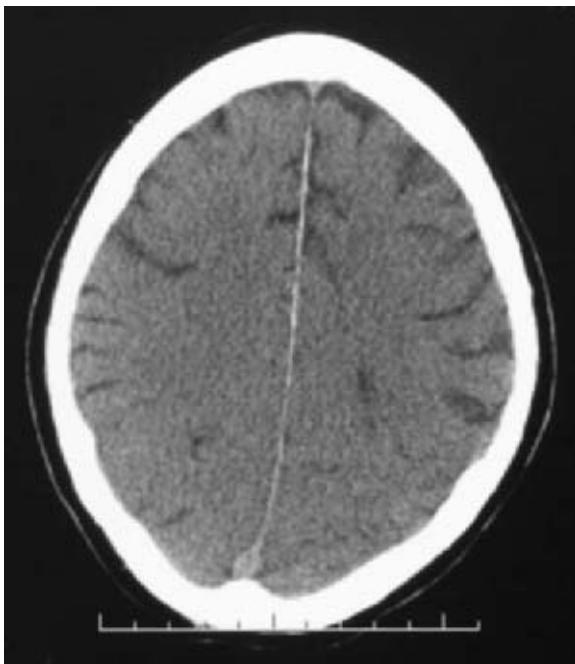

Figure 40-1. CT scan without contrast infusion after cardiac arrest demonstrating the loss of distinction between gray and white matter throughout the cerebral hemispheres. The patient remained comatose and became vegetative.

ing also become available. The authors' experience corroborates the general notion that the vital functions of patients with the brain death syndrome usually cannot be sustained for more than several days; in other words, the problem settles itself. In exceptional cases, however, the provision of adequate fluid, vasopressor, and respiratory support allows preservation of the somatic organism in a comatose state for longer periods.

Posthypoxic Neurologic Syndromes The permanent neurologic sequelae or *posthypoxic syndromes* observed most frequently are as follows:

1. *Persistent coma or stupor*, described above
2. With lesser degrees of cerebral injury, *dementia* with or without extrapyramidal signs
3. *Extrapyramidal (parkinsonian) syndrome with cognitive impairment* (discussed in relation to carbon monoxide poisoning)
4. *Choreoathetosis*
5. *Cerebellar ataxia*
6. *Intention or action myoclonus*
7. *A Korsakoff amnesic state*

If *ischemic hypoperfusion* dominates, the patient may also display the manifestations of watershed infarctions, situated between the end territories of the major cerebral vessels. The main syndromes that become evident soon after the patient awakens are:

1. *Visual agnosias including Balint syndrome and cortical blindness* (page 406), representing infarctions of the watershed between the middle and posterior cerebral arteries (Fig. 40-2)
2. *Proximal arm and shoulder weakness*, sometimes accompa-

nied by hip weakness (referred to as a "man in the barrel" syndrome), reflecting infarction in the territory between the middle and anterior cerebral arteries. These patients are able to walk, but their arms dangle and their hips may be weak.

The two watershed syndromes rarely coexist. The interested reader may consult the appropriate chapter in the text on neurologic intensive care by Ropper and associates for further details.

Seizures may or may not be a problem, and they are often resistant to treatment. Well-formed motor convulsions are infrequent. Myoclonus is more common and may be intermixed with fragmentary convulsions. Myoclonus is a grave sign in most cases, but it generally recedes after several hours or a few days. These movements are also difficult to suppress, as noted further on.

Delayed Postanoxic Encephalopathy This is a relatively uncommon and unexplained phenomenon. Initial improvement, which appears to be complete, is followed after a variable period of time (1 to 4 weeks in most instances) by a relapse, characterized by apathy, confusion, irritability, and occasionally agitation or mania. Most patients survive this second episode, but some are left with serious mental and motor disturbances (Choi; Plum et al). In still other cases, there appears to be progression of the initial neurologic syndrome with additional weakness, shuffling gait, diffuse rigidity and spasticity, sphincteric incontinence, coma, and death after 1 to 2 weeks. Exceptionally, there is yet another syndrome in which an episode of hypoxia is followed by slow deterioration, which progresses for weeks to months until the patient is mute, rigid, and helpless. In such cases the basal ganglia are affected more than the cerebral cortex and white matter as in the case studied by our colleagues Dooling and Richardson. Instances have followed cardiac arrest, drowning, asphyxiation, and carbon monoxide poisoning.

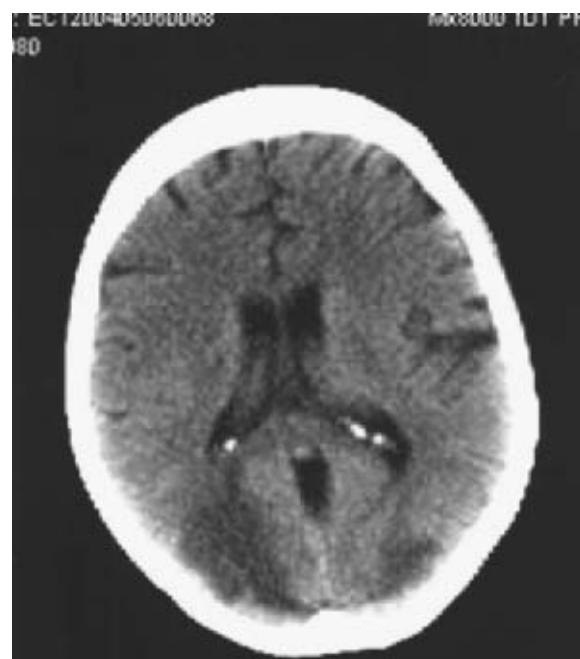

Figure 40-2. Watershed infarction between the middle and posterior cerebral arteries after brief cardiac arrest. The patient had Balint syndrome.

Prognosis of Hypoxic-Ischemic Brain Injury Several logistic models have been developed to predict the outcome of anoxic-ischemic coma. All of them incorporate several simple clinical features involving loss of motor, verbal, and pupillary functions in various combinations. The most often cited and extensive study of the prognostic aspects of coma following cardiac arrest is the one by Levy and colleagues of 150 patients who remained in coma for at least 6 h after cardiac arrest. It has provided the following guidelines: mortality from this state is high: 20 percent died on the first day and 64 percent by the end of 1 week. In terms of recovery, 17 percent of the patients who awakened had done so by 3 days, and only an additional 2 percent did so by 2 days. At the other extreme of the 31 percent of patients who were in a vegetative state at 1 day, 70 percent survived for 1 week, and only 3 patients recovered. Further details pertaining to prognosis are to be found in Chap. 17, "Coma and Related Disorders of Consciousness."

Once intoxication is excluded, the presence of fixed, dilated pupils and paralysis of eye movement for 24 to 48 h, along with absence of motor responses to painful stimuli, signify irreversible cerebral damage. We have never observed deep coma of this type lasting 5 days in an adult or more to be attended by full recovery. The question of what to do with patients in such states of protracted coma is a societal as much as a medical problem. The most that can be expected of the neurologist is to state the level and degree of brain damage, its cause, and the prognosis based on his own and published experience. One prudently avoids heroic, lifesaving therapeutic measures once the nature of this state has been determined with certainty.

Treatment of Hypoxic-Ischemic Encephalopathy Treatment is directed initially to the prevention of further hypoxic injury. As a clear airway is secured, the use of cardiopulmonary resuscitation, a cardiac defibrillator, or pacemaker has its place, and every second counts in their prompt utilization. Once cardiac and pulmonary function are restored, there is experimental and clinical evidence that reducing cerebral metabolic requirements by hypothermia has a slight beneficial effect on outcome and may also prevent the delayed worsening referred to above. The use of barbiturates has not met with the same success. Particular attention is drawn to the randomized trial conducted by Bernard and colleagues of mild hypothermia applied to unconscious patients immediately after cardiac arrest. They reduced the core temperature of affected patients to 33°C (91°F) within 2 h and demonstrated a doubling of the rate of survival and good outcome. These effects were evaluated by coarse measures of neurologic function, and these findings have been corroborated in the smaller trial reported by Zeiner et al. Vaso-dilator drugs, glutamate blockers, and calcium channel blockers are of no proven benefit despite their theoretical appeal and some experimental successes. Oxygen may be of value during the first hours but is probably of little use after the blood becomes well oxygenated. Corticosteroids ostensibly help to allay brain (possibly cellular) swelling, but again, their therapeutic benefit has not been corroborated by clinical trials.

Seizures should be controlled by the methods indicated in Chap. 16. If they are severe, continuous, and unresponsive to the usual anticonvulsant drugs, controlled respiration, continuous infusion of a drug such as midazolam, and eventually the suppression of their convulsive aspect with neuromuscular blocking agents may be required. Often the seizures cease after a few hours and are replaced by polymyoclonus. For the latter, clonazepam, 8 to 12 mg daily in divided doses may be useful, but the commonly used an-

ticonvulsants have little effect in our experience. This state of spontaneous and stimulus-sensitive myoclonus as well as persistent limb posturing usually presages a poor outcome. The striking disorder of delayed movement-induced myoclonus and ataxic tremor that appear after the patient awakens, described by Lance and Adams, is a special issue, discussed on page 89. Its treatment requires the use of multiple medications. Fever is treated with antipyretics or a cooling blanket combined with neuromuscular paralyzing agents.

Carbon Monoxide Poisoning

Strictly speaking, carbon monoxide (CO) is an exogenous toxin, but it is considered here because it produces a unique anoxia and one that is frequently associated with delayed neurologic deterioration. The extreme affinity of CO for hemoglobin (over 200 times that of oxygen) drastically reduces the oxygen content of blood and subjects the brain to prolonged hypoxia and acidosis. Cardiac toxicity and hypotension generally follow. Whether CO also has a direct toxic action on neuronal components is not settled. The effects on the brain for the most part simulate those caused by cardiac arrest. Neurologists are likely to encounter instances of CO poisoning in burn units and in patients who have attempted suicide or have been exposed accidentally to a faulty furnace or to car exhaust in a closed garage.

Early symptoms include headache, nausea, dyspnea, confusion, dizziness, and clumsiness. These occur when the carboxyhemoglobin level reaches 20 to 30 percent of total hemoglobin. Exposure to relatively low levels of CO from faulty furnaces and gasoline engines should be suspected as the cause of recurrent headaches and confusion that clear upon hospitalization or other change of venue. A cherry-red color of the skin may appear but is actually an infrequent finding; cyanosis is more common. At slightly higher levels of carboxyhemoglobin, blindness, visual field defects, and papilledema develop, and levels of 50 to 60 percent are associated with coma, decerebrate or decorticate posturing, seizures in a few patients, and generalized slowing of the EEG rhythms. The initial computed tomography (CT) scanning is normal or shows mild cerebral edema; later scans may show a characteristic lesion in the pallidum, as described below. Only if there has been associated hypotension does one see the same types of border-zone infarctions that appear after cardiac arrest.

Delayed neurologic deterioration 1 to 3 weeks (sometimes much longer) after CO exposure occurs more frequently than with other forms of cerebral hypoxia. In Choi's survey, this feature was observed in 3 percent of 2360 cases of CO poisoning and in 12 percent of those ill enough to be admitted to a hospital. Extrapiramidal features (parkinsonian gait and bradykinesia) predominated. Three-quarters of such patients were said to recover within a year. Discrete lesions centered in the globus pallidus bilaterally and sometimes the inner portion of the putamina are characteristic of CO poisoning that had produced coma (Fig. 40-3), but similar focal destruction may be seen after drowning, strangulation, and other forms of anoxia. The common feature among the delayed-relapse patients is a prolonged period of pure anoxia (before the occurrence of ischemia). Basal ganglial lesions may be quite prominent on CT scans even when delayed neurologic sequelae do not occur, but they are invariably present between 1 and 4 weeks in patients who develop a delayed extrapyramidal syndrome. In less severely affected patients, we have seen such lesions on CT and magnetic resonance imaging (MRI) resolve entirely.

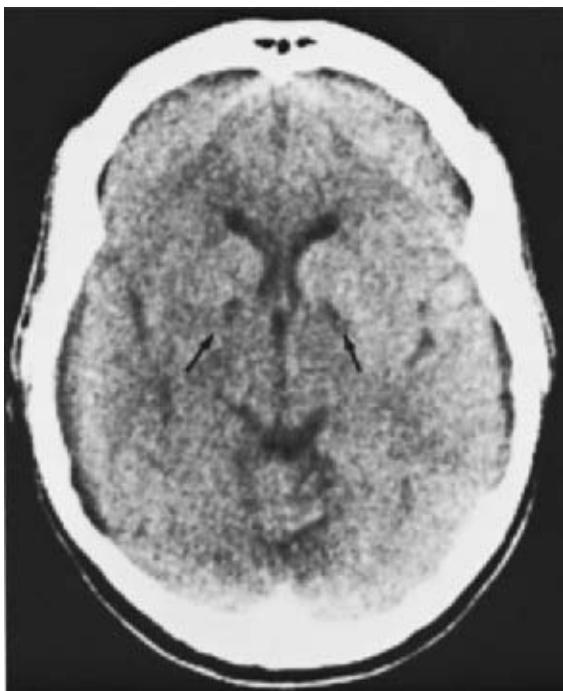

Figure 40-3. Unenhanced CT scan of the brain of a 30-year-old woman who attempted suicide by carbon monoxide inhalation. The only neurologic residua were a mild defect in retentive memory and areas of decreased attenuation in the pallidum bilaterally (*arrows*).

Initial treatment is with inspired oxygen. Because the half-life of CO (normally 5 hours) is greatly reduced by the administration of hyperbaric oxygen at 2 or 3 atmospheres, this treatment is recommended when the carboxyhemoglobin concentration is greater than 40 percent or in the presence of coma or seizures (Myers et al). This treatment reduces the incidence of cognitive sequelae from 46 to 25 percent according to a trial conducted by Weaver and colleagues. They administered three hyperbaric sessions in the first 24 h after exposure to CO.

High-Altitude (Mountain) Sickness

Acute mountain sickness is another special form of cerebral hypoxia. It occurs when a sea-level inhabitant abruptly ascends to a high altitude. Headache, anorexia, nausea and vomiting, weakness, and insomnia appear at altitudes above 8000 ft; on reaching higher altitudes, there may be ataxia, tremor, drowsiness, mild confusion and hallucinations. At 16,000 ft, according to Griggs and Sutton, 50 percent of individuals develop asymptomatic retinal hemorrhages, and it has been suggested that such hemorrhages also occur in the cerebral white matter. Extreme altitude sickness may result in fatal cerebral edema. The overexpression of vascular endothelial growth factor (VEGF), a protein originally noted for its effects on vascular permeability, has been implicated as the cause of cerebral edema in the experiments of Schoch and colleagues. With more prolonged exposure at these altitudes or with further ascent, affected individuals suffer mental impairment that may progress to coma. Hypoxemia at high altitude is intensified during sleep, as ventilation normally diminishes. Reference was made earlier to the observation of Hornbein and colleagues of a mild but possibly lasting memory impairment in even acclimated mountaineers who have been exposed to extremely high altitudes for several days.

The treatments for altitude illness are reviewed by Hackett and Roach.

Chronic mountain sickness, sometimes called Monge disease (after the physician who described the condition in Andean Indians of Peru), is observed in long-term inhabitants of high-altitude mountainous regions. Pulmonary hypertension, cor pulmonale, and secondary polycythemia are the main features. There is usually hypercarbia as well, with the expected degree of mild mental dullness, slowness, fatigue, nocturnal headache, and sometimes papilledema (see below). Thomas and colleagues have called attention to a syndrome of burning hands and feet in these groups of Peruvians, apparently another maladaptive response to high altitude.

Sedatives, alcohol, and a slightly elevated PCO₂ in the blood all reduce one's tolerance to high altitude. Dexamethasone and acetazolamide prevent and counteract mountain sickness to some extent. The most effective preventive measure is acclimatization by a 2- to 4-day stay at intermediate altitudes of 6000 to 8000 ft.

Hypercapnic Pulmonary Disease

Chronic obstructive pulmonary disease such as emphysema, fibrosing lung disease, neuromuscular weakness, and in some instances an inadequacy of the medullary respiratory centers each may lead to persistent respiratory acidosis, with elevated of PCO₂ and reduced in arterial PO₂. The complete clinical syndrome of chronic hypercapnia described by Austen, Carmichael, and Adams comprises *headache, papilledema, mental dullness, drowsiness, confusion, stupor and coma, and asterixis*. More typically, only some of these features are found. Some patients have a fast-frequency tremor. The headache tends to be generalized, frontal, or occipital and can be quite intense, persistent, steady, and aching in type; nocturnal occurrence is a feature of some cases. The papilledema is bilateral but may be slightly greater in one eye than in the other, and hemorrhages may encircle the choked disc (a later finding). Visual acuity is undiminished and the visual fields are full. The tendon reflexes are lively and plantar reflexes may be extensor. Intermittent drowsiness, indifference to the environment, inattentiveness, reduction of psychomotor activity, inability to perceive all the items in a sequence of events, and forgetfulness constitute the more subtle manifestations of this syndrome and may prompt the family to seek medical help. Such symptoms may last only a few minutes or hours, and one cannot count on their presence at the time of a particular examination. In fully developed cases, the CSF is under increased pressure; PCO₂ may exceed 75 mmHg, and the O₂ saturation of arterial blood ranges from 85 percent to as low as 40 percent. The EEG shows slow activity in the delta or theta range, which is sometimes bilaterally synchronous.

The mechanism of the cerebral disorder is said to be a direct CO₂ narcosis, but the biochemical details are not known. Normally the CSF is slightly acidotic in comparison to the blood, and the PCO₂ of the CSF is about 10 mmHg higher than that of the blood. With respiratory acidosis, the pH of the CSF falls (into the range of 7.15 to 7.25) and cerebral blood flow increases as a result of cerebral vasodilatation. However, the brain rapidly adapts to respiratory acidosis through the generation and secretion of bicarbonate by the choroid plexuses. Brain water content also increases, mainly in the white matter. In animal models of hypercarbia, blood and brain NH₃ is elevated, which may explain the similarity of the syndrome to that of hyperammonemic liver failure (Herrera and Kazemi).

The most effective therapeutic measures are ventilation with

a positive-pressure device, using oxygen if there is hypoxia. Oxygen supplementation is, of course, used cautiously in these patients in order to avoid suppressing respiratory drive—marginally compensated patients treated with excessive oxygen have lapsed into coma. Treatment of heart failure, phlebotomy to reduce the viscosity of the blood, and antibiotics to suppress pulmonary infection may be necessary. Often these measures result in a surprising degree of improvement, which may be maintained for months or years.

Unlike pure hypoxic encephalopathy, prolonged coma due to hypercapnia is relatively rare and in our experience has not led to irreversible brain damage. Papilledema and jerky, intermittent lapses of sustained muscular contraction (asterixis) are important diagnostic features. If aminophylline is administered for the treatment of the underlying pulmonary airway disease, there may be a tendency for seizures. The syndrome is apt to be mistaken for a brain tumor, confusional psychosis of other type, or a disease causing chorea or myoclonus. In the last instance, hypercapnia must be distinguished from other metabolic diseases presenting as chronic extrapyramidal syndromes, as described later in this chapter.

Hypoglycemic Encephalopathy

This condition is now relatively infrequent but is an important cause of confusion, convulsions, stupor, and coma; as such, it merits separate consideration as a metabolic disorder of the brain. The essential biochemical abnormality is a critical lowering of the blood glucose. At a level of about 30 mg/dL, the cerebral disorder takes the form of a confusional state, and one or more seizures may occur; at a level of 10 mg/dL, there is profound coma that may result in irreparable injury to the brain if not corrected immediately by the administration of glucose. As with most other metabolic encephalopathies, the rate of decline of blood glucose is a factor.

The normal brain has a glucose reserve of 1 to 2 g (30 mmol per 100 g of tissue), mostly in the form of glycogen. Since glucose is utilized by the brain at a rate of 60 to 80 mg/min, the glucose reserve will sustain cerebral activity for only about 30 min once blood glucose is no longer available. Glucose is transported from the blood to the brain by an active carrier system. Glucose entering the brain either undergoes glycolysis or is stored as glycogen. During normal oxygenation (aerobic metabolism), glucose is converted to pyruvate, which enters the Krebs cycle; with anaerobic metabolism, lactate is formed. The oxidation of 1 mol of glucose requires 6 mol of O_2 . Of the glucose taken up by the brain, 85 to 90 percent is oxidized; the remainder enters an amino acid pool and is utilized in the formation of proteins and other substances—notably neurotransmitters and particularly gamma-aminobutyric acid (GABA).

When blood glucose falls, the CNS can utilize nonglucose substrates to a variable extent for its metabolic needs, especially keto acids and intermediates of glucose metabolism such as lactate, pyruvate, fructose, and other hexoses. In the neonatal brain, which has a higher glycogen reserve, keto acids provide a considerable proportion of cerebral energy requirements; this also happens after prolonged starvation. However, in the face of severe and sustained hypoglycemia, these nonglucose substrates are not adequate to preserve the structural integrity of neurons, and eventually adenosine triphosphate (ATP) is depleted as well. If convulsions occur, they usually do so during a period of mental confusion; the convulsions have been attributed to an altered integrity of neuronal membranes and to elevated NH_3 and depressed GABA and lactate levels (Wilkinson and Prockop).

The brain is the only organ besides the heart that suffers severe functional and structural impairment under conditions of severe hypoglycemia. Beyond what is described above, the pathophysiology of the cerebral disorder has not been fully elucidated. It is known that hypoglycemia reduces O_2 uptake and increases cerebral blood flow. As with anoxia and ischemia, there is experimental evidence that the excitatory amino acid glutamate is involved in the damaging process. The levels of several brain phospholipid fractions decrease when animals are given large doses of insulin. However, the suggestion that hypoglycemia results in a rapid depletion and inadequate production of high-energy phosphate compounds has not been corroborated; some other glucose-dependent biochemical process must be implicated.

Etiology The most common causes of hypoglycemic encephalopathy are (1) accidental or deliberate overdose of insulin or an oral diabetic agent; (2) islet cell insulin-secreting tumor of the pancreas; (3) depletion of liver glycogen, which occasionally follows a prolonged alcoholic binge, starvation, or some form of acute liver disease such as acute nonicteric hepatoencephalopathy of childhood (Reye syndrome); (4) glycogen storage disease of infancy; and (5) an idiopathic hypoglycemia in the neonatal period and, less often, of infancy. Moderate degrees of hypoglycemia (50 mg/dL) may be observed with chronic renal insufficiency (Fisher et al). In the past, hypoglycemic encephalopathy was a not infrequent complication of “insulin shock” therapy for schizophrenia. In functional hyperinsulinism, as occurs in anorexia nervosa and dietary faddism, the hypoglycemia is rarely of sufficient severity or duration to damage the CNS.

Clinical Features The initial symptoms appear when the level of blood glucose has descended to about 30 mg/dL—nervousness, hunger, flushed facies, sweating, headache, palpitation, trembling, and anxiety. These gradually give way to confusion and drowsiness and occasionally to excitement, overactivity, and bizarre or combative behavior. Many of the early and mild symptoms relate to adrenal and sympathetic overactivity; therefore some of the manifestations may be muted in diabetic patients with neuropathy. In the next stage, forced sucking, grasping, motor restlessness, muscular spasms, and decerebrate rigidity occur, in that sequence. Myoclonic twitching and convulsions develop in some patients. Rarely there are focal cerebral deficits, the pathogenesis of which remains unexplained; according to Malouf and Brust, hemiplegia, corrected by intravenous glucose, was observed in 3 of 125 patients who presented with symptomatic hypoglycemia.

Blood glucose levels of approximately 10 mg/dL are associated with deep coma, dilatation of pupils, pale skin, shallow respiration, slow pulse, and hypotonia of limb musculature—the “medullary phase” of hypoglycemia. If glucose is administered before this level has been attained, the patient can be restored to normalcy, retracing the aforementioned steps in reverse order. However, once the medullary phase is reached, and particularly if it persists for a time before the hypoglycemia is corrected by intravenous glucose or spontaneously as a result of the gluconeogenic activities of the adrenal glands and liver, recovery is delayed for a period of days or weeks and may be incomplete as noted below.

The EEG is altered as the blood glucose falls, but the correlations are inexact. There is diffuse slowing in the theta or delta range. During recovery, sharp waves may appear and coincide in some cases with seizures.

A large dose of insulin, which produces intense hypoglyc-

mia, even of relatively brief duration (30 to 60 min), is more dangerous than a series of less severe hypoglycemic episodes from smaller doses of insulin, possibly because the former impairs or exhausts essential enzymes—a condition that cannot then be overcome by large quantities of intravenous glucose.

The major clinical differences between hypoglycemic and hypoxic encephalopathy lie in the setting and the mode of evolution of the neurologic disorder. The effects of hypoglycemia usually unfold more slowly, over a period of 30 to 60 min, rather than in a few seconds or minutes. The recovery phase and sequelae of the two conditions are quite similar. A severe and prolonged episode of hypoglycemia may result in permanent impairment of intellectual function as well as other neurologic residua, like those that follow severe anoxia. We have also observed states of protracted coma as well as relatively pure Korsakoff amnesia. However, one should not be hasty in prognosis, for we have observed slow improvement to continue for 1 to 2 years.

Recurrent hypoglycemia, as with an islet cell tumor, may masquerade for some time as an episodic confusional psychosis or convulsive illness; diagnosis then awaits the demonstration of low blood glucose or hyperinsulinism in association with the neurologic symptoms. We saw a man in the emergency department whose main complaint was episodic inability to dial a touch-tone phone and a mild mental fogginess; he was found to have an insulinoma.

According to Marks and Rose, who have written an authoritative monograph on the subject, lesser degrees and more chronic forms of low blood glucose may produce two other distinct but not mutually exclusive syndromes. One of these, categorized as *subacute hypoglycemia*, consists of drowsiness and lethargy, diminution in psychomotor activity, deterioration of social behavior, and confusion. Oral or intravenous glucose will immediately alleviate the symptoms. In the other syndrome, termed *chronic hypoglycemia*, there is a gradual deterioration of intellectual function, raising the question of dementia; in some reported instances, tremor, chorea, rigidity, cerebellar ataxia, and rarely signs of lower motor neuron involvement (*hypoglycemic amyotrophy*) are added. The last of these features has not been seen by the authors, who can only refer the reader to the report of Tom and Richardson.

These subacute and chronic forms of hypoglycemia have been observed in conjunction with islet cell hypertrophy and islet cell tumors of the pancreas, carcinoma of the stomach, fibrous mesothelioma, carcinoma of the cecum, and hepatoma. Supposedly an insulin-like substance is elaborated by these nonpancreatic tumors.

Functional or reactive hypoglycemia is the most ambiguous of all syndromes related to low blood glucose. This condition is usually idiopathic but may precede the onset of diabetes mellitus. The rise of insulin in response to a carbohydrate meal is delayed but then causes an excessive fall in blood glucose, to 30 to 40 mg/dL. The symptoms are malaise, fatigue, nervousness, headache, tremor, and so on, which may be difficult to distinguish from anxious depression. Not surprisingly, the term *functional hypoglycemia* has been much abused, being applied indiscriminately to a variety of complaints that would now be called chronic fatigue syndrome or simply anxiety neurosis. In fact, the syndrome of functional or reactive hypoglycemia is rare and its diagnosis requires the finding of an excessive reaction to insulin, a low blood glucose during the symptomatic period, and a salutary response to oral glucose. Treatment, which consists of a high-protein, low-carbohydrate diet, should be reserved for patients whose symptom complex correlates with pronounced hypoglycemia, as documented by a 5-h glucose tolerance test.

Pathologically, in all forms of hypoglycemic encephalopathy, the major damage is to the cerebral cortex. Cortical nerve cells degenerate and are replaced by microglial cells and astrocytes. The distribution of lesions is similar, though probably not identical to that in hypoxic encephalopathy. The cerebellar cortex is less vulnerable to hypoglycemia than to hypoxia. Auer has described the ultrastructural changes in neurons resulting from experimental hypoglycemia; with increasing duration of hypoglycemia and EEG silence, there are mitochondrial changes, first in dendrites and then in nerve cell soma, followed by nuclear membrane disruption leading to cell death.

Treatment of all forms of hypoglycemia obviously consists of correction of the hypoglycemia at the earliest possible moment. It is not known whether hypothermia or other measures will increase the safety period in hypoglycemia or alter the outcome. Seizures and twitching may not stop with anticonvulsants until the hypoglycemia is corrected.

Hyperglycemia

Two syndromes have been defined, mainly in diabetics: (1) hyperglycemia with ketoacidosis and (2) hyperosmolar nonketotic hyperglycemia.

In *diabetic acidosis*, the familiar picture is one of dehydration, fatigue, weakness, headache, abdominal pain, dryness of the mouth, stupor or coma, and Kussmaul type of breathing. Usually the condition has developed over a period of days in a patient known or proven to be diabetic. Often, the patient had failed to take a regular insulin dose. The blood glucose level is found to be more than 400 mg/dL, the pH of the blood less than 7.20, and the bicarbonate less than 10 meq/L. Ketone bodies and B-hydroxybutyric acid are elevated in the blood and urine, and there is a marked glycosuria. The prompt administration of insulin and repletion of intravascular volume correct the clinical and chemical abnormalities over a period of hours.

Of considerable interest is a small group of patients with diabetic ketoacidosis, such as those reported by Young and Bradley, in whom deepening coma and cerebral edema develop as the elevated blood level of glucose is corrected. Mild cerebral edema is commonly observed in children during treatment with fluids and insulin (Krane et al). This condition has been attributed by Prockop to an accumulation of fructose and sorbitol in the brain. The latter substance, a polyol that is formed during hyperglycemia, crosses membranes slowly, but once it does so is said to cause a shift of water into the brain and an intracellular edema. However, according to Fishman, the increased polyols in the brain in hyperglycemia are not present in sufficient concentration to be important osmotically; they may induce other metabolic effects related to the encephalopathy. These are matters of conjecture, since the increase of polyols has never been found. The brain edema in this condition is probably due to reversal of the osmolality gradient from blood to brain, which occurs with rapid correction of hyperglycemia.

The pathophysiology of the cerebral disorder in diabetic ketoacidosis is not fully understood. No consistent cellular pathology of the brain has been identified in the cases we have examined. Factors such as ketosis, tissue acidosis, hypotension, hyperosmolality, and hypoxia have not been identified. Attempts at therapy by the administration of urea, mannitol, salt-poor albumin, and dexamethasone are usually unsuccessful, though recoveries are reported.

In *hyperosmolar nonketotic hyperglycemia*, the blood glucose

is extremely high, over 600 mg/dL, but ketoacidosis does not develop or is mild. Osmolality is usually around 350 mosmol/L. There is also hemoconcentration and prerenal azotemia. Appreciation of the neurologic syndrome is generally credited to Wegierko, who published descriptions of it in 1956 and 1957. Most of the patients are elderly diabetics, but some were not previously known to have been diabetic. An infection, enteritis, pancreatitis, or a drug known to upset diabetic control (thiazides, prednisone, phenytoin) leads to polyuria, fatigue, confusion, stupor, and coma. Often the syndrome arises in conjunction with the combined use of corticosteroids and phenytoin (which inhibits insulin release), for example, in elderly patients with brain tumors. The use of osmotic diuretics enhances the risk. If the patient is seen before coma supervenes, seizures and focal signs such as a hemiparesis, a hemisensory defect, or a homonymous visual field defect may have erroneously suggested the possibility of a stroke. The mortality rate has been as high as 40 percent. Fluids should be replaced cautiously, using isotonic saline and potassium. Correction of the markedly elevated blood glucose requires relatively small amounts of insulin, since these patients often do not have a high degree of insulin resistance.

Hepatic Stupor and Coma (Hepatic or Portal-Systemic Encephalopathy)

Chronic hepatic insufficiency with portacaval shunting of blood is punctuated by episodes of stupor, coma, and other neurologic symptoms—a state referred to as *hepatic stupor, coma, or encephalopathy*. It was delineated by Adams and Foley in 1949. This state complicates all varieties of liver disease and is unrelated to jaundice or ascites. Less widely known is the fact that a surgical portal-systemic shunt (Eck fistula) is attended by the same clinical picture, in which case the liver itself may be little or not at all affected (see further on). Also, there are a number of hereditary hyperammonemic syndromes, usually first apparent in infancy or childhood (see Chap. 37), that lead to episodic coma with or without seizures. In all these states, it is common for an excess of protein derived from the diet or from gastrointestinal hemorrhage to induce or worsen the encephalopathy. Additional predisposing factors are hypoxia, hypokalemia, metabolic alkalosis, excessive diuresis, use of sedative hypnotic drugs, and constipation. Reye syndrome, a special type of acute nonicteric hepatic encephalopathy of children, is also associated with very high levels of ammonia in the blood (see further on).

Clinical Features The clinical picture of acute, subacute, or chronic hepatic encephalopathy consists essentially of a derangement of consciousness, presenting first as mental confusion with decreased psychomotor activity, occasionally with hyperactivity, followed by progressive drowsiness, stupor, and coma. The confusional state, before coma supervenes, is combined with a characteristic intermittency of sustained muscle contraction; this phenomenon, which was originally described in patients with hepatic stupor by Adams and Foley and called *asterixis* (from the Greek *sterixis*, a “fixed position”), is now recognized as a sign of various metabolic encephalopathies but is most prominent in this disorder (page 86). It is conventionally demonstrated by having the patient hold his arms outstretched with the wrists extended, but the same tremor can be elicited by any sustained posture, including that of the protruded tongue. A variable, fluctuating rigidity of the trunk and limbs, grimacing, suck and grasp reflexes, exaggeration

or asymmetry of tendon reflexes, Babinski signs, and focal or generalized seizures round out the clinical picture in a few patients.

The EEG is a sensitive and reliable indicator of impending coma, becoming abnormal during the earliest phases of the disordered mental state. Watson and Adams noted an EEG abnormality consisting of paroxysms of bilaterally synchronous slow or triphasic waves in the delta range, which at first predominate frontally and are interspersed with alpha activity and later, as the coma deepens, displace all normal activity (Fig. 2-3H, page 27). A few patients show only random high-voltage asynchronous slow waves.

This syndrome of hepatic encephalopathy is remarkably diverse in its course and evolution. It usually appears over a period of days to weeks and may terminate fatally; or, with appropriate treatment, the symptoms may regress completely or partially and then fluctuate in severity for several weeks or months. Persistent hepatic coma of the latter type proves fatal in about half of patients (Levy et al). In many patients, the syndrome is relatively mild and does not evolve beyond the stage of mental dullness and confusion, with asterixis and EEG changes. In yet others, a subtle disorder of mood, personality, and intellect may be protracted over a period of many months or even years; this chronic but nevertheless reversible mental disturbance need not be associated with overt clinical signs of liver failure (mainly jaundice and ascites) or other neurologic signs. Characteristically in these patients, an extensive portal-systemic collateral circulation can be demonstrated (hence the term *portal-systemic encephalopathy*) and an association established between the mental disturbance and an intolerance to dietary protein as well as raised blood ammonia levels (Summerskill et al).

The diversion of blood from the portal system into the vena cava after ligation of the portal veins was first performed in dogs by Eck in 1877. Probably the first and certainly most striking example in man was the case of pure Eck fistula reported by McDermott and Adams, in which a portacaval shunt was created during the removal of a pancreatic tumor. The liver was normal. Episodic coma occurred thereafter whenever dietary protein increased. Consciousness was restored on a protein-free diet, and coma could be induced again by ammonium chloride. Postmortem examination 2 years later confirmed the normal liver and showed cerebral changes of hepatic encephalopathy, as described below.

Finally, there is a group of patients (most of whom have experienced repeated attacks of hepatic coma) in whom an *irreversible* mild dementia and a disorder of posture and movement (grimacing, tremor, dysarthria, ataxia of gait, choreoathetosis) gradually appear. This condition of *chronic acquired hepatocerebral degeneration* must be distinguished from other dementing and extrapyramidal syndromes (see further on). A few cases of isolated spastic-ataxic paraparesis (so-called *hepatic myelopathy*) of unclear nature have also been described (page 1078).

The concentrations of blood NH₃, particularly if measured repeatedly in arterial blood samples, usually are well in excess of 200 mg/dL, and the severity of the neurologic and EEG disorders roughly parallels to the ammonia levels. With treatment, a fall in the NH₃ levels precedes clinical improvement. In the past, a provocative test of an oral dose of 6.0 g of NH₃Cl was used in uncertain cases to produce mild symptoms of hepatic encephalopathy.

Neuropathologic Changes The striking finding by Adams and Foley in patients who die in a state of hepatic coma is a diffuse increase in the number and size of the protoplasmic astrocytes in the deep layers of the cerebral cortex, lenticular nuclei, thalamus, substantia nigra, cerebellar cortex, and red, dentate, and pontine

nuclei, with little or no visible alteration in the nerve cells or other parenchymal elements. With periodic acid-Schiff (PAS) staining, the astrocytes are seen to contain characteristic glycogen inclusions. These abnormal glial cells are generally referred to as Alzheimer type II astrocytes, having been described originally in 1912 by von Hosslin and Alzheimer in a patient with Westphal-Strümpell pseudosclerosis (familial hepatolenticular degeneration, or Wilson disease). These astrocytes have been studied by electron microscopy in rats with surgically created portacaval shunts (Cavanagh; Norenberg); the cells show a number of striking abnormalities—swelling of their terminal processes, cytoplasmic vacuolation (distended sacs of rough endoplasmic reticulum), formation of folds in the basement membrane around capillaries, and an increase in both the number of mitochondria and enzymes that catabolize ammonia. Also, some degeneration in myelinated nerve fibers in the neuropil and an increase in the cytoplasm of oligodendrocytes are seen. In chronic cases, we have found neuronal loss in the deep layers of the cerebral and cerebellar cortex and in the lenticular nuclei as well as a vacuolization of tissue (possibly astrocyte vacuolation) resembling the lesions of Wilson disease.

The ubiquitous astrocytic alterations occur to some degree in all patients who die of progressive liver failure, and the degree of this glial abnormality corresponds generally to the intensity and duration of the neurologic disorder. Possibly, the astrocytic changes affect the synaptic activities of the neurons. The clinical and EEG features of hepatic encephalopathy as well as the astrocytic hyperplasia are more or less specific features of this metabolic disorder. Nevertheless, taken together in a setting of liver failure, they constitute a distinctive clinicopathologic entity.

Pathogenesis of Hepatic Encephalopathy The most plausible hypothesis relates hepatic coma to an abnormality of nitrogen metabolism, wherein ammonia, which is formed in the bowel by the action of urease-containing organisms on dietary protein, is carried to the liver in the portal circulation but fails to be converted into urea because of either hepatocellular disease, portal-systemic shunting of blood, or both. As a result, excess amounts of NH₃ reach the systemic circulation, where they interfere with cerebral metabolism in a way that is not yet fully understood. Certainly the ammonia theory best explains the basic neuropathologic change. Norenberg has proposed that the hypertrophy of the astrocytic cytoplasm and proliferation of the mitochondria and endoplasmic reticulum, as well as the increase in the astroglial glutamic dehydrogenase activity, reflect the heightened metabolic activity associated with ammonia detoxification. Removal of brain ammonia depends on the formation of glutamine, a reaction that is catalyzed by the ATP-dependent enzyme glutamine synthetase, which is localized in the astrocytes. It has been shown in experimental animals that hyperammonemia leads to a depletion of ATP in midbrain reticular nuclei. Whether this is the primary cause of coma has not been resolved.

Numerous alternative theories have been suggested, but most can be discounted or are unproved. One is that CNS function in cirrhotic patients is impaired by phenols or short-chain fatty acids derived from the diet or from bacterial metabolism of carbohydrate. Another theory holds that biogenic amines (e.g., octopamine), which arise in the gut and bypass the liver, act as false neurotransmitters, displacing norepinephrine and dopamine (Fischer and Baldessarini). Zieve has presented evidence that mercaptans (methanethiol, methionine), which are also generated in the gastrointestinal tract and removed by the liver, act in conjunction with

NH₃ to produce hepatic encephalopathy. This theory and others has been the subject of reviews by Butterworth and coworkers, by Zieve, by Rothstein and Herlong, and by Jones and Basile, to which the reader is referred for detailed information.

Also in recent years, manganese has emerged as a potential neurotoxin in the pathogenesis of hepatic encephalopathy (Kreiger et al; Pomier-Layrargues et al). In patients with chronic liver disease and with spontaneous or surgically induced portal-systemic shunts, manganese accumulates in the serum and in the brain, more specifically in the pallidum. This accumulation is readily discernible as a pallidal signal hyperintensity on T1-weighted MRI. Following liver transplantation, there is normalization of the MRI changes and of the associated extrapyramidal symptoms. The effects of manganese chelation on such patients have not been studied, and the mechanisms of accumulated manganese in the pathogenesis of hepatic encephalopathy are not known. None in our view is as persuasive as the case for ammonia. For some time, it has been known that hepatic encephalopathy is associated with increased activity of the inhibitory transmitter GABA in the cerebral cortex. It has also been observed that increased GABA-nergic neurotransmission may result from substances that inhibit the binding of endogenous benzodiazepine-like compounds to their receptors (Basile et al). Furthermore, these antagonists are found to have some clinical effect—transient arousal in patients with hepatic encephalopathy. The actions of benzodiazepines are mediated by these receptors; hence the designation *GABA-benzodiazepine theory*. The practicality of using benzodiazepine receptor antagonists, which are short-acting and reversible (e.g., flumazenil), in the treatment of hepatic encephalopathy remains to be determined (see Mullen), but they offer an interesting diagnostic test.

Until recently, the ammonia and the GABA-nergic-benzodiazepine hypotheses of the pathogenesis of hepatic encephalopathy had appeared to be unrelated and even mutually exclusive. However, there is evidence, reviewed by Jones and Basile, that ammonia, even in the modestly elevated concentrations that occur in liver failure, enhances GABA-nergic neurotransmission—a concept that may unify the two mechanisms.

Treatment Despite the incompleteness of our understanding of the role of disordered ammonia metabolism in the genesis of hepatic coma, an awareness of this relationship has provided the few effective means of treating this disorder: restriction of dietary protein; reduction of bowel flora by oral administration of neomycin or kanamycin, which suppress the urease-producing organisms in the bowel; and the use of enemas. The mainstay of treatment has been oral lactulose, an inert sugar that acidifies the colonic contents and greatly reduces bacterial activity. The sustained use of oral neomycin carries a risk of renal damage and ototoxicity and has therefore been relegated to second-line therapy. The salutary effects of these therapeutic measures, the common attribute of which is the lowering of the blood NH₃, further supports the theory of ammonia intoxication. Ultimately, in cases of intractable liver failure, transplantation becomes a treatment of last resort.

Other treatments, the values of which remain to be established, include the use of bromocriptine, the diazepine antagonist flumazenil, and keto-analogues of essential amino acids. Theoretically, the keto-analogues should provide a nitrogen-free source of essential amino acids (Maddrey et al), and bromocriptine, a dopamine agonist, should enhance dopaminergic transmission (Morgan et al). Administration of branched-chain amino acids may result in considerable improvement in mental status, but their effects have

been variable and associated with an increased mortality (Naylor et al). The transient beneficial effects of the benzodiazepine antagonist flumazenil have already been mentioned.

Fulminant Hepatic Failure and Cerebral Edema In *acute hepatitis*, confusional, delirious, and comatose states also occur, but their mechanisms are still unknown. Blood NH₃ may be elevated, but usually not to a degree that would be expected to affect the brain. Severe acute hepatic failure may cause hypoglycemia, which contributes to the encephalopathy and often presages a fatal outcome, but the levels of glucose typically detected do not provide an explanation for the encephalopathy.

Cerebral edema is a prominent finding in cases of fulminant hepatic failure from any cause and is the main cause of death in patients awaiting liver transplantation. The cerebral edema that occurs in these circumstances appears to be related to the rapidity of rise of blood ammonia, but it probably depends as well on additional metabolic derangements that complicate acute liver failure. The combination of rapidly evolving hepatic failure and massive cerebral edema is similar to that observed in the Reye syndrome, described below.

CT scanning is an effective means of detecting cerebral edema in patients with fulminant hepatic failure, and according to Wijdicks and colleagues, the degree of cerebral swelling is roughly proportional to the severity of encephalopathy. Since patients with fulminant hepatic failure can survive liver transplantation with few or no neurologic deficits, it is important to recognize cerebral edema early, before the stages of stupor and coma and greatly increased intracranial pressure have been established. Short of transplantation, death in these cases may sometimes be prevented by monitoring the intracranial pressure (as outlined by Lidofsky et al) and by the use of osmotic diuretics and hyperventilation, as detailed in Chaps. 31 and 35. Some survivors are nonetheless left with cerebral damage from raised intracranial pressure.

An additional issue that arises in assessing cerebral dysfunction in patients with liver disease is the possibility of adverse effects of medications. Individuals with hepatitis C who are treated with interferon alpha may develop a spectrum of problems ranging from subtle cognitive impairment to a subacutely worsening headache, vomiting, altered consciousness, and focal neurologic findings. The milder syndromes are associated with no or few MRI-visible lesions, but the severe ones are usually accompanied by signal changes in the white matter of the occipital lobes and elsewhere (posterior leukoencephalopathy, page 1040).

Reye Syndrome (Reye-Johnson Syndrome) This is a special type of nonicteric hepatic encephalopathy occurring in children and adolescents and characterized by acute brain swelling in association with fatty infiltration of the viscera, particularly the liver. Although individual cases of this disorder had been described for many years, its recognition as a clinical-pathologic entity dates from 1963, when a large series was reported from Australia by Reye and colleagues and from the United States by Johnson and coworkers. The disorder tends to occur in outbreaks (286 cases were reported to the Centers for Disease Control during a 4-month period in 1974). Mainly, these outbreaks were observed in association with influenza B virus and varicella infections, but a variety of other viral infections were implicated (influenza A, echovirus, reovirus, rubella, rubeola, herpes simplex, Epstein-Barr virus). Later it became apparent that the toxic or adjuvant effects of aspirin given during these infections played an important role in producing the disease.

Only occasional instances of Reye syndrome are observed now that the association with aspirin administration has become widely known and its use in children with viral infections has been interdicted.

Most patients are children, boys and girls being equally affected, but rare instances are known in infants (Huttenlocher and Trauner) and young adults. In most cases the encephalopathy is preceded for several days to a week by fever, symptoms of upper respiratory infection, and protracted vomiting. These are followed by the rapid evolution of stupor and coma, associated in many cases with focal and generalized seizures, signs of sympathetic overactivity (tachypnea, tachycardia, mydriasis), decorticate and decerebrate rigidity, and loss of pupillary, corneal, and vestibulo-ocular reflexes. One or two such cases were included in the series of acute “toxic encephalopathy” reported by Lyon and colleagues (page 603). In infants, respiratory distress, tachypnea, and apnea are the most prominent features.

The liver may be greatly enlarged, often extending to the pelvis and providing an important diagnostic clue as to the cause of the cerebral changes. Initially there is a metabolic acidosis, followed by a respiratory alkalosis (rising arterial pH and falling PCO₂). The CSF is usually under increased pressure and is acellular; glucose values may be low, reflecting the hypoglycemia. The serum glutamic-oxaloacetic transaminase (SGOT), coagulation times, and blood ammonia are increased, sometimes to an extreme degree. The EEG is characterized by diffuse arrhythmic delta activity, progressing to electrocerebral silence in patients who fail to survive. CT and MRI show the cerebral swelling but are difficult to interpret in these young individuals, who lack any adult brain atrophy.

The major *pathologic findings* are cerebral edema, often with cerebellar herniation, and infiltration of hepatocytes with fine droplets of fat (mainly triglycerides); the renal tubules, myocardium, skeletal muscles, pancreas, and spleen are infiltrated to a lesser extent. There are no inflammatory lesions in the brain, liver, or other organs. There is not full agreement as to the pathogenesis of this disorder.

Prognosis and Treatment In a series of children with blood ammonia levels greater than 500 mg/dL who were treated during the years 1967 to 1974, Shaywitz and colleagues reported a mortality of 60 percent. Once the child became comatose, death was almost inevitable. In more recent years, early diagnosis and initiation of treatment before the onset of coma have reduced the fatality rate to 5 to 10 percent. Treatment consists of the following measures: temperature control with a cooling blanket; nasotracheal intubation and controlled ventilation to maintain PCO₂ below 32 mmHg; intravenous glucose covered by insulin to maintain blood glucose at 150 to 200 mg/dL; administration of lactulose and neomycin enemas; control of intracranial pressure by means of continual monitoring and the use of hypertonic solutions (see Chap. 30); and the maintenance of fluid and electrolyte balance (Trauner). Upon recovery, cerebral function returns to normal unless there had been deep and prolonged coma or protracted elevation of intracranial pressure.

Uremic Encephalopathy and Twitch-Convulsive Syndrome

Episodic confusion and stupor and other neurologic symptoms may accompany any form of severe renal disease—acute or chronic. The cerebral symptoms attributable to uremia (first described by

Addison in 1832) are best discerned in normotensive individuals in whom renal failure develops rapidly. Apathy, fatigue, inattentiveness, and irritability are usually the initial symptoms; later, there is confusion, disturbance of sensory perception, hallucinations, dysarthria, tremor, and asterixis. Infrequently this takes the form of a toxic psychosis, with hallucinations, delusions, insomnia, or catatonia (Marshall). Characteristically these symptoms fluctuate from day to day or even from hour to hour. In some patients, especially those who become anuric, symptoms may come on rather abruptly and progress rapidly to a state of stupor and coma. In others, in whom uremia develops more gradually, mild visual hallucinations and a disorder of attention may persist for several weeks in relatively pure form. The EEG becomes diffusely and irregularly slow and may remain so for several weeks after the institution of dialysis. The CSF pressure is normal and the protein is not elevated unless there is a uremic or diabetic neuropathy. In several reports, meningismus and a low-grade mononuclear pleocytosis is mentioned, but we have not found this.

In acute renal failure, clouding of the sensorium is practically always associated with a variety of motor phenomena, which usually occur early in the course of the encephalopathy, sometimes when the patient is still mentally clear. The patient begins to twitch and jerk and may convulse. The myoclonic twitches involve parts of muscles, whole muscles, or limbs and are lightning-quick, arrhythmic, and asynchronous on the two sides of the body; they are incessant during both wakefulness and sleep. At times the movements resemble those of chorea or an arrhythmic tremor; asterixis is also readily evoked. The motor phenomena are often difficult to classify. The authors have preferred to describe the condition as a *uremic twitch-convulsive syndrome*.

Because of the similarity of this syndrome to tetany, measurement should be made of serum calcium and magnesium—and, of course, hypocalcemia and hypomagnesemia do occur in uremia. But often the values for these ions are normal or near normal, and the administration of calcium and magnesium salts has little effect. The resemblance of uremic encephalopathy to hepatic and other metabolic encephalopathies has been stressed by Raskin and Fishman, yet we are more impressed with differences than with similarities. We have observed the twitch-convulsive syndrome in association with a variety of diseases such as widespread neoplasia, delirium tremens, diabetes with necrotizing pyelonephritis, and lupus erythematosus, in which the blood urea nitrogen was only modestly elevated; but always the factor of renal failure was ultimately discovered.

As the uremia worsens, the patient lapses into a quiet coma. Unless the accompanying metabolic acidosis is corrected, Kussmaul breathing appears and gives way to Cheyne-Stokes breathing and death.

It is important to keep in mind that encephalopathy and coma in the patient with renal failure may be due to disorders other than uremia itself. The altered excretion of drugs leads to their accumulation, sometimes evoking excessive sedation even though serum concentrations are normal. Subdural and intracerebral hemorrhages may complicate uremia (and dialysis) because of clotting defects and hypertension, and chronically azotemic patients are prone to infections, including meningitis.

Since chronic uremia is so frequently associated with hypertension, a major problem also arises in distinguishing the cerebral effects of uremia from those of severe and accelerated hypertension. Volhard was the first to make this distinction; he introduced the term *pseudouremia* to designate the cerebral effects of malig-

nant hypertension and to separate them from true uremia. The term *hypertensive encephalopathy*, by which pseudouremia is now known, was first used by Oppenheimer and Fishberg. However, the myoclonic-twitch syndrome is not a component of hypertensive encephalopathy. The clinical picture of the latter disorder and its pathophysiology are discussed on page 728.

Pathogenesis Opinions vary widely as to the biochemical basis of uremic encephalopathy and the twitch-convulsive syndrome. Restoration of renal function completely corrects the neurologic syndrome, attesting to a functional disorder of subcellular type. Whether caused by the retention of organic acids, elevation of phosphate in the CSF (claimed by Harrison et al), or the action of urea or other toxins has never been settled. The data supporting the causative role of urea are ambiguous, just as they are for other putative endogenous agents (see Bolton and Young and the review by Burn and Bates). However, it can be stated that urea itself is not the sole inductive agent, since its infusion does not produce the syndrome in man or animals.

It would appear that every level of the CNS is affected, from spinal cord to cerebrum. The authors have been unable to detect cellular changes in the brain or spinal cord other than a mild hyperplasia of protoplasmic astrocytes in some cases, but never of the degree observed in hepatic encephalopathy. Cerebral edema is notably absent. In fact, CT scans and MRI regularly show an element of cerebral shrinkage, probably on the basis of hyperosmolarity. A peripheral neuropathy is also a common complication of uremia and is considered in Chap. 46.

Treatment In the treatment of uremic encephalopathy, the nature of the renal disease assumes paramount importance; if it is irreversible and progressive, the prognosis is poor without dialysis or renal transplantation. Improvement of encephalopathic symptoms may not be evident for a day or two after institution of dialysis. Convulsions, which occur in about one-third of cases, often preterminally, may respond to relatively low plasma concentrations of anticonvulsants, the reason being that serum albumin is depressed in uremia, increasing the unbound, therapeutically active portion of a drug. If there are severe associated metabolic disturbances, such as hyponatremia, the seizures may be difficult to control. One must be cautious in prescribing any of a large number of drugs in the face of renal failure, for inordinately high, toxic blood levels may result. Examples are aminoglycoside antibiotics (vestibular damage); furosemide (cochlear damage); and nitrofurantoin, isoniazid, and hydralazine (peripheral nerve damage).

Dialysis “Disequilibrium Syndrome” This term refers to a group of symptoms that may occur during and following hemodialysis or peritoneal dialysis in association with some degree of cerebral edema. The symptoms include headaches, nausea, muscle cramps, nervous irritability, agitation, drowsiness, and convulsions. The headache, which may be bilateral and throbbing and resemble common migraine, develops in approximately 70 percent of patients, while the other symptoms are observed in 5 to 10 percent, usually in those undergoing rapid dialysis or in the early stages of a dialysis program. The symptoms tend to occur in the third or fourth hour of dialysis and last for several hours. Sometimes they appear 8 to 48 h after the completion of dialysis. Originally these symptoms were attributed to the rapid lowering of serum urea, leaving the brain with a higher concentration of urea than the serum and resulting in a shift of water into the brain to equalize the os-

motic gradient (*reverse urea syndrome*). Now it is believed that the shift of water into the brain is akin to water intoxication and is due to the inappropriate secretion of antidiuretic hormone.

The symptoms of subdural hematoma, which in some series had in the past occurred in 3 to 4 percent of patients undergoing dialysis, now being less frequent, may be mistakenly attributed to the disequilibrium syndrome.

Dialysis Encephalopathy (Dialysis Dementia) This is a subacutely progressive syndrome that in the past complicated chronic hemodialysis. Characteristically the condition begins with a hesitant, stuttering dysarthria, dysphasia, and sometimes apraxia of speech, to which are added facial and then generalized myoclonus, focal and generalized seizures, personality and behavioral changes, and intellectual decline. The EEG is invariably abnormal, taking the form of paroxysmal and sometimes periodic sharp-wave or spike-and-wave activity (up to 500 mV and lasting 1 to 20 s), intermixed with abundant theta and delta activity. The CSF is normal except occasionally for increased protein.

At first the myoclonus and speech disorders are intermittent, occurring during or immediately after dialysis and lasting for only a few hours, but gradually they become more persistent and eventually permanent. Once established, the syndrome is usually steadily progressive over a 1- to 15-month period (average survival of 6 months in the 42 cases analyzed by Lederman and Henry).

The neuropathologic changes are said to be subtle and consist of a mild degree of microcavitation of the superficial layers of the cerebral cortex. Although the changes are diffuse, they have been found in one study to be more severe in the left (dominant) hemisphere than in the right and more severe in the left frontotemporal operculum than in the surrounding cortex (Winkelman and Ricanati). The disproportionate affection of the left frontotemporal opercular cortex putatively explains the distinctive disorder of speech and language. In the one case we have studied carefully, we could not be certain of any microscopic changes.

The most plausible view of the pathogenesis of dialysis encephalopathy is that it represented a form of aluminum intoxication (Alfrey et al), the aluminum being derived from the dialysate or from orally administered aluminum gels. In recent years, this disorder has disappeared, the result, in all likelihood, of the universal practice of purifying the water used in dialysis and thereby removing aluminum from the dialysate. This subject has been reviewed by Parkinson and coworkers.

Complications of Renal Transplantation The risk in immunosuppressed persons of developing a primary lymphoma of the brain or progressive multifocal leukoencephalopathy is well known and has been mentioned in previous chapters (page 651). An entirely different encephalopathy that is marked by widespread visual symptoms and edema of the cerebral white matter, evident on the MRI, but mainly occipital occurs after the administration of cyclosporine and other immunosuppressant drugs. The pattern "reversible posterior leukoencephalopathy" on MRI is not specific, being seen also in patients with hypertensive encephalopathy, eclampsia, intrathecal methotrexate, and other conditions (see Table 43-1, page 1040). Systemic fungal infections had in the past been found at autopsy in about 45 percent of patients who had had renal transplants and long periods of immunosuppressive treatment; in about one-third of these patients, the CNS was involved. *Cryptococcus*, *Listeria*, *Aspergillus*, *Candida*, *Nocardia*, and *Histoplasma* are the usual organisms. Recent experience suggests a lower rate of infec-

tion. Other CNS infections that have complicated transplantation are toxoplasmosis and cytomegalic inclusion disease.

In some nutritionally depleted uremic patients who are subjected to treatment that involves major shifts of plasma water and electrolytes, diseases unrelated to uremia may develop. In our necropsy material, we have also found examples of Wernicke-Korsakoff disease and central pontine myelinolysis. A bleeding diathesis may result in subdural or cerebral hemorrhage, as already mentioned.

Encephalopathy Associated with Sepsis and Burns

Bolton and Young have drawn attention to the frequent occurrence, in severely septic patients, of a drowsy or confusional state that is reversible and not explained by hepatic, pulmonary, or renal failure, electrolyte imbalance, hypotension, drug intoxication, or a primary lesion of the brain. They called the condition "septic encephalopathy." According to their surveys, 70 percent of patients become disoriented and confused within hours of the onset of severe systemic infection; in a few cases, this state may progress to stupor and coma. Notably there are no signs of asterixis, myoclonus, or focal cerebral disorder, but paratonia is common, as is the later development of a polyneuropathy.

The encephalopathic state that occurs with severe systemic infection may also develop independently of sepsis, as a component of a syndrome of multiple organ failure and, according to some authors, a complication of widespread cutaneous burns (Aikawa et al). Others of our colleagues have questioned the validity of this last category and have instead found explanatory electrolyte disorders (particularly hyponatremia, see page 974), sepsis, or multiple brain abscesses (Winkelman, personal communication).

It has been useful in clinical work to distinguish these encephalopathies of infection and multiorgan failure from those due to isolated hepatic or renal disease. The lack of a biochemical marker and the confounding effects of hypotension during sepsis (septic shock) leave doubt as to pathogenesis. Altered phenylalanine metabolism and circulating cytokines have been proposed as causes, without firm evidence. Of interest in two of our fatal cases was the presence of *brain purpura*, but this has otherwise been an infrequent finding. Here, the white matter of the cerebrum and cerebellum was speckled with myriads of pericapillary hemorrhages and zones of pericapillary necrosis. This pathologic reaction is non-specific, having also been seen in some of our cases of viral pneumonia, heart failure with morphine overdose, and arsenic intoxication.

Disorders of Sodium, Potassium, and Water Balance

Drowsiness, confusion, stupor, and coma, in conjunction with seizures and sometimes with other neurologic deficits, may have as their basis a more or less pure abnormality of electrolyte or water balance. Only brief reference is made to some of these—such as hypocalcemia, hypercalcemia, hypophosphatemia, and hypomagnesemia—since they are considered in other parts of the text.

Hyponatremia Among the many causes of hyponatremia, the *syndrome of inappropriate antidiuretic hormone secretion (SIADH)* is of special importance, because it may complicate neurologic diseases of many types—head trauma, bacterial meningitis

and encephalitis, cerebral infarction, subarachnoid hemorrhage, neoplasm, and Guillain-Barré syndrome. The diagnosis of SIADH should be suspected in any critically ill neurologic or neurosurgical patient who excretes urine that is hypertonic relative to the plasma. As the hyponatremia develops, there is a decrease in alertness, which progresses through stages of confusion to coma, often with convulsions. *As with many other metabolic derangements, the severity of the clinical effect is related to the rapidity of decline in serum Na.* Lack of recognition of this state may allow the serum Na to fall to dangerously low levels, 100 meq/L or lower. One's first impulse is to administer NaCl intravenously, but this must be done cautiously, because in most of these patients the intravascular volume is already expanded and there is a risk of congestive heart failure. Most cases respond to the restriction of fluid intake—to 500 mL per 24 h if the serum Na is less than 120 meq/L and to 1000 mL per 24 h if less than 130 meq/L. Even when the Na reaches 130 meq/L, the fluid intake should not exceed 1500 mL per 24 h. In extreme cases of hyponatremia with stupor or seizures, infusion of NaCl is necessary. The amount of NaCl to be infused can be calculated from the current and the target levels of serum Na by assuming that the infused sodium load is distributed throughout the total body water content ($0.6 \times \text{weight in kilograms}$):

$$\frac{[(\text{Target Na} - \text{starting Na}) \times 0.6] \times \text{weight (kg)}}{\text{infused Na load (meq)}}$$

The desired volume of normal saline can then be determined by keeping in mind that its sodium concentration is 154 meq/L and that of 3 percent (hypertonic) saline solution is 462 meq/L. If hypertonic saline is administered, it is usually necessary to simultaneously reduce intravascular volume with furosemide, beginning with a dose of 0.5 mg/kg intravenously, and to increase the dosage until a diuresis is obtained. Guidelines to prevent an overly rapid correction of Na are elaborated further on in relation to central pontine myelinolysis (no more than 10 mmol/L in the first 24 h). Although the syndrome of SIADH is usually self-limiting, it may continue for weeks or months, depending on the type of associated brain disease.

It must be emphasized that not all patients with intracranial disorders who manifest hyponatremia and natriuresis have SIADH. In fact, in many such patients, renal loss of salt is the cause of hyponatremia and, in contrast to SIADH, results in decreased blood volume. This process has been termed "cerebral salt wasting" (Nelson et al). Sodium loss in these circumstances is attributable to the production by the heart or brain of a potent polypeptide, atrial natriuretic factor. As discussed in Chap. 34, under "Subarachnoid Hemorrhage," the distinction between SIADH and cerebral salt wasting is of more than theoretical importance, insofar as fluid restriction to correct hyponatremia may be dangerous in patients with salt wasting, particularly in those with vasospasm after ruptured intracranial aneurysms.

Arieff has emphasized the hazards of *postoperative hyponatremia* in a series of 15 patients, all of them women, in whom *severe hyponatremia* followed elective surgery. About 48 h after these patients had recovered from anesthesia, their serum Na fell to an average level of 108 meq/L; the urinary sodium to 68 mmol/L, and the urinary osmolality was 501 mosmol/kg, at which point generalized seizures occurred, followed by respiratory arrest. Of the 15 women, 5 died, but there were no diagnostic pathologic findings and no lesions of central pontine myelinolysis (see below). Seven patients whose serum Na was corrected slowly improved over a

period of several days but then developed progressive drowsiness and increasing nausea, headache, and obtundation, followed by a recurrence of seizures and coma. These patients survived in a persistent vegetative state. We find the syndrome difficult to interpret and have not encountered cases of this sort. The initial hyponatremia may have been the result of SIADH.

An important consideration in the management of severe hyponatremia and hyperosmolality, as mentioned earlier, is *the rapidity with which these abnormalities are corrected and the danger of provoking central pontine myelinolysis* and related brainstem, cerebellar, and cerebral lesions (extrapontine myelinolysis). These issues are considered below, in the section on central pontine myelinolysis.

Hypernatremia Severe hypernatremia ($\text{Na} > 155 \text{ meq/L}$) and dehydration are observed in diabetes insipidus, the neurologic causes of which include head trauma with damage to the pituitary stalk (Chap. 27), and in nonketotic diabetic coma, protracted diarrhea in infants, and the deprivation of fluid intake in the stuporous patient. The last condition is usually associated with a brain lesion that impairs consciousness. Exceptionally, in patients with chronic hydrocephalus, the hypothalamic thirst center is rendered inactive, and severe hypernatremia, stupor, and coma may follow a failure to drink. In hypernatremia from any cause, the brain volume is manifestly reduced in CT scans. Retraction of the cerebral cortex from the dura has been known to rupture a bridging vein and cause a subdural hematoma.

As is true for hyponatremia, the degree of CNS disturbance in hypernatremia is generally related to the rate at which the serum Na rises. Slowly rising values, to levels as high as 170 meq/L, may be surprisingly well tolerated. Rapid elevations of sodium shrink the brain, especially in infants. Extremely high levels cause impairment of consciousness with asterixis, myoclonus, seizures, and choreiform movements. In addition, muscular weakness, rhabdomyolysis, and myoglobinuria have been reported.

It should be noted that hyponatremia is usually accompanied by hypo-osmolality of the serum and hypernatremia by hyperosmolality. However, there is no strict correlation between serum osmolarity and neurologic dysfunction. Instead, the rapidity of change, as already emphasized, plays a major role. In hyponatremia plus hypo-osmolality, Fishman finds an increase in intracellular water and a diminution in intracellular K; but in our view it is the dehydration that is more critical and coincides with the neuronal derangement. In hypernatremia plus hyperosmolality, the neurons do not lose water as much as do other cells, a compensatory reaction that Fishman had attributed to the presence of "idiogenic osmoles"—possibly glucose, glucose metabolites, and amino acids. The impairment of neuronal function in this state is not understood. Theoretically one would expect neuronal shrinkage and possibly alteration of the synaptic surface of the cell.

Hypo- and Hyperkalemia The main clinical effect of *hypokalemia* ($K, 2.0 \text{ meq/L}$ or less) is generalized muscular weakness (see Chap. 48). A mild confusional state may also be added but is very infrequent. The condition is readily corrected by adding K to intravenous fluid and infusing it at no more than 4 to 6 meq/h. *Hyperkalemia* (above 7 meq/L) also may manifest itself by generalized muscle weakness, although the main effects are changes in the electrocardiogram (ECG), possibly leading to cardiac arrest.

Other Metabolic Encephalopathies Limitation of space permits only brief reference to other metabolic disturbances that may present as episodic confusion, stupor, or coma. The most important members of this group are summarized below.

Hypercalcemia This is defined as an elevation of the serum calcium concentration above 10.5 mg/dL. If the serum protein content is normal, Ca levels greater than 12 mg/dL are required to produce neurologic symptoms. However, with low serum albumin levels, an increased proportion of the serum Ca is in the unbound or ionized form (upon which the clinical effects depend), and symptoms may occur with serum Ca levels as low as 10 mg/dL.

In young persons, the most common cause of hypercalcemia is hyperparathyroidism (either primary or secondary); in older persons, osteolytic bone tumors, particularly metastatic carcinoma and multiple myeloma, are often causative. Less common causes are vitamin D intoxication, prolonged immobilization, hyperthyroidism, sarcoidosis, and decreased calcium excretion (renal failure).

Anorexia, nausea and vomiting, fatigue, and headache are usually the *initial symptoms*, followed by confusion (rarely a delirium) and drowsiness, progressing to stupor or coma in untreated patients. A history of recent constipation is common. Diffuse myoclonus and rigidity occur occasionally, as do elevations of spinal fluid protein (up to 175 mg/100 mL). Convulsions are uncommon.

Hypocalcemia The usual manifestations are paresthesias, tetany, and seizures. With severe and persistent hypocalcemia, altered mental status in the form of depression, confusion, dementia, or personality change can occur. Anxiety to the point of panic attack is also known. Even coma may result, in which case there may be papilledema due to increased intracranial pressure. Aside from the raised pressure, the CSF shows no consistent abnormality. This increase in intracranial pressure may be manifest by headache and papilledema without altered mentation or with visual obscurations. Hypoparathyroidism is discussed again further on, in the section on extrapyramidal syndromes.

Other Electrolyte and Acid-Base Disorders Severe metabolic acidosis from any cause produces a syndrome of drowsiness, stupor, and coma, with dry skin and Kussmaul breathing. The CNS depression does not correlate with the concentration of ketones. Possibly, there are associated effects on neurotransmitters. It is often not possible to separate the effects of acidosis from those due to an underlying condition or toxic ingestion.

In infants and children, acidosis may occur in the course of hyperammonemia, isovaleric acidemia, maple syrup urine disease, lactic and glutaric acidemia, hyperglycinemia, and other disorders, which are described in detail in Chap. 37. High-voltage slow activity predominates in the EEG, and correction of the acidosis or elevated ammonia level restores CNS function to normal provided that coma was not prolonged or complicated by hypoxia or hypotension. In uncomplicated acidotic coma, we have observed no recognizable neuropathologic change by light microscopy.

Encephalopathy due to *Addison disease* (adrenal insufficiency) may be attended by episodic confusion, stupor, or coma without special identifying features; it is usually precipitated in the addisonian patient by infection or surgical stress. Hemorrhagic destruction of the adrenals in meningococcal meningitis (Waterhouse Friderichsen syndrome) is another cause. Hypotension and diminished cerebral circulation and hypoglycemia are the most readily recognized metabolic abnormalities; measures that correct these conditions reverse the adrenal crisis in some instances.

The various neurologic syndromes that result from electrolytic disorders are reviewed by Laureno.

Central Pontine Myelinolysis

In 1950, Adams and Victor observed a rapidly evolving quadriplegia and pseudobulbar palsy in a young alcoholic man who had entered the hospital 10 days earlier with symptoms of alcohol withdrawal. Postmortem examination several weeks later disclosed a large, symmetrical, essentially demyelinative lesion occupying the greater part of the base of the pons. Over the next 5 years, three additional cases (two alcoholic patients and one with scleroderma) were studied clinically and pathologically, and in 1959 these four cases were reported by Adams et al under the heading of *central pontine myelinolysis* (CPM). This term was chosen because it denotes both the main anatomic localization of the disease and its essential pathologic attribute: the remarkably unsystematic dissolution of the sheaths of myelinated fibers and the sparing of neurons. Once attention was focused on this distinctive lesion, many other reports appeared. The exact incidence of this disease is not known, but in a series of 3548 consecutive autopsies in adults, the typical lesion was found in 9 cases, or 0.25 percent (Victor and Laureno).

Pathologic Features One is compelled to define this disease in terms of its pathologic anatomy, because this stands as its most certain feature. Transverse sectioning of the fixed brainstem discloses a grayish discoloration and fine granularity in the center of the basis pontis. The lesion may be only a few millimeters in diameter, or it may occupy almost the entire basis pontis. There is always a rim of intact myelin between the lesion and the surface of the pons. Posteriorly it may reach and involve the medial lemnisci and, in the most advanced cases, other tegmental structures as well. Very rarely, the lesion encroaches on the midbrain, but inferiorly it does not extend as far as the medulla. Exceptionally the extensive pontine lesions may be associated with identical myelinolytic foci symmetrically distributed in the thalamus, subthalamic nucleus, striatum, internal capsule, corpus callosum, amygdaloid nuclei, lateral geniculate body, white matter of the cerebellar folia, and deep layers of the cerebral cortex and subjacent white matter ("extrapontine myelinolysis"; Wright et al).

Microscopically, the fundamental abnormality consists of destruction of the myelinated sheaths throughout the lesion, with relative sparing of the axons and intactness of the nerve cells of the pontine nuclei. These changes always begin and are most severe in the geometric center of the pons, where they may proceed to frank necrosis of tissue. Reactive phagocytes and glial cells are in evidence throughout the demyelinative focus, but oligodendrocytes are depleted. Signs of inflammation are conspicuously absent.

This constellation of pathologic findings provides easy differentiation of the lesion from infarction and the inflammatory demyelinations of multiple sclerosis and postinfectious encephalomyelitis. Microscopically, the lesion resembles that of Marchiafava-Bignami disease (Chap. 41), with which it is rarely associated. In the chronic alcoholic, Wernicke disease is not infrequently associated with CPM, but the lesions bear no resemblance to one another in terms of topography and histology.

Clinical Features Central pontine myelinolysis occurs only sporadically, with no hint of a genetic factor. The two sexes are affected equally, and the patients do not fall into any one age period. Whereas the cases first reported had occurred in adults, there are now many reports of the disease in children, particularly in those with severe burns (McKee et al).

The outstanding clinical characteristic of CPM is its invariable association with some other serious, often life-threatening disease. In more than half the cases, it has appeared in the late stages of chronic alcoholism, often in association with Wernicke disease and polyneuropathy. Among the other medical conditions and diseases with which CPM has been conjoined are chronic renal failure being treated with dialysis, hepatic failure, advanced lymphoma, carcinoma, cachexia from a variety of other causes, severe bacterial infections, dehydration and electrolyte disturbances, acute hemorrhagic pancreatitis, and pellagra. The changes in serum sodium concentration, with which the process is closely aligned, are discussed below.

In many patients with CPM there are no symptoms or signs that betray the pontine lesion, presumably because it is so small, extending only 2 to 3 mm on either side of the median raphe and involving only a small portion of the corticopontine or pontocerebellar fibers. In others, the presence of CPM is obscured by coma from a metabolic or other associated disease. Probably only a minority of cases, exemplified by the first patient observed by Adams, Victor, and Mancall, are recognized during life. In this patient, a serious alcoholic with delirium tremens and pneumonia, there evolved, over a period of several days, a flaccid paralysis of all four limbs and an inability to chew, swallow, or speak (thus simulating occlusion of the basilar artery). Pupillary reflexes, movements of the eyes and lids, corneal reflexes, and facial sensation were spared. In some instances, however, conjugate eye movements are limited, and there may be nystagmus. With survival for several days, the tendon reflexes become more active, followed by spasticity and extensor posturing of the limbs on painful stimulation. Some patients are left in a state of mutism and paralysis with relative intactness of sensation and comprehension (pseudocoma, or locked-in syndrome).

The capacity of CT scanning but especially MRI to visualize the pontine lesion has greatly increased the frequency of premortem diagnoses. The MRI discloses a characteristic "bat wing" lesion of the basis pontis in typical cases (Fig. 40-4), although this change may become evident only several days after the onset of symptoms. Brainstem auditory evoked responses also disclose the lesions that encroach upon the pontine tegmentum.

Variants of this syndrome are being encountered with increasing frequency. Two of our elderly patients, with confusion and stupor but without signs of corticospinal or pseudobulbar palsy, recovered; however, they were left with a severe dysarthria and cerebellar ataxia lasting many months. After 6 months, these patients' nervous system function was essentially restored to normal. In reference to the pathogenesis of this lesion, originally both patients had serum Na levels of 99 meq/L, but information about the rate of correction of serum Na was not available. Another of our patients developed a typical locked-in syndrome after the rapid correction of a serum sodium of 104 meq/L. He showed large symmetrical lesions of the frontal cortex and underlying white matter but no pontine lesion (by MRI).

Brainstem infarction due to basilar artery occlusion may be simulated by pontine myelinolysis. Sudden onset or step-like progression of the clinical state, asymmetry of long tract signs, and more extensive involvement of tegmental structures of the pons as well as the midbrain and thalamus are the distinguishing characteristics of vertebrobasilar thrombosis or embolism. On MRI studies, an evolving infarction shows signal changes on diffusion-weighted imaging, while the primary finding in CPM is brightness of the T2-weighted images. Massive pontine demyelination in

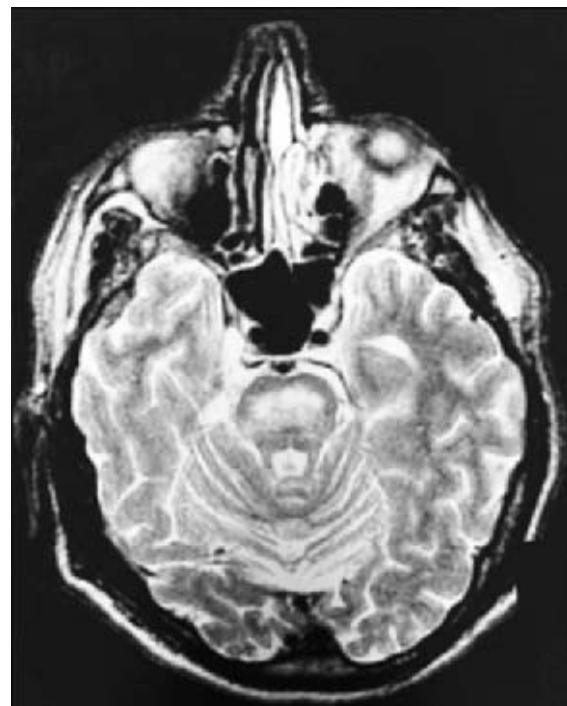

Figure 40-4. T2-weighted MRI showing the typical lesion of central pontine myelinolysis in an alcoholic patient.

acute or chronic relapsing multiple sclerosis rarely produces a pure basis or pons syndrome. The clinical features and context provide the clues to correct diagnosis.

Etiology and Pathogenesis Nutritional deficiency is a commonly invoked cause of CPM, because it is observed so frequently in chronic wasting diseases and particularly in malnourished alcoholics, often in association with Wernicke disease. Nevertheless, there are many cases in which a nutritional factor cannot be incriminated. As mentioned in the section on hyponatremia, the rapid correction of the serum sodium to normal or higher than normal levels is an almost obligate antecedent of CPM. Significant hyponatremia, always less than 130 meq/L and usually much less, has been present in all our patients and in all the patients reported by Burcar and colleagues and by Karp and Laureno. The importance of serum sodium in the pathogenesis of this disease was demonstrated experimentally by Laureno. Dogs were made severely hyponatremic (100 to 115 meq/L) by repeated injections of vasopressin and intraperitoneal infusions of water. The hyponatremia was corrected rapidly by infusion of hypertonic (3%) saline, following which the dogs developed a spastic quadriplegia and showed, at autopsy, pontine and extrapontine lesions that were indistinguishable in their distribution and histologic features from those of the human disease. Hyponatremia alone or slowly corrected hyponatremia (<15 meq/dL in the initial 24 h) did not produce the disease.

McKee and colleagues have adduced evidence that extreme serum hyperosmolality and not necessarily the rapid correction or overcorrection of hyponatremia is the important factor in the pathogenesis of CPM. They found the characteristic pontine and extrapontine lesions in 10 of 139 severely burned patients who were examined after death. Each of their patients with CPM had suffered a prolonged, nonterminal episode of severe serum hyperosmolality,

which coincided temporally with the onset of the lesion, as judged by its histologic features. Hyponatremia was not present, and no other independent factors—such as hypernatremia, hyperglycemia, or azotemia—correlated with the development of CPM. These are valid observations but they cannot easily be reconciled with the usual circumstances of rapid correction of hyponatremia.

At the present time all one can say is that specific myelinated regions or zones of the brain, most often the center of the base of the pons, have a special susceptibility to some acute metabolic fault (mostly rapid correction or overcorrection of hyponatremia, and possibly hyperosmolality).

Therapeutic guidelines for the correction of hyponatremia are still being considered. Karp and Laureno, on the basis of their experience and that of Sterns et al, have suggested that the hyponatremia be corrected by no more than 10 meq/L in the initial 24 h and by no more than about 21 meq/L in the initial 48 h.

ACQUIRED METABOLIC DISEASES PRESENTING AS PROGRESSIVE EXTRAPYRAMIDAL SYNDROMES

These syndromes are usually of mixed type—i.e., they include a number of basal ganglionic and cerebellar symptoms in various combinations and may emerge as part of an acquired chronic hepatocerebral degeneration or chronic hypoparathyroidism or as sequelae to kernicterus, hypoxic, or hypoglycemic encephalopathy. The basal ganglionic-cerebellar symptoms that result from severe anoxia and hypoglycemia have been described in the preceding section and in Chaps. 4 and 5. Kernicterus is considered on page 878, with the neurologic diseases of infancy and childhood, and calcification of the basal ganglia and cerebellum (due to chronic parathyroid deficiency) on page 834, with the inherited metabolic disorders, and further on in this chapter. It must be realized, however, that acquired hypoparathyroidism may also lead to calcification of the basal ganglia. We have also observed choreiform movements in patients with hyperosmolar coma and with severe hyperthyroidism, ascribed by Weiner and Klawans to a disturbance of dopamine metabolism.

Chronic Acquired (Nonwilsonian) Hepatocerebral Degeneration

Patients who survive an episode or several episodes of hepatic coma are sometimes left with residual neurologic abnormalities such as tremor of the head or arms, asterixis, grimacing, choreic movements and twitching of the limbs, dysarthria, ataxia of gait, or impairment of intellectual function. These symptoms may worsen with repeated attacks of stupor and coma. In a few patients with chronic liver disease, permanent neurologic abnormalities become manifest in the absence of discrete episodes of hepatic coma. In either circumstance, these patients deteriorate neurologically over a period of months or years. Examination of their brains discloses foci of destruction of nerve cells and other parenchymal elements in addition to a widespread transformation of astrocytes—changes very much similar to those of Wilson disease.

Probably the first to describe this acquired type of hepatocerebral degeneration was van Woerkom (1914), whose report appeared only 2 years after Wilson's classic description of the familial form. A full account of the cases reported since that time as well as of our own extensive experience with this disorder is contained in the article by Victor, Adams, and Cole, listed in the References.

Clinical Features The first symptom may be a tremor of the outstretched arms, fleeting arrhythmic twitches of the face and limbs (resembling either myoclonus or chorea), or a mild unsteadiness of gait with action tremor. As the condition evolves over months or years, a rather characteristic dysarthria, ataxia, wide-based, unsteady gait, and choreoathetosis—mainly of the face, neck, and shoulders—are joined in a common syndrome. Mental function is slowly altered, taking the form of a simple dementia with a seeming lack of concern about the illness. A coarse, rhythmic tremor of the arms appearing with certain sustained postures, mild corticospinal tract signs, and diffuse EEG abnormalities complete the clinical picture. Other less frequent signs are muscular rigidity, grasp reflexes, tremor in repose, nystagmus, asterixis, and action or intention myoclonus. In essence, each of the neurologic abnormalities observed in patients with acute hepatic encephalopathy are also part of chronic hepatocerebral degeneration, the only difference being that the abnormalities are evanescent in the former and irreversible and progressive in the latter.

As a rule, all measurable hepatic functions are altered, but the chronic neurologic disorder correlates best with an elevation of serum ammonia (usually greater than 200 mg/dL). Unlike Wilson disease, where the cirrhosis usually remains occult for a long time, there is no question about its presence in the acquired syndrome; jaundice, ascites, and esophageal varices are manifest in most of the acquired cases. Wilson disease, which enters into the differential diagnosis, is usually not difficult to differentiate on clinical grounds, although the distinction in some cases requires the critical evidence of familial occurrence, Kayser-Fleischer rings (never found in the acquired type), and certain biochemical abnormalities (diminished serum ceruloplasmin, elevated serum copper, and elevated urinary copper excretion—see page 830).

Pathology The chronic cerebral symptoms, like the transient ones, may occur with all varieties of chronic liver disease. The cerebral lesion is localized more regularly in the cortex than is the case in Wilson disease. In some specimens an irregular gray line of necrosis or gliosis can be observed throughout both hemispheres, and the lenticular nuclei may appear shrunken and discolored. These lesions resemble hypoxic ones and may be concentrated in the vascular border zones, but they tend to spare the hippocampus, globus pallidus, and deep folia of the cerebellar cortex—the sites of predilection in anoxic encephalopathy. Microscopically, a widespread hyperplasia of protoplasmic astrocytes is visible in the deep layers of the cerebral cortex and in the cerebellar cortex as well as in thalamic and lenticular nuclei and other nuclear structures of the brainstem. In the necrotic zones, the medullated fibers and nerve cells are destroyed, with marginal fibrous gliosis; at the cortico-medullary junction, in the striatum (particularly in the superior pole of the putamen), and in the cerebellar white matter, polymicrocavitation may be prominent. Protoplasmic astrocytic nuclei contain PAS-positive glycogen granules. Some nerve cells appear swollen and chromatolyzed, taking the form, we believe, of the so-called Opalski cells usually associated with Wilson disease. The similarity of the neuropathologic lesions in the familial and acquired forms of hepatocerebral disease is striking.

Pathogenesis It is evident that a close relationship exists between the acute, transient form of hepatic encephalopathy (hepatic coma) and the chronic, largely irreversible hepatocerebral syndrome; frequently one blends imperceptibly into the other. As noted above, this relationship is reflected in the pathologic findings as well. Reducing the serum ammonia by the measures that are effective in

acute hepatic encephalopathy will cause a recession of many of the chronic neurologic abnormalities—not completely, but to an extent that permits the patient to function better.

It appears that the parenchymal damage in the chronic disease simply represents the most severe degree of a pathologic process that in its mildest form is reflected in an astrocytic hyperplasia alone.

Kernicterus

Kernicterus, formerly a common cause of congenital choreoathetosis, has now been virtually eliminated. It is discussed on page 878.

Hypoparathyroidism

This condition and pseudohypoparathyroidism (page 834) were mentioned in relation to the hereditary metabolic disorders. In the past, the usual cause of hypoparathyroidism was surgical removal of the parathyroid glands during subtotal thyroidectomy, although there were always idiopathic cases as well. With the more widespread use of radiation and drug therapy for thyroid disease, the number of surgically created cases has become small in proportion to nonsurgical ones. The latter may occur in pure form, presumably as an agenesis of the parathyroid glands, with unmeasurable levels of parathyroid hormone in the blood, or as part of the DiGeorge syndrome of agenesis of the thymus and parathyroid glands, organs that are embryologically derived from the third and fourth branchial clefts. Hypoparathyroidism is also part of a familial disorder in which a deficiency of thyroid, ovarian, and adrenal function, pernicious anemia, and other defects are combined, based presumably on a derangement of autoimmune mechanisms. Other causes are intestinal malabsorption, pancreatic insufficiency, and vitamin D deficiency. In all instances the low levels of parathormone and normal responses to injected hormone permit the recognition of a primary defect of the parathyroid glands and distinguish it from all other conditions in which there is hypocalcemia and hyperphosphatemia.

The clinical manifestations, mainly attributable to the effects of hypocalcemia, are tetany, paresthesias, muscle cramps, laryngeal spasm, and convulsions. Children with this disease may be irritable and show behavioral changes. In adults with chronic hypocalcemia, calcium deposits occur in the basal ganglia, dentate nuclei, and cerebellar cortex. In such patients we have observed unilateral tremor, a restless choreoathetotic hand, bilateral rigidity, slowness of movement and flexed posture resembling Parkinson disease, and ataxia of the limbs and gait—in various combinations. Interestingly, the multiple skeletal and developmental abnormalities that characterize both pseudo- and pseudo-pseudohypoparathyroidism (short stature, round face, short neck, stocky body build, shortening of metacarpal and metatarsal bones and phalanges from premature epiphyseal closure) are rarely seen in pure hypoparathyroidism.

A similar deposition of ferrocalc in the walls of small blood vessels of the lenticular and dentate nuclei and to a lesser extent in other parts of the brain is a common finding in normal older individuals (Fahr disease). It also occurs in animals. Occasionally it reaches a degree of severity that destroys striatal or dentate neurons. In such cases, films of the skull and particularly CT scans will reveal the deposits. Cases of Fahr disease have been reported for years (Fig. 37-9, page 835), but the cause of the deposits is un-

known. Apparently some protein in the capillary walls has an avidity for both calcium and iron.

ACQUIRED METABOLIC DISEASES PRESENTING AS CEREBELLAR ATAXIA

Cerebellar Ataxia Associated with Myxedema

The association of myxedema and cerebellar ataxia has been mentioned sporadically in medical writings since the latter part of the nineteenth century. Interest in this problem was revived in more recent years by Jellinek and Kelly, who described 6 such cases. All of them showed an ataxia of gait; in addition, some degree of ataxia of the arms and dysarthria were present in 4 instances, and nystagmus in 2. Cremer and coworkers have reported a similar clinical experience, based on a study of 24 patients with either primary or secondary hypothyroidism.

There have been only a few reports of the pathologic changes, and these are far from satisfactory. The myxedematous patient described by Price and Netsky had also been a serious alcoholic, and the clinical signs (ataxia of gait and of the legs) and pathologic changes (loss of Purkinje cells and gliosis of the molecular layer, most pronounced in the vermis) could be distinguished from those due to alcoholism and malnutrition. Scattered throughout the nervous system of their case were unusual glycogen-containing bodies, similar but not identical to corpora amylocitae. These structures, designated myxedema bodies by Price and Netsky, were also observed in the cerebellar white matter of a second case of myxedema; there were no other neuropathologic changes, however, and this patient had shown no ataxia during life. It is difficult to know whether these peculiar bodies have anything to do with myxedema. If they do, it should be possible to demonstrate them in more than two cases. We have not seen them in one carefully studied case of myxedema, nor have they been described by others. Thyroid medication corrects the defect in motor coordination, raising doubt as to whether it could be based on a visible structural lesion.

The various causes of cerebellar ataxia, including the metabolic ones, are summarized in Table 5-1 (page 78). Notable metabolic disorders, some heritable, in which ataxia may be a leading manifestation include GM₂ gangliosidosis, possibly sprue (discussed below), and a large number of neonatal and infantile aminoacidopathies.

Effects of Hyperthermia on the Cerebellum

The damaging effects of *hyperthermia*, like those of anoxia, involve the brain diffusely. In the case of hyperthermia, however, the changes are disproportionately severe in the cerebellum. The acute manifestations of profound hyperthermia are coma and convulsions, frequently complicated by shock and renal failure. Patients who survive the initial stage of the illness frequently show signs of widespread cerebral affection, such as confusion and pseudobulbar and spastic paralysis. These abnormalities tend to resolve gradually, leaving the patient with a more or less pure disorder of cerebellar function.

The most extensive account of the pathologic effects of hyperthermia is that of Malamud and colleagues. These authors studied 125 fatal cases of heat stroke, but their observations are prob-

ably applicable to hyperthermia of other types. In patients who survived less than 24 h, the changes consisted mainly of a loss of some of the Purkinje cells and swelling, pyknosis, and disintegration of those that remained. In cases surviving beyond 24 h, there was almost complete degeneration of the Purkinje cells, with gliosis throughout the cerebellar cortex as well as degeneration of the dentate nuclei. The changes in the cerebellar cortex were equally pronounced in the hemispheres and vermis. The unanswered question is whether high temperature alone is an adequate cause or whether it must be combined with hypoxia and ischemia. It is of interest that we have not seen this syndrome in patients with infective fevers, malignant hyperthermia, or the malignant neuroleptic syndrome—either the neuropathologic changes or the clinical cerebellar syndrome in survivors.

Cerebellar Syndromes Associated with Celiac Disease (Sprue, Gluten Enteropathy)

Most often, the neurologic association with this disease has been a peripheral neuropathy as described on page 1142. In addition, a progressive cerebellar ataxia of gait and limbs, sometimes with polymyoclonus in association with a gluten-sensitive enteropathy, has been the subject of several reports. The underlying cause is an intestinal allergy to gluten in wheat that produces a villus atrophy of the intestinal mucosa. It has been called celiac disease of children and sprue in adults. Between 0.5 and 1 percent of the Caucasian population are affected with the intestinal disorder. The classic features are diarrhea and malabsorption but many individuals are asymptomatic (see also page 993).

The neurologic disorder may appear several years after onset of the enteropathy and, in addition to ataxia, usually includes signs of peripheral neuropathy and, in some cases, myelopathy and encephalopathy (dementia) or psychiatric symptoms (Hallert et al). A rare spinocerebellar syndrome has been described by Cooke and Smith. According to Finelli et al, neurologic abnormalities occur in approximately 10 percent of cases of adult celiac sprue. This subject has been reviewed by Bhatia et al and extensively by Hadjivassiliou et al. The latter authors emphasize the frequent occurrence of ataxia in patients with gluten sensitivity (indicated by circulating antibodies to gliadin (which is another term for gluten) and more specifically, antibodies to transglutaminase and endomysium) but, curiously, often without overt signs of bowel disease. There is also an association of sprue in more than 90 percent of patients with the HLA DQ2 and DQ8 genotype. The few cases that have come to autopsy have shown severe cerebellar atrophy, a finding that may also be disclosed by MRI. Hadjivassiliou et al observed lymphocytic infiltration and perivascular cuffing in the cerebellar cortex and peripheral nerves in one autopsied case but not in another, changes that they took to represent immunologic injury to these parts.

Despite these associations, some authors have been skeptical of a “gluten ataxia” (see the editorial by Cross and Golumbek and the contrary case for a valid connection by Hadjivassiliou and colleagues, 2002). Reports of improvement in the ataxia following the institution of a gluten-free diet have been conflicting. The situation is further complicated by the finding that antigliadin antibodies (which are not autoantibodies but are directed against gluten, the offending agent), while not specific for celiac disease, do correspond to the presence of neurologic manifestations (ataxia and neuropathy); however, the more specific antiendomysium and

antitransglutaminase autoantibody markers of sprue have little apparent relation to the presence of neurologic disease. Even more confusing is the claim that half of these patients will have one or another antibody but no clinical enteropathy, making it necessary to perform a small bowel biopsy to detect villous atrophy. A gluten-free diet is necessary, not only to reduce the enteropathy, if present, but also to reduce the chances of the later development of a bowel lymphoma. The medical issues relating to celiac disease and the use of antibody tests and bowel biopsy are reviewed by Farrell and Kelly.

We have sought evidence by antibody testing and bowel biopsy of sprue in numerous patients with an ataxia of obscure origin and have only once found it. Nevertheless, the evidence presented in the writings of several authors, particularly Hadjivassiliou, suggest that sprue may underlie some cases of subacute ataxia in adults. Always to be considered in the differential diagnosis is paraneoplastic cerebellar degeneration and Creutzfeldt-Jakob disease.

Vitamin E deficiency may induce a similar syndrome with features of spinocerebellar dysfunction (see page 251).

Jejunoileal bypass operations, in addition to causing a chronic arthropathy, neuropathy, and vasculitic skin lesions, may give rise to an episodic confusion and cerebellar ataxia associated with a lactic acidosis and abnormalities of pyruvate metabolism. Overfeeding and fasting are provocative factors (Dahlquist et al).

ACQUIRED METABOLIC DISEASE PRESENTING AS PSYCHOSIS AND DEMENTIA

The point has been made that milder forms of metabolic diseases that cause episodic stupor and coma, if persistent, may have a protracted course and are then difficult to distinguish from the dementias. Examples are associated with chronic hepatic encephalopathy and the syndromes of chronic hypoglycemia, chronic hypercalcemia (in multiple myeloma, metastatic cancer, and sarcoidosis), and dialysis encephalopathy. Unlike the common types of dementia described in Chap. 21, the acquired metabolic diseases are nearly always accompanied by a degree of drowsiness, inattentiveness, and reduced alertness; i.e., by a clouding of the sensorium and inaccurate perceptions and interpretations—attributes that usually allow an encephalopathic confusional state to be distinguished from a dementia. The presence of asterixis is also an aid. If the onset of the illness is abrupt rather than gradual and of brief duration and if therapy reverses the condition, restoring full mental clarity, the conclusion is justified that one is dealing with a confusional state; but at any one time in the active phase of the disease the clinical state may resemble dementia.

In general hospitals, an episodic confusional state lasting days and weeks in the course of a medical illness or following an operation should always raise the suspicion of one of the aforementioned metabolic derangements (or an adverse effect of a drug). Usually, however, all of these causes can be excluded, and one falls back on a rather unsatisfactory interpretation—that a combination of drugs, fever, toxemia, and unspecific metabolic disorders is responsible. The “septic encephalopathy” described earlier in this chapter conforms to this ambiguous notion.

In the endocrine encephalopathies, described below, the clinical phenomena may be even more abstruse, although they are notable because they often take the form of a unique delirium. Confusional states may be combined with agitation, hallucinations, delusions, anxiety, and depression, and the time span of the illness

may be in terms of weeks and months rather than days. Certain aspects of the endocrine psychoses are discussed further on page 1130.

Cushing Disease and Corticosteroid

Psychoses (See also Chap. 58)

Derangements of mental function that follow administration of adrenocorticotrophic hormone (ACTH) and then of corticosteroids have become the prototypes of iatrogenic psychoses. The same disturbances of mental function may accompany Cushing disease (page 1330).

Experience with this neuropsychiatric condition came originally from observations of patients receiving ACTH and later from those receiving prednisone for a variety of neurologic and medical diseases. With low doses there is usually no psychic effect other than a sense of well-being and decreased fatigability. At higher doses (60 to 100 mg/day of prednisone), approximately 10 to 15 percent of patients become overly active, emotionally labile, and unable to sleep. Unless the dose is promptly reduced, there follows a progressive shift in mood, usually toward euphoria and hypomania—but sometimes toward depression and then inattentiveness, distractibility, and mild confusion. The EEG becomes less well modulated and slower frequencies appear. A minority of patients experience frank hallucinations and delusions, giving the illness a truly psychotic stamp and raising the suspicion of schizophrenia or manic-depressive disease. In nearly all instances, however, this mixture of confusion and mood change, in association with disordered cognitive function, distinguishes the iatrogenic corticosteroid psychosis. Withdrawal of medication relieves the symptoms, but full recovery may take several days to a few weeks, at which time, as with all confusional states and deliria, the patient has only a fragmentary recollection of events that occurred during the illness.

The neurologic basis of this condition is poorly understood. Its attribution to premorbid personality traits or a disposition to psychiatric illness lacks convincing documentation. Part of the difficulty is the lack of knowledge of the role of these endocrine agents in normal cerebral metabolism. We have only incomplete knowledge, for example, as to how they act to reduce the volume of the edematous cerebral tissue around a tumor or to shrink the brain. Critical studies of cellular or subcellular metabolism and morphologic changes are lacking. “Cerebral atrophy” (ventricular enlargement and sulcal widening) has been shown radiologically in patients with Cushing disease and after a prolonged period of corticosteroid therapy, but the basis of this change also is unclear (Momose et al). In most cases of brain shrinkage, withdrawal of steroids has led to a reduction in ventricular size, as documented by repeated CT scans.

In patients with Cushing disease due to adrenal or basophilic pituitary tumors, mental changes suggestive of dementia and enlarged ventricles are not unusual. Here again there is a peculiar combination of mood changes and impaired cognitive function. A frank psychosis may occur. This condition is described more completely in Chap. 58 and the attendant proximal myopathy, in Chap. 51.

Thyroid Encephalopathies

Hyperthyroidism The neurology of thyrotoxicosis has proved to be elusive. Allusions to psychosis are frequent in the medical literature, and thyrotoxic patients have been observed with mental

confusion, seizures, manic or depressive attacks, and delusions. Action tremor is almost universal, and chorea occurs occasionally in various combinations with muscular weakness and atrophy, periodic paralysis, and myasthenia. In descriptions of abnormal movements, it is often not clear whether it was chorea, tremor, myoclonus, or just fidgetiness that was observed. Treatment of the hyperthyroidism gradually restores the mental state to normal, leaving one with no explanation of what had happened to the CNS.

Thyroid crisis or “storm” refers to a fulminant increase in the symptoms and signs of thyrotoxicosis—extreme restlessness, tachycardia, fever, vomiting, and diarrhea—leading to delirium or coma. In the past, this was a not uncommon postoperative event in patients poorly prepared for thyroid surgery. Now it is seen mainly in patients with inadequately treated or untreated thyrotoxicosis complicated by serious medical or surgical illness.

Hashimoto Encephalopathy Brain and associates described an encephalopathy consisting of confusion, altered consciousness, and prominent myoclonus in patients with Hashimoto disease. The details of this curious syndrome were further elaborated by Shaw and colleagues and by Chong. Some cases have had a relapsing course over months or years. It is important to note that most have had normal thyroid function. There are in these cases, however, high titers of several antithyroid antibodies, particularly antibodies against thyroid peroxidase and thyroglobulin; some affected individuals have more than one such antibody. Ferracci and colleagues have found evidence of the production of these antibodies in the nervous system and of their presence in spinal fluid. One must be cautious, however, in interpreting the presence of antithyroid antibodies in the blood, since they are detected in many people without an encephalopathy, particularly older women, and in two-thirds of patients with Graves disease.

The most commonly observed syndrome is of confusion or stupor accompanied by multifocal myoclonus. Seizures—including myoclonic and rarely nonconvulsive status epilepticus—hemiparesis, ataxia, psychosis, and unusual tremors, including those of the palate, have been reported in individual cases. Some of the reports have included children. Often there are others members of the family with a different autoimmune disease. It has been the myoclonic aspect of the encephalopathy, a feature of all of our observed cases, that has led to consideration of this diagnosis. It is not uncommon for such cases to be mistaken for Creutzfeldt-Jakob disease (subacute spongiform encephalopathy). Early descriptions of the illness included a pleocytosis of the spinal fluid and white matter lesions, but we have not noted these abnormalities. What limited pathology there is, in a case studied after 5 months of illness, has shown only nonspecific activation of microglial cells (Perrot et al).

Treatment The encephalopathic symptoms and high titers of antithyroid antibodies respond well to steroid therapy (see Chong). In the case reported by Newcomer and associates, a rapid reversal of thyrotoxic coma (and corticospinal signs) was effected by plasma exchange, in parallel with a reduction in T_4 and T_3 levels, and similar results have been reported by Boers and Colebatch. The circulating antibodies and the response to corticosteroids and plasma exchange implicate an immune pathogenesis, perhaps similar to paraneoplastic “limbic encephalitis” (see page 585) and to lupus, as well as to the rare encephalitis that may accompany thymoma.

Hypothyroidism As a rule, the myxedematous patient is slow to react and psychomotor activity is reduced; but only in exceptional

cases have we noted a significant change in cerebral function. When such a change has been observed, we have been especially impressed with drowsiness, inattentiveness, and apathy. In two cases observed by our colleagues, the somnolence was so extreme that the patients could not stay awake long enough to be fed or examined. They were in a state of hypothermic stupor but exhibited no other neurologic abnormality. The extreme somnolence can be reversed within a few days by thyroid medication.

Hypothyroidism is associated with a number of distinctive myopathic disturbances, which are discussed in Chap. 51. The ataxia and peripheral neuropathy that are sometimes observed in patients with myxedema were described earlier and in Chap. 46.

Cretinism and Neonatal Myxedema This form of severe hypothyroidism, occurring during intrauterine life (hypothyroidism in mother and fetus) or postnatally as a hereditary or acquired thyroid disease, is probably the most frequent and potentially preventable and correctable metabolic mental defect in the world. A perspective on its relative frequency among neonatal metabolic disorders is given in Table 37-1. Although the condition is most common in goitrous regions where there is a lack of iodine, it may also be due to any of several genetically determined defects in thyroxin synthesis that have come to light in recent years (Vassart et al). In areas of endemic cretinism, additional factors may be operative, such as the widespread ingestion of cassava, which contains a toxic goitrogen that inhibits the uptake of iodine by the thyroid.

As a rule, the symptoms and signs of congenital thyroid deficiency are not recognizable at birth but become apparent only after a few weeks; more often the diagnosis is first made between the sixth and twelfth months of life. Physiologic jaundice tends to have been severe and prolonged (up to 3 months), and this, along with widening of the posterior fontanelle and mottling of the skin, should raise suspicion of the disease.

In general, two types of early life hypothyroidism are recognized—sporadic and endemic. The sporadic type occurs occasionally in developed countries (less than once in 4000 births) and is a consequence of a congenital metabolic or anatomic disorder of the thyroid gland. At birth, the gland is either absent or represented by cysts, indicating a failure of development or a destructive lesion. In the sporadic form, in the latter part of the first year, stunting of growth and delay in psychomotor development become evident. Untreated, the child is severely retarded but placid and good-natured; such children sleep contentedly for longer periods than normal children. Sitting, standing, and walking are delayed. Movements are slow, and if tendon reflexes can be obtained, their relaxation time is clearly delayed. The body temperature is low, and the extremities are cold and cyanotic. Although the head is small, the fontanelles may not close until the sixth or seventh year, and there is delayed ossification. This type of hypothyroidism is preventable by treatment with thyroid hormone.

Endemic cretinism is most common in developing countries, with an estimated incidence in some areas of 5 to 15 percent. Stanley and DeLong and colleagues, on the basis of epidemiologic surveys in Ecuador, Zaire, and western China, have distinguished two forms of endemic cretinism—neurologic and myxedematous. The occurrence of the two different types is governed by the timing, duration, and severity of the iodine deficiency (Thilly et al).

The *neurologic form of endemic cretinism* is characterized by varying degrees of deaf-mutism or lesser degrees of hearing loss, dysarthria, proximal limb and truncal rigid-spastic motor disorder involving mainly the lower extremities, and mental deficiency of a

characteristic type. In the most severely affected, there is also strabismus, kyphoscoliosis, underdevelopment of leg muscles, and frontal lobe release signs. Bone age, head size, and height are normal and there are none of the coarse facial features of the myxedematous form. In the so-called *myxedematous form of endemic cretinism*, short stature, microcephaly, coarse facial features, and retarded psychomotor development are the main features. There is no deafness or spastic rigidity of the limbs. In typical instances, the face is pale and puffy; the skin dry; the hair coarse, scanty, and dry; the eyelids thickened; the thickened lips parted by the enlarged tongue; the forehead low; and the base of the nose broad. There are fat pads above the clavicles and in the axillae. The abdomen is protuberant, often with an umbilical hernia, and the head is small—a physical appearance that prompted William Boyd to remark: “What was intended to be created in the image of God has turned out to be the pariah of nature, all for the want of a little thyroid.”

DeLong and others attribute neurologic cretinism to a lack of available iodine in the mother and fetus during the second and third trimesters of pregnancy; neither mother nor fetus elaborate thyroxine. The first and part of the second trimester developmental period, which does not require iodine or thyroxine, passes normally and the general morphology of the brain is normal. It is during the latter part of the second trimester, when the cochleas and the neuronal population of the cerebral cortex and basal ganglia are forming, that these structures suffer irreparable damage. The effects of this midfetal hypothyroidism and iodine deficiency cannot be corrected by giving thyroid hormone at birth and thereafter. It can be prevented only by providing iodine therapy to the mother before and during the first trimester of pregnancy (Cao et al). The myxedematous form of cretinism is more likely to occur from lack of thyroid hormone in the late second and the third trimesters.

The mental defect ranges from apathy and absence of social interaction to an alert, cooperative state, but a backwardness in higher-order thinking and verbal facility is always evident. Retentive memory and apperception are commensurate with overall intellectual competence as judged by the level of mental associations and capacity for abstract thought. The status of the thyroid gland varies; among neurologic cretins, about half are goitrous or have palpable glands; in the rest, the glands are atrophied; practically all the myxedematous cretins are athyreotic. Although typical examples of neurologic and myxedematous hypothyroidism are readily distinguished, both types may exist in the same endemic area, and the stigmata of both forms may be recognized in the same individual. The QRS complex of the ECG is of low voltage; the EEG is slower than normal, with less alpha activity; the CSF contains an excess of protein (50 to 150 mg/dL); and the serum T_3 and T_4 , protein-bound iodine, and radioactive iodine uptake are all subnormal. Serum cholesterol is increased (300 to 600 mg/dL).

At autopsy the brain of neurologic cretinism, though small, is normally formed, with all central and brainstem structures and cortical sulcation intact. A reduction in number of nerve cells was described by Marinesco, especially in the fifth cortical layer, but others have not confirmed this finding. The use of Golgi and other silver techniques has shown decreased interneuronal distances (packing density is increased, as in the immature cortex) where there is a deficiency of neuropil. The latter change is due to a poverty of dendritic branchings and crossings, and presumably there is a decrease of the synaptic surfaces of cells (Eayrs). Thyroid hormone appears to be essential, not for neuronal formation and migration but for dendritic-axonal development and organization.

There is substantial evidence that the administration of iodide

nated oil to hypothyroid women before and during the first trimester of pregnancy prevents sporadic and endemic cretinism, as already noted. Treatment begun during the second trimester protects the fetal brain to a varying degree. Treatment that is started after the beginning of the third trimester does not improve the neurologic status, although head growth and statural development may improve slightly (Cao et al). In sporadic cretinism, if the condition is recognized early, say at birth, and treated consistently with thyroid hormones, statural and mental development can be stimulated to normal or near-normal levels. The extent of recovery depends on the severity and duration of intrauterine hypothyroidism, i.e., its duration before treatment was begun and the adequacy of therapy. In most patients, some degree of mental deficiency persists throughout life.

"Pancreatic Encephalopathy" This term was introduced by Rothermich and von Haam in 1941 to describe what they considered to be a fairly uniform clinical state in patients with acute abdominal symptoms referable to pancreatic disease, mainly pancreatitis. The encephalopathy, as they described it, consisted of an agitated, confused state, sometimes with hallucinations and clouding of consciousness, dysarthria, and changing rigidity of the

limbs—all of which fluctuated over a period of hours or days. Coma and quadriplegia have been reported. At autopsy, a variety of lesions have been described; two cases have had central pontine myelinolysis and others have had small foci of necrosis and edema, petechial hemorrhages, and "demyelination" scattered through the cerebrum, brainstem, and cerebellum. These have been uncritically attributed to the action of released lipases and proteases from the action of pancreatic enzymes (see review of this subject by Sharf and Levy). The term *pancreatic encephalopathy* has also been applied to a depressive illness that seems to occur with disproportionate frequency before the symptoms of a pancreatic cancer become apparent. Also notable in our experience are numerous cases of pancreatic cancer and sequential cerebral emboli from nonbacterial thrombotic (marantic) endocarditis.

The status of pancreatic encephalopathy, in the authors' opinion, is uncertain. Pallis and Lewis also express reservations and suggest that before such a diagnosis can be seriously entertained in a patient with acute pancreatitis, one must exclude delirium tremens, shock, renal failure, hypoglycemia, diabetic acidosis, hyperosmolality, and hypocalcemia or hypercalcemia—any one of which may complicate the underlying disease. Other cases conform to the encephalopathy of multiorgan failure, discussed earlier.

CHAPTER 41

DISEASES OF THE NERVOUS SYSTEM DUE TO NUTRITIONAL DEFICIENCY

Among nutritional disorders, those of the nervous system occupy a position of special interest and importance. The early studies of beriberi, at the turn of the century, were largely responsible for the discovery of thiamine, and consequently for the modern concept of deficiency disease. A series of notable achievements in the science of nutrition followed the discovery of vitamins. Despite such progress, a number of diseases due to nutritional deficiency—and particularly those of the nervous system—continue to represent a worldwide health problem of serious proportions. In Far Eastern communities, where the diet consists mainly of highly milled rice, there is still a significant incidence of beriberi. In other underdeveloped countries, deficiency diseases are endemic, the result of chronic dietary deprivation. And the ultimate effects on the nervous system of mass starvation, involving large portions of the African continent, is alarming to contemplate.

It comes as a surprise to many physicians that deficiency diseases still occur in the United States and other parts of the western world. To a large extent this is attributable to the prevalence of alcoholism. Relatively less common causes are dietary faddism and impaired absorption of dietary nutrients (which occurs in patients with celiac sprue, pernicious anemia, or surgical exclusion of portions of the gastrointestinal tract—for treatment of obesity or for other reasons). Finally, there are the deficiencies induced by the use of vitamin antagonists or certain drugs, such as isonicotinic acid hydrazide (INH), which is used in the treatment of tuberculosis and interferes with the enzymatic function of pyridoxine.

General Considerations

The term *deficiency* is used throughout this chapter in its strictest sense to designate disorders that result from *the lack of an essential nutrient or nutrients in the diet or from a conditioning factor that increases the need for these nutrients*. The most important of these nutrients are the vitamins, more specifically, members of the B group—thiamine, nicotinic acid, pyridoxine, pantothenic acid, riboflavin, folic acid, and cobalamin (vitamin B₁₂). Most deficiency diseases cannot be related to the lack of a single vitamin (subacute combined degeneration of the cord, due to vitamin B₁₂ deficiency, is a notable exception). Usually the effects of several vitamin deficiencies can be recognized. This statement should not obscure the fact that particular manifestations of deficiency disease (e.g., the ocular palsies of Wernicke disease) are indeed related to a deficiency of a specific nutrient, nor should it diminish the need to identify such relationships.

Nutritional diseases of the nervous system are not simply a matter of vitamin deprivation. Practically always, the general signs of undernutrition, such as circulatory abnormalities and loss of subcutaneous fat and muscle bulk, are associated. Furthermore, a total lack of vitamins, as in starvation, is rarely associated with the classic deficiency syndromes of beriberi or pellagra; a certain amount of food is necessary to produce them. An excessive intake of car-

bohydrate relative to the supply of thiamine favors the development of a thiamine deficiency state. All deficiency diseases, including those of the nervous system, are influenced by factors such as exercise, growth, pregnancy, and infection, which increase the need for essential nutrients, and by disorders of the liver and the gastrointestinal tract, which may interfere with the synthesis and absorption of these nutrients.

As already mentioned, alcoholism is an important factor in the causation of nutritional diseases of the nervous system. Alcohol acts mainly by displacing food in the diet but also by adding carbohydrate calories (alcohol is burned almost entirely as carbohydrate), thus increasing the need for thiamine. There is some evidence as well that alcohol impairs the absorption of thiamine and other vitamins from the gastrointestinal tract.

In infants and young children, a reduction of protein and caloric intake (so-called protein-calorie malnutrition, or PCM) has a devastating effect on body growth. Whether or not PCM also hinders the growth of the brain, with consequent effects on intellectual and behavioral development, cannot be answered as readily. The data bearing on this matter are discussed in the last part of the chapter.

While conceding that deficiency diseases of the nervous system may occur in pure form, and are so described in the following pages, more often the symptoms of other deficiencies are added; i.e., the deficiency diseases occur in various combinations. Characteristic also of the nutritional diseases is the potential for involvement of both the central and peripheral nervous systems, an attribute shared only with certain metabolic disorders.

The following deficiency diseases are discussed in this chapter:

1. Wernicke disease and Korsakoff psychosis (*thiamine deficiency*)
2. Nutritional polyneuropathy (neuropathic beriberi, *probably associated with thiamine deficiency*)
3. Deficiency amblyopia (nutritional optic neuropathy; “tobacco-alcohol” amblyopia)
4. Pellagra with remarks on spinal spastic ataxia and encephalopathy [*nicotinic acid (niacin) deficiency*]
5. The syndrome of amblyopia, painful neuropathy, and orogenital dermatitis (so-called Strachan syndrome)
6. Subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency)
7. Neurologic disorders due to a *deficiency of pyridoxine and possibly other B vitamins* (pantothenic acid, riboflavin, folic acid)
8. Inherited disorders of vitamin E metabolism

In addition, attention is drawn to several distinctive neurologic disorders in which nutritional deficiency may play a role, although this has not been proved: (1) “alcoholic” cerebellar degeneration,

(2) primary degeneration of the corpus callosum (Marchiafava-Bignami disease), and (3) central pontine and extrapontine myelinolysis, which is more closely aligned with the rapid correction of hyponatremia, as discussed in the previous chapter. Also, some comments are made about PCM, the neurologic disorders consequent upon intestinal malabsorption, and the rare hereditary vitamin-responsive diseases. Deficiencies of trace elements, because of their rarity, are not discussed; only iodine deficiency (cretinism) is of much importance in humans, and it was discussed in the prior chapter on acquired metabolic diseases. Deficiencies of other essential dietary elements have been reviewed by Fowden and colleagues.

The Wernicke-Korsakoff Syndrome

Wernicke disease and the Korsakoff amnesic state are common neurologic disorders that have been recognized since the 1880s. *Wernicke disease* (originally called polioencephalitis hemorrhagica superioris) is characterized by nystagmus, abducens and conjugate gaze palsies, ataxia of gait, and mental confusion. These symptoms develop acutely or subacutely and may occur singly or, more often, in various combinations. Wernicke disease is due specifically to a deficiency of thiamine and is observed mainly though far from exclusively in alcoholics.

The *Korsakoff amnesic state* (Korsakoff psychosis) is a unique mental disorder in which retentive memory is impaired out of proportion to all other cognitive functions in an otherwise alert and responsive patient. This amnesic disorder, like Wernicke disease, is most often associated with alcoholism and malnutrition, but it may be a symptom of various other diseases that have their basis in lesions of the medial thalamus or the inferomedial portions of the temporal lobes, such as infarction in the territory of the temporal lobe branches of the posterior cerebral arteries, hippocampal damage after cardiac arrest, third ventricular tumors, or herpes simplex encephalitis. A Korsakoff type of memory disturbance may also follow lesions that involve the basal septal nuclei of the frontal lobe. Transient impairments of retentive memory of the Korsakoff type may be the salient manifestations of temporal lobe epilepsy, concussive head injury, and a unique disorder known as transient global amnesia. The anatomic basis of the Korsakoff amnesic syndrome is discussed further in Chap. 21.

In the alcoholic, nutritionally deficient patient, Korsakoff amnesia is usually associated with and follows the occurrence of Wernicke disease. Stated another way, *Korsakoff psychosis* is the psychic manifestation of Wernicke disease. For this reason and others elaborated below, the term *Wernicke disease* or *Wernicke encephalopathy* should be applied to a symptom complex of ophthalmoplegia, nystagmus, ataxia, and an acute apathetic-confusional state. If an enduring defect in learning and memory is added, the symptom complex is appropriately designated as the *Wernicke-Korsakoff syndrome*.

Historical Note In 1881, Carl Wernicke first described an illness of sudden onset characterized by paralysis of eye movements, ataxia of gait, and mental confusion. Swelling of the optic discs and retinal hemorrhages were also said to be present. His observations were made in three patients, of whom two were alcoholics and one was a young woman with persistent vomiting following the ingestion of sulfuric acid. In each of these patients there was progressive stupor and coma, culminating in death. The pathologic changes described by Wernicke consisted of punctate hemorrhages, primarily affecting the gray matter around the third and fourth ven-

tricles and aqueduct of Sylvius; he considered these changes to be inflammatory in nature and confined to the gray matter, hence his designation “polioencephalitis hemorrhagica superioris.” In the belief that Gâyet had described an identical disorder in 1875, the term *Gâyet-Wernicke* is used frequently by French authors. Such a designation is hardly justified insofar as the clinical signs and pathologic changes in Gâyet’s patient differed from those of Wernicke’s patients in all essential details.

In a similar vein, a number of early writers, beginning with Magnus Huss in 1852, made casual reference to a disturbance of memory in the course of chronic alcoholism. However, the first comprehensive account of this disorder was given by the Russian psychiatrist S. S. Korsakoff in a series of articles published between 1887 and 1891 (for English translation and commentary, see reference by Victor and Yakovlev). Korsakoff stressed the relationship between “neuritis” (a term used at that time for all types of peripheral nerve disease) and the characteristic disorder of memory, which he believed to be “two facets of the same disease” and which he called “psychosis polyneuritica.” But he also made the points, generally disregarded by subsequent authors, that neuritis need not accompany the characteristic amnesic syndrome and that both disorders could affect nonalcoholic as well as alcoholic patients. His clinical descriptions were remarkably complete and have hardly been surpassed to the present day. It is of interest that the relationship between Wernicke disease and Korsakoff polyneuritic psychosis was appreciated neither by Wernicke nor by Korsakoff. Murawieff, in 1897, first postulated that a single cause was responsible for both. The intimate clinical relationship was established by Bonhoeffer in 1904, who stated that in all cases of Wernicke disease he found neuritis and an amnesic psychosis. Confirmation of this relationship on pathologic grounds came much later (for further details, see the monograph by Victor et al).

Clinical Features The incidence of the Wernicke-Korsakoff syndrome cannot be stated with precision, but it has, until relatively recent years, been a common disorder, judging from our experience. At the Cleveland Metropolitan General Hospital, for example, in a consecutive series of 3548 autopsies in adults (for the period 1963 to 1976), our colleague M. Victor found the pathognomonic lesions in 77 cases (2.2 percent). The disease affects males only slightly more often than females, and the age of onset is fairly evenly distributed between 30 and 70 years. In the past two decades, the incidence of the Wernicke-Korsakoff syndrome has fallen significantly in the alcoholic population. However, it is being recognized with increasing frequency among nonalcoholic patients in a variety of clinical settings, mainly iatrogenic ones.

The triad of clinical features described by Wernicke—ophthalmoplegia, ataxia, and disturbances of mentation and consciousness—is still clinically useful provided that the diagnosis is suspected and the signs are carefully sought. Often the disease begins with ataxia, followed in a few days or weeks by mental confusion; or there may be the more or less simultaneous onset of ataxia, nystagmus, and ophthalmoplegia with or without confusion. Less often, one component of this triad may be the sole manifestation of the disease. Timely treatment with thiamine prevents the permanent amnesic component of the disease. A description of each of the major manifestations follows.

Oculomotor Abnormalities The diagnosis of Wernicke disease is made most readily on the basis of the ocular signs. These consist of (1) nystagmus that is both horizontal and vertical, (2) weakness or paralysis of the lateral rectus muscles, and (3) weakness or pa-

ralysis of conjugate gaze. Usually there is some combination of these abnormalities (see Chap. 14).

Next to nystagmus, the most frequent ocular abnormality is lateral rectus weakness, which is bilateral but not necessarily symmetrical and is accompanied by diplopia and internal strabismus. With complete paralysis of the lateral rectus muscles, nystagmus is initially absent in the abducting eyes, but it becomes evident as the weakness improves. The palsy of conjugate gaze varies from merely a nystagmus on extreme gaze to a complete loss of ocular movement in that direction. This applies to both horizontal and vertical movements, abnormalities of the former being somewhat more frequent. Paralysis of downward gaze is an unusual manifestation, but a pattern that simulates internuclear ophthalmoplegia has been seen. In advanced stages of the disease there may be a complete loss of ocular movements, and the pupils, which are otherwise usually spared, may become miotic and nonreacting. Ptosis, small retinal hemorrhages, involvement of the near-far focusing mechanism, and evidence of optic neuropathy occur occasionally, but we and our colleagues have never observed papilledema in this disease. Although the aforementioned ocular signs are highly characteristic of Wernicke disease, disappearance of nystagmus and an improvement in ophthalmoparesis within hours or a day or two of the administration of thiamine confirms the diagnosis.

Ataxia Essentially the ataxia is one of stance and gait; in the acute stage of the disease, it may be so severe that the patient cannot stand or walk without support. Lesser degrees are characterized by a wide-based stance and a slow, uncertain, short-stepped gait; the mildest degrees are apparent only in tandem walking. In contrast to the gross disorder of locomotion is a relative infrequency of limb ataxia and intention tremor; when present, they are more likely to be elicited by heel-to-knee than by finger-to-nose testing. Dysarthric, scanning speech is present only rarely.

Disturbances of Consciousness and Mentation These are present in some form in all but 10 percent of patients. Several related types of deranged mentation and consciousness can be recognized. By far the most common disturbance is a *global confusional state*. The patient is apathetic, inattentive, and indifferent to his surroundings. Spontaneous speech is minimal and many questions are left unanswered, or the patient may suspend conversation and drift off to sleep, although he can be aroused without difficulty. Such questions as are answered by the patient betray disorientation in time and place, misidentification of those around him, and an inability to grasp the immediate situation. Many of the patient's remarks are irrational and lack consistency from one moment to another. If the patient's interest and attention can be maintained long enough to ensure adequate testing, one finds that memory and learning ability are also impaired. In response to the administration of thiamine or an adequate diet, the patient rapidly becomes more alert and attentive and more capable of taking part in mental testing. Then the most prominent abnormality is one of retentive memory (Korsakoff amnesia state).

About 15 percent of patients show the signs of alcohol withdrawal, i.e., hallucinations and other disorders of perception, confusion, agitation, tremor, and overactivity of autonomic nervous system function. These symptoms are evanescent in nature and usually mild in degree.

Although drowsiness is a common feature of the global confusional state, stupor and coma are rare as *initial* manifestations of Wernicke disease. However, if the early signs of the disease are not recognized and the patient remains untreated, there occurs a progressive depression of the state of consciousness, with stupor,

coma, and death in a matter of a week or two, just as occurred in Wernicke's original cases. Autopsy series of Wernicke disease are heavily weighted with cases of the latter type, often undiagnosed during life (Harper; Torvik et al.).

Some patients are alert and responsive from the time they are first seen and already show the characteristic features of the Korsakoff amnesia state. In a small number of such patients, the amnesia state is the only manifestation of the syndrome, and no ocular or ataxic signs (other than possibly nystagmus) can be discerned. The memory disorder, which constitutes the chronic and truly crippling feature of the Wernicke-Korsakoff syndrome, is described below.

The Amnesia State As indicated in Chap. 21, the core of the amnesia disorder is a defect in learning (*anterograde amnesia*) and a loss of past memories (*retrograde amnesia*). The defect in learning (memorization) can be remarkably severe. The patient may be incapable, for example, of committing to memory three simple facts (such as the examiner's name, the date, and the time of day) despite countless attempts; the patient can repeat each fact as it is presented, indicating that he understands what is wanted of him and that "registration" is intact; but by the time the third fact is repeated, the first may have been forgotten. However, certain subtle learning may take place; for example, with repeated trials, the patient may learn complex tasks such as mirror writing or how to negotiate a maze, despite no recollection of ever having been confronted with these tasks.

Anterograde amnesia is always coupled with a disturbance of past or remote memory (retrograde amnesia). The latter disorder is usually severe in degree, though rarely complete, and covers a period that antedates the onset of the illness by several years. Characteristically, a few isolated events and information from the past are retained, but these are related without regard for the intervals that separated them or for their proper temporal sequence. Usually the patient "telescopes" events; sometimes the opposite occurs. This aspect of the memory disorder becomes prominent as the initial (global confusional) stage of the illness subsides and some improvement in memory function occurs; this may account for certain instances of confabulation (see below).

It is probably true that memories of the recent past are more severely impaired than those of the remote past (Ribot's rule); language, computation, knowledge acquired in school, and all habitual actions are preserved. This is not to say that all remote memories are intact. These are not as readily tested as more recent memories; the two are therefore difficult to compare. It is our impression that there are gaps and inaccuracies in memories of the distant past in practically all cases of the Korsakoff amnesia state and serious impairments in many.

It should be emphasized that the cognitive impairment of the Korsakoff patient cannot be explained in terms of memory loss alone, even though this is the most critical functional loss. Psychologic testing discloses that certain cognitive and perceptual functions that depend little or not at all on retentive memory are also impaired. The most consistent failure is with the digit symbol task and, to a lesser degree, with arithmetic and block design. Also as a rule, the Korsakoff patient has no insight into his illness and is characteristically apathetic and inert, lacking in spontaneity and initiative and indifferent to everything and everybody around him. However, the patient has a relatively normal capacity to reason with data immediately before him.

Confabulation has generally been considered to be a specific feature of Korsakoff psychosis. The validity of this view depends

largely on how one defines confabulation, and there is no uniformity of opinion on this point. The observations of our colleague M. Victor do not support the oft-repeated statement that the Korsakoff patient fills the gaps in his memory with confabulation. In the sense that gaps in memory exist and that whatever the patient supplies in place of the correct answers fills these gaps, the statement is incontrovertible. It is hardly explanatory, however. The implication that confabulation is a deliberate attempt to hide the memory defect, out of embarrassment or for other reasons, is probably not correct. In fact, the opposite seems to pertain: as the patient improves and becomes more aware of a defect in memory, the tendency to confabulate diminishes.

In our experience, confabulation can be associated with both phases of the Wernicke-Korsakoff syndrome: the initial phase, in which profound general confusion dominates the disease; and the convalescent phase, in which the patient recalls fragments of past experience in a distorted fashion. Events that were separated by long intervals are juxtaposed or related out of sequence, so that the narrative has an implausible or fictional aspect. Whether one designates the latter defect as confabulation or as a particular defect of retentive memory is academic. In the chronic, stable state of the disease, confabulation is usually absent. These and other aspects of confabulation are discussed more fully in the monograph by Victor and colleagues.

Other Clinical Abnormalities Signs of *peripheral neuropathy* are found in more than 80 percent of patients with the Wernicke-Korsakoff syndrome. In most the neuropathic disease is mild and does not account for the disorder of gait, but it may be so severe that stance and gait cannot be tested. In a small number, retrobulbar optic neuropathy is added. Despite the frequency of peripheral neuropathy, overt signs of beriberi heart disease are rare. However, indications of disordered cardiovascular function—such as tachycardia, exertional dyspnea, postural hypotension, and minor electrocardiographic abnormalities—are frequent; occasionally, the patient dies suddenly, following only slight exertion. These patients may show an elevation of cardiac output associated with low peripheral vascular resistance—abnormalities that revert to normal after the administration of thiamine. *Postural hypotension* and *syncope* are common findings in Wernicke disease and are probably due to impaired function of the autonomic nervous system, more specifically to a defect in the sympathetic outflow (Birchfield). There may be mild *hypothermia*, loss of libido, and impotence. Patients with the Korsakoff amnesic state may have a demonstrably *impaired olfactory discrimination*. This deficit, like the notable apathy present in most Wernicke patients, is probably attributable to a lesion of the mediodorsal nucleus of the thalamus and its connections and not to a lesion of the peripheral olfactory system (Mair et al).

Ancillary Laboratory Findings The acute lesions of the Wernicke-Korsakoff syndrome, both the medial thalamic and periaqueductal ones, can be demonstrated by magnetic resonance imaging (MRI) (Donnal et al; Varnet et al). The changes are most apparent on the FLAIR and T2-weighted images but also on diffusion-weighted sequences; the latter is worthy of emphasis because changes of Wernicke disease may be mistaken for infarction on these images. Imaging is particularly useful in patients in whom stupor or coma has supervened or in whom ocular and ataxic signs are otherwise inevident (Victor, 1990). With clinical improvement, the imaging changes are reversible.

The cerebrospinal fluid (CSF) in uncomplicated cases of the Wernicke-Korsakoff syndrome is normal or shows only a modest

elevation of the protein content. Protein values above 100 mg/dL or a pleocytosis should suggest the presence of a complicating illness—subdural hematoma, meningeal infection, and herpes encephalitis being the most common.

Vestibular function, as measured by the response to standard ice-water caloric tests, is universally impaired in the acute stage of Wernicke disease (Ghez). Vertigo is not a complaint, however. To this abnormality of function, which is more or less symmetrical, the term *vestibular paresis* has been applied. It probably accounts for the severe disequilibrium in the initial stage of the illness.

Blood pyruvate is elevated in untreated Wernicke disease, but blood transketolase activity is a more accurate index of the thiamine deficiency. Transketolase, one of the enzymes of the hexose monophosphate shunt, requires thiamine pyrophosphate (TPP) as a co-factor. In normal adult subjects, transketolase values (expressed as sedoheptulose-7-phosphate produced per milliliter per hour) range from 90 to 140 mg and the TPP effect from 0 to 10 percent, depending on the degree of vitamin supplementation. Before specific treatment with thiamine, patients with Wernicke disease show a marked reduction in their transketolase activity (as low as one-third of normal values) and a striking TPP effect (up to 50 percent). Restoration of these values toward normal occurs within a few hours of the administration of thiamine, and completely normal values are usually attained within 24 h.

An additional abnormality of transketolase has been described by Blass and Gibson. They found that transketolase in cultured fibroblasts from four alcoholics with Wernicke-Korsakoff disease bound TPP less avidly than did the transketolase from control lines. Presumably this defect would be insignificant if the diet were adequate but would be deleterious if the diet were low in thiamine. These findings, which have been corroborated by Mukherjee and colleagues, suggest a hereditary factor in the genesis of Wernicke-Korsakoff disease and possibly may explain why only a small proportion of nutritionally deficient alcoholics develop this disease.

Only about half the patients with Wernicke-Korsakoff disease show electroencephalographic (EEG) abnormalities, consisting of diffuse mild to moderate slow activity. Total cerebral blood flow and cerebral oxygen and glucose consumption may be greatly reduced in the acute stages of the disease, and these defects may still be present after several weeks of treatment (Shimojyo et al). These observations indicate that significant reductions in brain metabolism need not be reflected in EEG abnormalities or in depression of the state of consciousness and that the latter is more a function of the location of the lesion than of the overall degree of metabolic defect.

Course of the Illness The mortality rate in the acute phase of Wernicke disease was 17 percent in the series of patients collected by Victor and Adams. The fatalities were attributable mainly to hepatic failure and to infection (pneumonia, pulmonary tuberculosis, and septicemia being the most common). Some deaths were undoubtedly due to the effects of thiamine deficiency that had reached an irreversible stage.

Most patients respond in a fairly predictable manner to the administration of thiamine, as detailed further on. The most dramatic improvement is in the ocular manifestations, as already mentioned. Recovery begins often within hours after the administration of thiamine and practically always within several days. This effect is so constant that a failure of the ocular palsies to respond to thiamine should raise doubts about the diagnosis of Wernicke disease. Sixth nerve palsies, ptosis, and vertical gaze palsies recover completely within a week or two in most cases, but vertical nys-

tagmus may sometimes persist for several months. Horizontal gaze palsies recover completely as a rule, but in 60 percent of cases a fine horizontal nystagmus remains as a permanent sequela. In this respect, horizontal nystagmus is unique among the ocular signs.

In comparison with the ocular signs, improvement of ataxia is somewhat delayed. About 40 percent of patients recover completely from ataxia. The remainder recover incompletely or not at all and are left with a slow, shuffling, wide-based gait and inability to walk tandem. The residual gait disturbances and horizontal nystagmus provide a means of identifying obscure and chronic cases of dementia as alcoholic-nutritional in origin. Vestibular function improves at about the same rate as the ataxia of gait, and recovery is usually but not always complete.

The early symptoms of apathy, drowsiness, and global confusion invariably recede, and as they do the defect in memory and learning stands out more clearly. However, the memory disorder, once established, recovers completely or almost completely in only 20 percent of patients. The remainder are left with varying degrees of permanent disability.

It is apparent from the foregoing account that Wernicke disease and Korsakoff psychosis are not separate diseases but that *the changing ocular and ataxic signs and the transformation of the global confusional state into an amnesic syndrome are simply successive stages in a single disease process*. Of 186 patients in the series of Victor and Adams who presented with Wernicke disease and survived the acute illness, 157 (84 percent) showed this sequence of clinical events. As a corollary, a survey of alcoholic patients with Korsakoff psychosis in a state mental hospital disclosed that in most the illness had begun with the symptoms of Wernicke disease and that about 60 percent of them still showed the ocular cerebellar stigmata of Wernicke disease many years after the onset. The same type of continuum cannot be invoked to explain alcoholic-nutritional cerebellar degeneration that most often arises as an independent illness and not as a residual of the ataxia of Wernicke disease.

Neuropathologic Findings and Clinicopathologic Correlation

Patients who die in the acute stages of Wernicke disease show symmetrical lesions in the paraventricular regions of the thalamus and hypothalamus, mammillary bodies, periaqueductal region of the midbrain, floor of the fourth ventricle (particularly in the regions of the dorsal motor nuclei of the vagus and vestibular nuclei), and superior cerebellar vermis. Lesions are consistently found in the mammillary bodies and less consistently in the other areas. The microscopic changes are characterized by varying degrees of necrosis of parenchymal structures. Within the area of necrosis, nerve cells are lost, but usually some remain; some of these are damaged but others are intact. Myelinated fibers are more affected than neurons. These changes are accompanied by a prominence of the blood vessels, although in some cases there appears to be a primary endothelial proliferation and evidence of recent or old petechial hemorrhage. In the areas of parenchymal damage there is astrocytic and microglial proliferation. Discrete hemorrhages were found in only 20 percent of our cases, and many appeared to be agonal in nature. The cerebellar changes consist of a degeneration of all layers of the cortex, particularly of the Purkinje cells; usually this lesion is confined to the superior parts of the vermis, but in advanced cases the cortex of the most anterior parts of the anterior lobes is involved as well. Of interest is the fact that the lesions of Leigh's encephalomyopathy—a mitochondrial disorder implicating pyruvate metabolism—have been found (page 843); these

bear a close resemblance to those of Wernicke disease but have a slightly different distribution and histologic characteristics.

The ocular muscle and gaze palsies are attributable to lesions of the sixth and third nerve nuclei and adjacent tegmentum and the nystagmus to lesions in the regions of the vestibular nuclei. The latter are also responsible for the loss of caloric responses and probably for the gross disturbance of equilibrium that characterizes the initial stage of the disease. The lack of significant destruction of nerve cells in these lesions accounts for the rapid improvement and the high degree of recovery of oculomotor and vestibular functions. The persistent ataxia of stance and gait is due to the lesion of the superior vermis of the cerebellum; ataxia of individual movements of the legs is attributable to an extension of the lesion into the anterior parts of the anterior lobes. Hypothermia, which occurs sometimes as a presenting feature of Wernicke disease, is probably attributable to lesions in the posterior and posterolateral nuclei of the hypothalamus (experimentally placed lesions in these parts have been shown to cause hypothermia or poikilothermia in monkeys).

The topography of the neuropathologic changes in patients who die in the chronic stages of the disease, when the amnesic symptoms predominate, is much the same as the changes in the acute stages of Wernicke disease. Apart from the expected differences in age of the glial and vascular reactions, the only important difference has to do with the involvement or lack of involvement of the medial dorsal and anterior nuclei of the thalamus. The medial parts of these nuclei were consistently involved in the patients who had shown the Korsakoff amnesic state during life; they were not affected in patients who had had no persistent amnesic symptoms in the series of Victor and Adams. The mammillary bodies were affected in all of the patients, both those with the amnesic defect and those without. These observations suggest that the lesions responsible for the memory disorder are those of the thalamus, predominantly of parts of the medial dorsal nuclei (and their connections with the medial frontal and temporal lobes and amygdaloid nuclei, i.e., a thalamic amnesic state), and not those of the mammillary bodies, as is frequently stated. It is also notable that the hippocampal formations, the site of damage in most other types of Korsakoff memory loss, are intact.

Treatment of the Wernicke-Korsakoff Syndrome Wernicke disease constitutes a medical emergency; its recognition (or even the suspicion of its presence) demands the *immediate administration of thiamine*. The prompt use of thiamine prevents progression of the disease and reverses those lesions that have not yet progressed to the point of fixed structural change. As emphasized earlier, in patients who show only ocular signs and ataxia, the administration of thiamine is crucial in preventing the development of an irreversible amnesic state.

Although 2 to 3 mg of thiamine may be sufficient to modify the ocular signs, much larger doses are needed to sustain improvement and replenish the depleted thiamine stores—50 mg intravenously and 50 mg intramuscularly—the latter dose being repeated each day until the patient resumes a normal diet.

In order to avoid precipitating Wernicke disease, it has also become standard practice in emergency departments to administer 50 to 100 mg of thiamine simultaneously if intravenous fluids that contain glucose are being infused. It is also advisable to give B vitamins to alcoholic patients who are seen for other reasons in the emergency department. The chronic alcoholic (or the nonalcoholic with persistent vomiting) exhausts his body stores of thiamine

in a matter of 7 or 8 weeks, during which time the administration of glucose may serve to precipitate Wernicke disease or cause an early form of the disease to progress rapidly. The further management of Wernicke disease involves the use of a balanced diet and all the B vitamins, since the patient is usually deficient in more than thiamine alone.

A problem in management may arise once the patient has recovered from Wernicke disease and the amnesic syndrome becomes prominent. As indicated above, only a minority of such patients (less than 20 percent in our series) recover; moreover, the time of recovery may be delayed for several weeks or even months, and then it proceeds very slowly over a period of many months. The extent to which the amnesic symptoms will recover cannot be predicted accurately during the acute stages of the illness; one must guard against the premature commitment of the patient to a mental hospital. Interestingly, the alcoholic Korsakoff patient, once more or less recovered, seldom demands alcohol but will drink it if it is offered.

Infantile Wernicke-Beriberi Disease This term designates an acute and frequently fatal disease of infants, which until recently was common in rice-eating communities of the Far East. It affects only breast-fed infants, usually in the second to the fifth months of life. Acute cardiac symptoms dominate the clinical picture, but neurologic symptoms (aphonia, strabismus, nystagmus, spasmoid contraction of facial muscles, and convulsions) have been described in many of the cases. This syndrome can be reversed dramatically by the administration of thiamine, so that some authors prefer to call it *acute thiamine deficiency in infants*. In the few neuropathologic studies that have been made, changes like those of Wernicke disease in the adult have been described.

Infantile beriberi bears no consistent relationship to beriberi in the mother. Infants of mothers with overt signs of beriberi may be quite normal. Conversely, mothers of infants with beriberi may themselves be free of the disease. The absence of beriberi in the mothers of affected infants suggests that infantile beriberi might be due to a toxic factor in breast milk, but such a factor, if it exists, has never been isolated. The levels of thiamine in the breast milk of such mothers have not been measured, however.

Rarely, the clinical manifestations of beriberi in infancy represent an inherited (autosomal recessive) thiamine-dependent state, responding to the continued administration of massive doses of thiamine (Mandel et al; see also Table 41-3, further on).

NUTRITIONAL POLYNEUROPATHY (NEUROPATHIC BERIBERI)

Most physicians in the western world have only a dim notion about beriberi, which they recall as an ill-defined, predominantly cardiac disorder occurring among the rice-eating people of the Orient. In fact, beriberi is a distinct clinical entity that is not confined to any particular part of the world. Essentially it is a disease of the heart and of the peripheral nerves (which may be affected separately), with or without edema, the latter feature providing the basis for the classic division into "wet" and "dry" forms. The cardiac manifestations range from tachycardia and exertional dyspnea to acute and rapidly fatal heart failure. This is the most dramatic manifestation of beriberi, but it is uncommon. Here we are concerned with the affection of the peripheral nerves, or *neuropathic beriberi*, as it is called.

That beriberi is essentially a degenerative disorder of the peripheral nerves was established in the late nineteenth century by the classic studies of the Dutch investigators Eijkman, Pekelharing and Winkler, and Grijns. Only after beriberi gained acceptance as a nutritional disease (this followed Funk's discovery of vitamins in 1911) was it suspected that the neuropathy of alcoholics was also nutritional in origin. The similarity between beriberi and alcoholic neuropathy was commented upon by several authors, but it was Shattuck, in 1928, who first seriously discussed the relationship of the two disorders. He suggested that "polyneuritis of chronic alcoholism was caused chiefly by failure to take or assimilate food containing a sufficient quantity of vitamin B . . . and might properly be regarded as true beriberi." Convincing evidence that "alcoholic neuritis" is not due to the neurotoxic effect of alcohol was supplied by Strauss. He allowed 10 patients to continue their daily consumption of whiskey while they consumed a well-balanced diet supplemented with yeast and vitamin B concentrates; the peripheral nerve symptoms improved in every case. Our own observations support Strauss's contention that alcoholic polyneuropathy is essentially a nutritional disease.

Clinical Features The symptomatology of nutritional polyneuropathy is diverse. In fact, many patients are asymptomatic, and evidence of peripheral nerve affection is found only on clinical or electromyographic examination. In the latter circumstance the neuropathic signs are mild in degree, consisting of thinness and tenderness of the leg muscles, loss or depression of the Achilles reflexes and perhaps of the patellar reflexes, and at times a patchy blunting of pain and touch sensation over the feet and shins.

The majority of patients, however, are symptomatic—weakness, paresthesias, and pain being the usual complaints. The symptoms are insidious in onset and slowly progressive, but occasionally they seem to evolve or to worsen rapidly over a matter of days. The initial symptoms are usually referred to the distal portions of the limbs and progress proximally if the illness remains untreated. The feet are always affected earlier and more severely than the hands. Most often some aspect of motor disability constitutes the chief complaint, but in about one-quarter of the patients the main complaints are pain and paresthesias. The painful syndrome has been prominent in the patients we have encountered in recent years. The discomfort takes several forms: a dull, constant ache in the feet or legs; sharp and lancinating pains, momentary in duration, like those of tabes dorsalis; sensations of cramping or tightness in the muscles of the feet and calves; or band-like feelings around the legs. Coldness of the feet is a common complaint but is purely subjective. Far more distressing are feelings of heat or "burning" affecting mainly the soles, less frequently the dorsal aspects of the feet. The dysesthesias fluctuate in severity and characteristically are worsened by contactual stimuli, sometimes to the point where the patient cannot walk or bear the touch of bedclothes, despite the relative preservation of motor power. The term *burning feet* has been applied to this syndrome, but it is not particularly apt, since the patient also complains of other types of paresthesias and pain, and these symptoms may involve the hands as well as the feet.

Examination discloses varying degrees of motor, sensory, and reflex loss. As the symptoms suggest, the signs are symmetrical, usually more severe in distal than in proximal portions of the limbs, and often confined to the legs. The disproportionate affection of motor power may be striking, taking the form of a foot and wrist drop; but even in these patients the proximal muscles are usually affected as well (indicated by difficulty in arising from a squatting

position). In other patients, all the leg muscles are affected more or less equally, and in a few, weakness appears to be most severe in the proximal muscles. Absolute paralysis of the legs is observed only rarely; immobility due to contractures at the knees and ankles is a more common occurrence. Tenderness of muscles on deep pressure is a highly characteristic finding, elicited most readily in the muscles of the feet and calves. Deep tendon reflexes in the legs are almost always lost, even when weakness is slight in degree. In the arms, tendon reflexes are sometimes retained despite a loss of strength in the hands. In those in whom pain and dysesthesias are prominent and motor loss is slight, the reflexes at knee and ankle may be retained or even of greater than average briskness.

Excessive sweating of the soles and dorsal aspects of the feet and of the volar surfaces of the hands and fingers is a common manifestation of alcohol-induced nutritional neuropathy. Postural hypotension is sometimes associated. These symptoms are indicative of involvement of the peripheral sympathetic nerve fibers.

Sensory loss or impairment may involve all the modalities, although one may be affected out of proportion to the others. One cannot predict from the patient's symptoms which mode of sensation might be affected disproportionately. In patients with impairment of superficial sensation (i.e., touch, pain, and temperature), the border between impaired and normal sensation is not sharp but shades off gradually over a considerable vertical extent of the limbs.

Patients in whom pain is the outstanding symptom do not constitute a distinct group in terms of their neurologic signs. Pain and dysesthesias may be prominent in patients with either severe or slight degrees of motor, reflex, and sensory loss. The term *hyperesthetic* is used commonly to designate the exquisitely painful form of neuropathy but is not well chosen; as pointed out on page 118, one is usually able, by using finely graded stimuli, to demonstrate an elevated threshold to painful, thermal, and tactile stimuli in the "hyperesthetic" zone. Once the stimulus is perceived, however, it has a painful and diffuse, unpleasant quality (hyperpathia). Tactile evocation of pain or burning is an example of allodynia.

In most patients with nutritional polyneuropathy, only the limbs are involved and the abdominal, thoracic, and bulbar muscles are usually spared; however, we have encountered two cases in which there was sensory loss in the pattern of an escutcheon over the anterior thorax and abdomen. In the most advanced instances of neuropathy, hoarseness and weakness of the voice and dysphagia due to affection of the vagus nerves may be added to the clinical picture.

Some idea of the incidence of the motor, reflex, and sensory abnormalities and the combinations in which they occur can be obtained from Table 41-1, which is based on Victor's examination of 189 nutritionally depleted alcoholic patients. Noteworthy is the fact that only 66 (35 percent) of the 189 patients showed the clinical picture of polyneuropathy in its entirety—i.e., a symmetrical impairment or loss of tendon reflexes, sensation, and motor power affecting legs more than the arms and the distal more than the proximal segments of the limbs. In the remaining patients, the motor-reflex-sensory signs occurred in various combinations, as indicated in Table 41-1.

Stasis edema and pigmentation, glossiness, and thinness of the skin of the lower legs and feet are common findings in patients with severe forms of neuropathy. Major dystrophic changes, in the form of perforating plantar ulcers and painless destruction of the bones and joints of the feet (ulcero-osteolytic neuropathy; "Charcot

Table 41-1
Clinical findings in nutritional polyneuropathy

NEUROPATHIC ABNORMALITY	LEGS (189 CASES)	ARMS (57 CASES)
Loss of reflexes alone	45 (24) ^a	6 (10) ^b
Loss of sensation alone	10 (5)	10 (18)

forefeet"), have been described but are rare. Repeated trauma to insensitive parts and superimposed infection are thought to be responsible for the neuropathic arthropathy.

The CSF is usually normal, although a modest elevation of protein content is found in a small number of cases. Electromyographic (EMG) findings include mild to moderate degrees of slowing of motor and sensory conduction and a marked reduction of the amplitudes of sensory action potentials; the motor conduction velocities in distal segments of the nerves may be reduced, while conduction in proximal segments is normal. Denervated muscles show fibrillation potentials.

Pathologic Features The essential pathologic change is one of axonal degeneration, with destruction of both axon and myelin sheath. Segmental demyelination may also occur, but only in a small proportion of fibers. This change may be difficult to discern in myelin-stained sections of whole nerve trunks, but it can be observed in teased nerve fibers stained with osmium. The most pronounced changes are observed in the distal parts of the longest and largest myelinated fibers in the crural and, to a lesser extent, brachial nerves. In advanced cases the degenerative changes extend into the anterior and posterior nerve roots. The vagus and phrenic nerves and paravertebral sympathetic trunks may be affected in advanced cases.

Anterior horn and dorsal root ganglion cells undergo chromatolysis, indicating axonal damage. Degenerative changes in the posterior columns are seen in some cases and are probably secondary to the changes in the dorsal spinal roots.

Pathophysiology The nutritional factor(s) responsible for the neuropathy of alcoholism and beriberi have not been defined precisely. Because of the difficulties in producing peripheral neuropathy in mammals by means of a thiamine-deficient diet, several investigators in the past questioned the idea that thiamine is the antineuritic vitamin. Very few of the animal experiments undertaken to settle this point are satisfactory from a nutritional and pathologic point of view. Nevertheless, several studies in birds and humans do indeed indicate that uncomplicated thiamine deficiency may result in peripheral nerve disease. The necessity of either accepting or rejecting the specific role of thiamine became less urgent when it was demonstrated, in both animals and humans, that a deficiency of pyridoxine or of pantothenic acid could also result in degeneration of the peripheral nerves (see Swank and Adams).

The question of whether polyneuropathy in the alcoholic patient might be due to the direct toxic effects of alcohol and not to

a nutritional deficiency has again been raised from time to time (see, for example, Denny-Brown and Behse and Buchthal). The evidence for this view is not compelling, either on clinical or on experimental grounds, as already mentioned (see reference to Strauss, in introductory section on nutritional neuropathy). The data presented recently by Koike and colleagues, ostensibly in favor of the existence of a true alcoholic neuropathy, suggest that thiamine is not the proximate cause, but in our view they present no convincing support of a direct toxic effect of alcohol. The interested reader will find a detailed critique of this subject in the chapters by Victor and by Windebank in the second and third editions, respectively, of *Peripheral Neuropathy*, edited by Dyck and coworkers.

Treatment and Prognosis The first consideration is to supply adequate nutrition in the form of a balanced diet supplemented with B vitamins. Equally important is to make certain that the patient follows the prescribed diet. If persistent vomiting or other gastrointestinal complications prevent the patient from eating, then parenteral feeding becomes necessary; the vitamins may be given intramuscularly or added to intravenous fluids.

Where pain and sensitivity of the feet are the major complaints, the pressure of bedclothes may be avoided by placing a cradle support over the legs. Aching of the limbs may be related to their immobility, in which case they should be moved passively on frequent occasions. Aspirin or acetaminophen is usually sufficient to control hyperpathia; occasionally codeine in doses of 15 to 30 mg must be added. Obviously, opiates and addicting synthetic analgesics should be avoided. Some of our patients with severe burning pain (similar to causalgia) in the feet had in the past been helped temporarily by blocking the lumbar sympathetic ganglia or by epidural injection of analgesics. The response to phenytoin, carbamazepine, and gabapentin has been inconsistent in our experience. Adrenergic blocking medication has been of little value and mexiletine, of uncertain benefit.

The regeneration of peripheral nerves, which may take many months, will be of no avail if the muscles have been allowed to undergo contracture and the joints to become fixed. In cases of severe paralysis, molded splints should be applied to the arms, hands, legs, and feet during periods of rest. Pressure on the heels and elbows can be avoided by padding the splints and by turning the patient frequently or by asking the patient to do so. As soon as the patient's general condition permits, the limbs must be passively moved through a full range of movement several times daily. As function returns, more vigorous physiotherapeutic measures can be undertaken.

Recovery from nutritional polyneuropathy is a slow process. In the mildest cases there may be a considerable restoration of motor function in a few weeks. In severe forms of the disease, several months may pass before the patient is able to walk unaided. The sensory features and pain in particular may be slower to recover, having taken a year on one of our recently observed patients. The slowness of recovery creates a special problem for the alcoholic patient, in whom the great danger to continued recovery is the resumption of drinking and inadequate diet. Suitable arrangements must therefore be made for close supervision during the long and tedious convalescence.

Pellagra

In the early 1900s, pellagra attained epidemic proportions in the southern United States and in the alcoholic population of large

urban centers. Since 1940, its has diminished greatly because of the general practice of enriching bread with niacin. Nevertheless, among the vegetarian, maize-eating people of underdeveloped countries and among the black population of South Africa, pellagra is still a common disease (Bomb et al, Shah et al, Ronthal and Adler). In developed countries, pellagra is practically confined to alcoholics (Ishii and Nishihara, Spivak and Jackson, Serdaru et al).

Clinical Features in Typical Cases In its fully developed form, pellagra affects the skin, alimentary tract, and hematopoietic and nervous systems. The early symptoms may be mistaken for those of a neurosis. Insomnia, fatigue, nervousness, irritability, and feelings of depression are common complaints; examination may disclose mental dullness, apathy, and an impairment of memory. Sometimes an acute confusional psychosis dominates the clinical picture. Untreated, these symptoms may progress to a dementia. Pellagra may not only produce insanity but occasionally result from it, by virtue of the anorexia and refusal of food that accompany certain mental illnesses. The dermatologic feature, often permitting one to make a confident diagnosis, is a *scaly dermatitis in sun-exposed areas*. Diarrhea and glossitis or other forms of mucous membrane disorder may be accompaniments. (Hence the alliterative triad dementia-dermatitis-diarrhea). The *spinal cord* manifestations have not been clearly described; in general, the signs are referable to both the posterior and lateral columns, predominantly the former. Signs of *peripheral nerve affection* are relatively less common and are indistinguishable from those of neuropathic beriberi.

Pathologic Changes These are most readily discerned in the large cells of the motor cortex, the cells of Betz, and are seen to a lesser extent in the smaller pyramidal cells of the cortex, the large cells of the basal ganglia, the cells of the cranial motor and dentate nuclei, and the anterior horn cells of the spinal cord. The affected cells appear swollen and rounded, with eccentric nuclei and loss of the Nissl bodies (frequently referred to as "axonal reaction"). In the pathologic material of Hauw and associates, the chromatolytic changes were most pronounced in the brainstem nuclei (upper reticular and pontine) and not in the Betz cells. They concluded that these changes were not due to a retrograde axonal lesion but did not comment on the status of the spinal cord.

The spinal cord lesions in pellagra take the form of a symmetrical degeneration of the dorsal columns, especially of Goll, and to a lesser extent of the corticospinal tracts. Such a posterior column degeneration, affecting a specific system of fibers, is likely to be secondary to degeneration of the dorsal root ganglion cells or posterior roots. The reason for the corticospinal tract degeneration is not clear. The few studies of the peripheral nerves in pellagra have disclosed changes like those in alcoholics and other patients with nutritional deficiency.

Etiology It has been known since 1937—when Elvehjem and coworkers showed that nicotinic acid cured black tongue, a pellagra-like disease in dogs—that this vitamin is effective in the treatment of pellagra. Many years before, Goldberger had demonstrated the curative effects of dietary protein and proposed that pellagra was caused by a lack of specific amino acids (see Terris). Now it is known that pellagra may result from a deficiency of either nicotinic acid or tryptophan, the amino acid precursor of nicotinic acid. One milligram of nicotinic acid is formed from 60 mg of tryptophan, a process for which pyridoxine is essential. (Because niacin can be biosynthesized from tryptophan, this is not strictly speaking a vitamin deficiency disorder.) The relationship of niacin to tryptophan metabolism explains the frequent occurrence of pel-

lagra in persons who subsist mainly on corn, which contains only small amounts of tryptophan and niacin—some of the niacin being in bound form and unavailable for absorption.

It should be pointed out that, in experimental subjects, only the cutaneous-gastrointestinal-neurasthenic manifestations of pellagra have been produced by the feeding of tryptophan- or niacin-deficient diets; neurologic abnormalities were not produced by these diets (Goldsmith). As a corollary, only the dermal, gastrointestinal, and neurasthenic manifestations respond to treatment with niacin and tryptophan; neurologic disturbances in pellagrins have proved to be recalcitrant to prolonged treatment with nicotinic acid, although the peripheral nerve disorder may subsequently respond to treatment with thiamine. In monkeys, degeneration of peripheral nerves as well as the unique cerebrocortical changes of pellagra were induced by a deficiency of pyridoxine (Victor and Adams, 1956). Swank and Adams described degeneration of the peripheral nerves in pyridoxine- and pantothenic acid-deficient swine, and Vilter and colleagues produced polyneuropathy in human subjects rendered pyridoxine-deficient; these subjects also showed seborrheic dermatitis and glossitis (indistinguishable from that of niacin deficiency) and the cheilosis and angular stomatitis that are usually attributed to riboflavin deficiency. The foregoing observations indicate that certain lingual and cutaneous manifestations of pellagra may be produced by a deficiency of pyridoxine or other B vitamins and that the neurologic manifestations of pellagra are most likely due to pyridoxine deficiency.

In the special case of Hartnup disease (which resembles pellagra in most respects including the dermatitis), a niacin deficiency is believed to result from the high excretion of indicans and indole metabolites (see page 818).

Nutritional Spinal Spastic and Ataxic Syndrome This syndrome is observed occasionally in nutritionally depleted alcoholics. The main clinical signs are spastic weakness of the legs, with absent abdominal and increased tendon reflexes, clonus, extensor plantar responses, and a loss of position and vibratory senses. In our experience, this syndrome is usually associated with other nutritional disorders, such as Wernicke disease and peripheral and optic neuropathy. In prisoner-of-war camps, the "spastic syndrome" was observed in association with mental and emotional changes and dimness of vision, and at times with widespread muscular rigidity, confusion, coma, and death. The latter syndrome has never been studied pathologically, so that it is impossible to state whether the lesions are the same as or different from those of pellagra or from Strachan syndrome, described further on.

The syndromes of tropical spastic paraparesis and of lathyrism, another form of spastic paraplegia common in India and certain parts of Africa, were for many years suspected of being nutritional in origin but are now known to be due to a virus and a toxin, respectively. These and other types of tropical spastic paraplegia are discussed in greater detail with the spinal cord diseases (Chap. 44). A chronic tropical disease of the peripheral nerves, called "ataxic neuropathy of Nigeria," has been attributed to the ingestion of inadequately detoxified cassava (Osuntokun). Another form of spastic ataxia called "konzo" has been attributed to the production of cyanide by an ingested toxic glycoside in individuals who are protein deficient. The differential diagnosis of spastic ataxia is quite broad and includes especially multiple sclerosis.

Nicotinic Acid Deficiency Encephalopathy Under this title, Jolliffe and coworkers, in 1940, described an acute cerebral syndrome in alcoholic patients consisting of clouding of consciousness,

progressing to extrapyramidal rigidity and tremors ("cogwheel" rigidity) of the extremities, uncontrollable grasping and sucking reflexes, and coma. Some of their patients showed overt manifestations of nutritional deficiency, such as Wernicke disease, pellagra, scurvy, and polyneuropathy. These authors concluded that the encephalopathy represented an acute form of nicotinic acid deficiency, since most of their patients recovered when treated with a diet of low vitamin B content supplemented by intravenous glucose and saline and large doses of nicotinic acid. Sydenstricker and colleagues (1938) had previously reported the salutary effects of nicotinic acid on the unresponsive state observed in elderly undernourished patients, and Spillane (1947) described a similar syndrome and response to nicotinic acid in the indigent Arab population of the Middle East.

The status of this syndrome and its relation to pellagra are uncertain. The clinical, nutritional, and pathologic features were never delineated precisely. Serdaru and associates reported 22 presumed examples of this syndrome in the alcoholic population of the Salpêtrière clinic in Paris, all diagnosed retrospectively after the finding in postmortem material of pellagra-like changes in nerve cells. Prominent were confusional states, oppositional, paratonic rigidity (*gegenhalten*), ataxia, and polymyoclonia—a picture somewhat like that described by Jolliffe and coworkers (above). Skin lesions were absent. We have not encountered identical cases among the undernourished patients in the alcoholic populations of Boston and Cleveland.

Deficiency Amblyopia (Nutritional Optic Neuropathy) "Tobacco-Alcohol Amblyopia" (See also Chap. 13)

These terms refer to a characteristic form of visual impairment that results from nutritional deficiency. The defect in vision is due to a lesion of the optic nerves, more or less confined to the region of the papillomacular bundle.

Typically, the patient complains of dimness or blurring of vision for near and distant objects, evolving gradually over a period of several days or weeks. Examination discloses a reduction in visual acuity due to the presence of central or centrocecal scotomas, which are larger for colored than for white test objects. Pallor of the temporal portion of the optic disc is observed in some cases. These abnormalities are bilateral and roughly symmetrical and, if untreated, may progress to blindness and irreversible optic atrophy. With nutritious diet and vitamin supplements, improvement occurs in all but the most chronic cases, the degree of recovery depending upon the severity of the amblyopia and particularly upon its duration before therapy is instituted.

Although the precise deficiency responsible for this disease cannot be named, its nutritional basis was established beyond doubt during World War II and the Korean War, when innumerable instances were observed in prisoners of war who had been confined for prolonged periods under conditions of severe dietary deprivation. Fisher described the optic nerve lesions in four such patients who had died of unrelated causes between 8 and 10 years after the onset of amblyopia. In each case there was a loss of myelin and axis cylinders restricted to the region of the papillomacular fibers. Of the four cases, three also showed demyelination of the posterior columns of the spinal cord, no doubt an expression of the associated sensory polyradiculopathy.

In the western world, a visual disorder indistinguishable clinically and pathologically from that observed in prisoners of war is observed infrequently, mainly among undernourished alcoholics.

For many years this has been referred to as *tobacco-alcohol amblyopia*, with the implication that the visual loss is due to the toxic effects of alcohol, tobacco, or both. Actually, the evidence is overwhelming that so-called tobacco-alcohol amblyopia is due to nutritional deficiency and not to toxic exposure. A specific nutrient has not been identified, however. There are data in humans and in animals that under certain conditions a deficiency of one or more of the B vitamins—thiamine, vitamin B₁₂, and perhaps riboflavin—may cause degenerative changes in the optic nerves, a situation that pertains in the peripheral nerves as well.

In the 1960s, a popular theory held that the combined effects of vitamin B₁₂ deficiency and chronic poisoning by cyanide (generated in tobacco smoke) were responsible for “tobacco amblyopia.” Vitamin B₁₂ deficiency is a rare but undoubtedly cause of optic neuropathy (page 994), but the notion that cyanide or other substances in tobacco smoke have a damaging effect on the optic nerves is supported neither by logic nor by experimental data (see reviews of Potts and of Victor). Clinically, instances of Leber hereditary optic atrophy, a mitochondrial disorder, may be mistaken for “tobacco-alcohol amblyopia”—an error that should be made less often because the former disorder can now be identified by mitochondrial DNA testing.

Recent outbreaks of an apparently nutritional or perhaps toxic optic neuropathy occurred in Cuba during 1991–1993 and in Tanzania. In both instances the optic neuropathy was frequently associated with peripheral neuropathy; therefore these conditions are considered below, with the Strachan syndrome.

Syndrome of Amblyopia, Painful Neuropathy, and Orogenital Dermatitis (“Strachan Syndrome”)

There remains to be considered a neurologic syndrome that almost certainly is nutritional in origin but does not conform clinically to beriberi or pellagra, the classic deficiency diseases. This syndrome was originally observed by Strachan in 1897 among Jamaican sugar cane workers. The main symptoms in his patients were pain, numbness, and paresthesias of the extremities; objectively there was ataxia of gait, weakness, wasting, and loss of deep tendon reflexes and sensation in the limbs. Dimness of vision and impairment of hearing were common findings, as were soreness and excoriation of the mucocutaneous junctions of the mouth. This disorder, originally known as “Jamaican neuritis,” was quickly recognized in other parts of the world, particularly in the undernourished populations of tropical countries. Subsequently, many cases of this syndrome were observed in the besieged population of Madrid during the Spanish Civil War and during World War II among prisoners of war in North Africa and the Far East.

As indicated earlier, a massive outbreak of a similar disorder, affecting more than 50,000 persons, occurred in Cuba from late 1991 through 1993. The association of this epidemic with widespread dietary deprivation and the salutary response of both optic and peripheral nerve symptoms to treatment with B vitamins suggests a nutritional causation (see *Morbidity and Mortality Weekly Report* and the report of the Cuba Neuropathy Field Investigation Team, cited in the References). Shortly thereafter, Plant and colleagues reported on a similar outbreak of optic and peripheral neuropathy from Tanzania.

The clinical descriptions from these varied sources are not entirely uniform, but certain features are common to all of them and occur with sufficient frequency to allow the delineation of the

neurologic syndrome; it appears to be identical to the one described by Strachan. The core disorder is an affection of the peripheral and optic nerves. The former consists mainly of sensory symptoms and signs, and the latter is characterized by the subacute evolution of failing vision, which, if untreated, may progress to complete blindness and pallor of the optic discs. Deafness and vertigo are generally uncommon, but in some outbreaks among prisoners of war these symptoms were frequent enough to earn the epithet “camp dizziness.” In all these respects the syndrome differs from beriberi. Along with the neurologic signs there may be varying degrees of stomatoglossitis, corneal degeneration, and genital dermatitis (the orogenital syndrome). These mucocutaneous lesions are unlike those of pellagra and riboflavin deficiency.

There have been only a few neuropathologic studies of this syndrome. Aside from the changes in the papillomacular bundle of the optic nerve, which are similar to the deficiency amblyopia discussed above, the most consistent abnormality has been a loss of myelinated fibers in each column of Goll adjacent to the midline. Fisher has interpreted this change to indicate a degeneration of the central processes of the bipolar sensory neurons of the dorsal root ganglia. The fact that the primary sensory neuron is the main site of the neuropathic disorder is consistent with the predominantly sensory symptomatology. The present authors find it difficult to draw a sharp dividing line between the nutritional peripheral (and optic) neuropathy described above and the Strachan syndrome.

The Neurologic Manifestations of Vitamin B₁₂ Deficiency

The spinal cord, brain, optic nerves, and peripheral nerves may all be affected by vitamin B₁₂ (cobalamin) deficiency, giving rise to one of the classic neurologic syndromes. The spinal cord is usually affected first and often exclusively. The term *subacute combined degeneration* (SCD) is customarily reserved for the spinal cord lesion of vitamin B₁₂ deficiency and serves to distinguish it from other types of spinal cord disease that happen to involve the posterior and lateral columns (loosely referred to as *combined system disease*). Whether the peripheral neuropathy is a primary component of the disease or is secondary to damage of the fibers of entry in the dorsal cord has been debated, but the available pathologic evidence favors the former.

The hematologic effects of vitamin B₁₂ deficiency—i.e., *pernicious anemia*—and its neurologic manifestations are distinctive insofar as they usually result not from a dietary lack of vitamin B₁₂ but from the failure to transfer minute amounts of this nutrient across the intestinal mucosa—“starvation in the midst of plenty,” as Castle aptly put it. In the classic disease, this failure derives from the chronic absence of an intrinsic factor, which is secreted (along with hydrochloric acid) by the parietal cells of the gastric mucosa and transports cobalamin (extrinsic factor in the diet) to the ileum, where it is absorbed into the portal system. This is referred to as a *conditioned deficiency*, since it is conditional on the lack of an intrinsic factor.

The hematologic and neurologic manifestations of vitamin B₁₂ deficiency also occasionally complicate other malabsorptive disorders: celiac sprue; extensive gastric or ileal resections; overgrowth of intestinal bacteria in “blind loops,” anastomoses, diverticula, and other conditions resulting in intestinal stasis; and infestation with cobalamin-metabolizing fish tapeworm (*Diphyllobothrium latum*). Rare instances of vitamin B₁₂ deficiency are observed in lactovegetarians and in infants nursed by mothers de-

ficient in vitamin B₁₂; vitamin B₁₂ deficiency may also be due to a rare genetic defect of methylmalonyl coenzyme A (CoA) mutase (Table 41-2).

Here it should also be mentioned that interference with methionine synthetase, a methylcobalamin-dependent enzyme, is produced by chronic exposure to nitrous oxide. A megaloblastic state, as well as the neurologic features of subacute combined degeneration, is induced by this gas. This illness in the modern day arises in operating room personnel (we have seen it in anesthesia nurses), occasionally in dentists, and in abusers of the gas. Whether a pre-existing marginal store of B₁₂ is a predisposing factor is unknown. Cases of subacute combined degeneration have also been described in patients with marginal B₁₂ stores who had received nitrous oxide general anesthesia during surgery. Serum B₁₂ levels are usually in the low normal range, but measurements of methylmalonic acid are elevated (see further on).

Clinical Manifestations Symptoms of nervous system disease occur in the majority of patients with pernicious anemia. The patient first notices mild general weakness and paresthesias consisting of tingling, “pins and needles” feelings, or other vaguely described sensations. The paresthesias involve the hands and feet, more often

the former, and tend to be constant and steadily progressive and the source of much distress. As the illness progresses, the gait becomes unsteady and stiffness and weakness of the limbs, especially of the legs, develop. If the disease remains untreated, an ataxic paraparesis evolves, with variable degrees of spasticity.

Early in the course of the illness, when only paresthesias are present, there may be no objective signs. Later, examination discloses a disorder of the posterior and lateral columns of the spinal cord, predominantly of the former. *Loss of vibration sense is by far the most consistent sign*; it is more pronounced in the feet and legs than in the hands and arms and frequently extends over the trunk. Position sense is usually impaired as well. The motor signs, usually limited to the legs, include a mild symmetrical loss of strength in proximal limb muscles, spasticity, changes in tendon reflexes, clonus, and extensor plantar responses. At first, the patellar and Achilles reflexes are found to be diminished as frequently as they are increased; they may even be absent. With treatment, the reflexes may return to normal or become hyperactive. The gait at first is predominantly ataxic, later ataxic and spastic.

Loss of superficial sensation below a segmental level on the trunk may occur in isolated instances, but such a finding should suggest the alternative possibility of some other disease of the spi-

Table 41-2
Mechanisms whereby malabsorption may be related to neurologic disease

GASTROINTESTINAL DEFECT	SUBSTANCE MALABSORBED	ASSOCIATED NEUROLOGIC DISORDER
Localized gastric lesions:		
Pernicious anemia	Vitamin B ₁₂	Myelopathy, optic neuropathy, etc.
Congenital lack of intrinsic factor	Vitamin B ₁₂	Myelopathy, neuropathy, etc.
Partial gastrectomy	Vitamin B ₁₂	Myelopathy, neuropathy, etc.
	Vitamin D	Osteomalacic myopathy
Lesions of small intestine:		
Predominantly proximal	? Water-soluble vitamins	? Hypovitaminosis B
	Vitamin D	? Osteomalacic myopathy
	Folic acid	Probably none
	Vitamin B ₁₂	Neuropathy, myelopathy, etc.
Predominantly distal	Vitamin B ₁₂	Myoclonus, ataxia, etc.
Diffuse		Neuropathy, myelopathy, etc.
Bacterial contamination of small bowel (jejunal diverticulosis, blind-loop syndrome, strictures)	Vitamin B ₁₂	
Congenital absorptive defect	“Neutral” amino acids	Hartnup disease
	Tryptophan	“Blue diaper” syndrome
	Methionine	“Oast-house” urine disease
	Folic acid	Mental retardation, seizures, ataxia, choreoathetosis
	Vitamin B ₁₂	Neuropathy, myelopathy
	Fat-soluble vitamins	Xerophthalmia
Transmucosal transport disorders associated with steatorrhea:		Keratomalacia
Endocrine causes		? Osteomalacic myopathy
Postirradiation		
Drug-induced		
Defective synthesis of chylomicrons with prolonged intestinal malabsorption	Vitamin E (carrier lipoprotein not synthesized in liver)	Bassen-Kornzweig disease, spinocerebellar degeneration with polyneuropathy
Infiltration of villous cores	Fats (defective chylomicron release)	Encephalopathy of Whipple disease
Competition for essential nutrients (e.g., fish tapeworm)	Vitamin B ₁₂	Neuropathy, myelopathy

nal cord. However, two of our patients have described a band-like sensation around the thorax. The defect of cutaneous sensation may take the form of impaired tactile, pain, and thermal sensation over the limbs in a distal distribution, implicating the small fibers of the peripheral nerves or the spinothalamic tracts, but such findings are also relatively uncommon. The Lhermitte phenomenon (paresthesias down the spine or across the shoulders induced by rapid flexion of the neck) is a common finding if sought.

The nervous system involvement in subacute combined degeneration is roughly symmetrical, and sensory disturbances precede the motor ones; predominantly motor involvement from the beginning and a definite asymmetry of motor or sensory findings maintained over a period of weeks or months should always cast doubt on the diagnosis.

Mental signs are said to be frequent, ranging from irritability, apathy, somnolence, suspiciousness, and emotional instability to a marked confusional or depressive psychosis or intellectual deterioration. Lindenbaum and coworkers have reported cases in which neuropsychiatric symptoms, responsive to vitamin B₁₂, were present without spinal cord or peripheral nerve abnormalities. In our clinical material, symptoms of dementia have not been frequent and always followed the spinal cord disorder.

Visual impairment due to optic neuropathy may occasionally be the earliest or sole manifestation of pernicious anemia; examination discloses roughly symmetrical centrocecal scotomata and optic atrophy in the most advanced cases (page 215). The fact that visual evoked potentials may be abnormal in vitamin B₁₂-deficient patients without clinical signs of visual impairment suggests that the visual pathways may be affected more often than is evident from the neurologic examination alone. A small number of patients have symptoms of autonomic dysfunction, including urinary sphincteric symptoms and impotence.

The CSF is usually normal; in some cases there is a moderate increase in protein. The EMG shows slowing of sensory conduction or reduced-amplitude sensory potentials. Almost always, according to Hemmer and colleagues, somatosensory evoked potentials reveal delayed conduction or absent responses; these changes are known to recover with treatment. Quite remarkable, as these authors indicate, is the finding on MRI of a T2 signal change that demarcates the posterior columns of the cord, as shown in Fig. 41-1. In two of our cases, these have taken the form of well-defined linear changes within the posterior columns on axial scans of the cervical cord.

Neuropathologic Changes The pathologic process takes the form of a diffuse though uneven degeneration of white matter of the spinal cord and occasionally of the brain. The earliest histologic event is a swelling of myelin sheaths, characterized by the formation of intramyelinic vacuoles and separation of myelin lamellae. This is followed by a coalescence of small foci of tissue destruction into larger ones, imparting a vacuolated, sieve-like appearance to the tissue—an appearance also observed in the myelopathy of AIDS and rarely in lupus erythematosus. The myelin sheaths and axis cylinders are both involved in the degenerative process, the former more obviously and perhaps earlier and more severely than the latter. There is relatively little fibrous gliosis in the early lesions, but in more chronic ones, particularly those in which considerable tissue is destroyed, the gliosis is pronounced. The changes begin in the posterior columns of the lower cervical and upper thoracic segments of the cord and spread from this region up and down the cord as well as forward into the lateral and anterior columns. The lesions are not limited to specific systems of fibers within the pos-

Figure 41-1. Sagittal spinal T2-weighted MRI in subacute combined degeneration showing signal changes in the posterior columns. The patient had markedly reduced vibration and position sense and a Romberg sign; the tendon reflexes were preserved and there were no corticospinal tract or peripheral nerve signs. (Courtesy of Dr. James Corbett.)

terior and lateral funiculi but are scattered irregularly through the white matter. For this reason, the term *combined system disease*, which is often used loosely to designate the myelopathy of pernicious anemia, is a less appropriate term than *subacute combined degeneration*.

In rare instances, foci of spongy degeneration are found in the optic nerves and chiasm and in the central white matter of the brain (Adams and Kubik). The peripheral nerves may show a loss of myelin, but there is no unequivocal evidence that axons are significantly affected.

It has been shown by Victor and Laureno that monkeys sustained on a vitamin B₁₂-deficient diet for a prolonged period develop neuropathologic changes indistinguishable from those of subacute combined degeneration in humans (Agamanolis et al.). The time required for the production of central nervous system changes in monkeys—33 to 45 months—is comparable to the time required to deplete the vitamin B₁₂ stores of patients with pernicious anemia in whom parenteral vitamin B₁₂ therapy had been discontinued. It is noteworthy that vitamin B₁₂-deprived monkeys

do not become anemic, despite the prolonged period of vitamin B₁₂ deficiency. Also, in distinction to the human condition, involvement of the optic nerves is particularly severe in the monkey and probably precedes the degeneration of the spinal cord. The optic nerve lesions appear first in the papillomacular bundles, in the retrolbulbar portions of the nerves; it subsequently spreads beyond the confines of this bundle and caudally in the optic nerves, chiasm, and tracts. These changes are much the same as those of “tobacco-alcohol amblyopia” (see above). The peripheral nerves were not affected in the experimentally produced vitamin B₁₂ deficiency.

The paresthesias, impairment of deep sensation, and ataxia are due to lesions in the posterior columns. Weakness, spasticity, increased tendon reflexes, and Babinski signs depend on involvement of the corticospinal tracts. The spinothalamic tracts may rarely be involved in the pathologic process, which explains the occasional finding of a sensory level for pain and temperature on the trunk, as already noted. The distal and symmetrical impairment of superficial sensation and loss of tendon reflexes that occur in some patients are best explained by involvement of peripheral nerves and are reflected in nerve conduction studies (see further on, under “Diagnosis”).

Pathogenesis *Methylcobalamin* is an essential cofactor in the conversion of homocysteine to methionine. An impairment of this reaction due to a deficiency of cobalamin is thought to cause a failure of DNA synthesis, accounting for the hematologic abnormalities and particularly for the production of megaloblasts. However, since neurons do not divide, this sequence of chemical events does not explain the central nervous system abnormalities. One of the better-understood functions of vitamin B₁₂ is its role as a coenzyme in the methylmalonyl CoA–mutase reaction. In this reaction, which is a key step in propionate metabolism, methylmalonyl CoA is transformed to succinyl CoA, which subsequently enters the Krebs cycle. A lack of the cobalamin-dependent enzyme methylmalonyl CoA mutase leads to the accumulation of methylmalonyl CoA and its precursor, propionyl CoA. According to this theorized mechanism, propionyl CoA displaces succinyl CoA, which is the usual primer for the synthesis of even-chain fatty acids; this results in the anomalous insertion of odd-chain fatty acids into membrane lipids, such as are found in myelin sheaths. Conceivably this biochemical abnormality underlies the lesions of myelinated fibers that characterize the disease. However, Carmel and associates have described a hereditary form of cobalamin deficiency in which methylmalonyl CoA mutase activity was normal, despite the presence of typical neurologic abnormalities. In their view, the primary failure is one of methylation of homocysteine to methionine, i.e., a failure of the methionine synthetase reaction, for which the coenzyme methylcobalamin is necessary.

Evidence for the latter view comes also from the observations, mentioned earlier, that prolonged administration of nitrous oxide (N₂O) may produce not only megaloblastic changes in the marrow (Amess et al) but also a sensorimotor polyneuropathy, often combined with signs of involvement of the posterior and lateral columns of the spinal cord (Layzer). Probably N₂O produces its effects by inactivating the methylcobalamin-dependent enzyme methionine synthetase. These and other hypotheses are discussed by Jandl, Carmel and colleagues, and Beck.

The role of *folate deficiency* in the genesis of SCD is less certain. One known clinical mistake has been to treat pernicious anemia by giving folic acid; this corrects the anemia but may worsen or even evoke the spinal cord lesions. There are, nevertheless,

a few reported examples of cerebral and spinal cord lesions indistinguishable from those due to vitamin B₁₂ deficiency in patients with defective folate metabolism—both in adults with acquired deficiency (Pincus) and in children with an inborn metabolic error (Clayton et al).

Diagnosis The main differential diagnostic considerations of the combined sensory and motor features are cervical spondylosis (page 1073), multiple sclerosis of the cervical cord (page 778), rarities such as the female carrier state of adrenoleukodystrophy (adrenomyeloneuropathy, page 836), and non-B₁₂-deficient combined system disease (page 1078). The last of these refers to an obscure myelopathic process that affects the posterior and lateral columns subacutely but is unassociated with any form of B₁₂ deficiency or related enzyme derangement. Recent reports suggest that this process may be the result of an incompletely understood acquired type of copper deficiency. It has been as frequent, in our cases, as the classic type due to B₁₂ deficiency. This entity is mentioned on page 1078 with other diseases of the spinal cord.

The chief obstacle to *early diagnosis* is the lack of parallelism that may exist between the hematologic and neurologic signs, occurring particularly in patients who have taken dietary or medicinal folate. Anemia may also at times be absent, sometimes for many months, even in patients who have not taken folate. In a retrospective study of 141 patients with neuropsychiatric abnormalities due to cobalamin deficiency, there were 19 patients in whom both the hematocrit and mean red blood cell volume were normal (Lindenbaum et al); in these patients, subtle morphologic abnormalities—hypersegmented polymorphonuclear leukocytes and megaloblastosis in bone marrow smears—were almost always found if carefully sought.

Laboratory Diagnosis Serum cobalamin should be measured whenever the diagnosis of vitamin B₁₂ deficiency is in question. Microbiologic assay (using *Euglena gracilis*) is the most accurate measurement, but the method is time-consuming and cumbersome and has been largely replaced by a commercial radioisotope dilution assay (the inexpensive chemiluminescence assay is an alternative but slightly less dependable). With the radioassay, a serum B₁₂ level of less than 100 pg/mL is usually associated with neurologic symptoms and signs of vitamin B₁₂ deficiency. A level below 200 pg/mL that is unassociated with symptoms calls for further investigation of cobalamin deficiency. However, even serum levels of 200 to 300 pg/mL may still be associated (in 5 to 10 percent of cases) with cobalamin deficiency. High serum concentrations of cobalamin metabolites—methylmalonic acid (normal range, 73 to 271 nmol/L) and homocysteine (normal range 5.4 to 16.2 mmol/L) are probably the most reliable indicators of an intracellular cobalamin deficiency and can be used to corroborate the diagnosis (Allen et al; Lindenbaum et al). It must be emphasized that the serum cobalamin level is not a measure of total body cobalamin. In a patient who stops absorbing ingested cobalamin, the serum levels may remain in the normal range for a long time despite decreasing tissue reserves. In patients who have received vitamin B₁₂ parenterally, the two-stage Schilling test is a more reliable indicator of cobalamin deficiency, since it uncovers a defect in absorption of the vitamin; however, the Schilling test has been supplanted for routine diagnosis by the measurement of antibodies to intrinsic factor and parietal cells.

Achlorhydria is almost invariably present in patients with pernicious anemia; its presence can be detected by measuring the se-

rum gastrin level. Antibodies to gastric parietal cells are also present in as many as 90 percent of patients with cobalamin deficiency, but this test often yields false-positive results. The finding of serum antibodies against intrinsic factor is diagnostically specific but demonstrable in only 60 percent of cases in most series.

Low cobalamin levels with or without the clinical signs of deficiency may occur in patients with atrophic gastritis or after subtotal gastrectomy. The malabsorption in such cases is thought to be due to a failure to extract cobalamin from food rather than a failure of the intrinsic factor mechanism ("food-cobalamin malabsorption"); since the absorption of free cobalamin is normal, the Schilling test is unimpaired (Carmel). Infection of the gastric mucosa with *Helicobacter pylori* has been implicated in some cases. There are also inherited defects in the gene for intrinsic factor that render it ineffective.

The results of nerve conduction tests have varied in vitamin B₁₂-deficient patients. Early in the course of SCD, nerve conduction may be normal, but in our experience most patients with neurologic symptoms have slowing of distal sensory conduction; others have found reduced amplitudes and minor signs of denervation, suggestive of axonal change. In patients with normal peripheral nerve studies, the somatosensory evoked potentials may show abnormalities attributable to central conduction delays, implicating the posterior columns as the cause of the sensory symptoms (Fine and Hallett). In advanced cases, motor conduction and late responses may be affected to a slight degree. These ambiguities reflect the inconsistent and poorly understood role of the peripheral neuropathic component in this disease.

As already mentioned, the MRI may show lesions in the posterior columns, particularly extending through the cervical and upper thoracic cord, and less often, in the lateral columns. The frequency of these findings, however, is not known, and their absence cannot be considered evidence against the diagnosis.

Treatment The diagnosis of SCD demands the administration of vitamin B₁₂ and the continuation of treatment for a long period or the rest of the patient's life. In cases of pernicious anemia, the patient is given 1000 µg of cyanocobalamin or hydroxycobalamin intramuscularly each day for several days. The usual approach has been to repeat the injection weekly for a month and then monthly for the remainder of the patient's life. Although most of the injected cobalamin is excreted, these patients must be flooded with the vitamin because the repletion of cobalamin tissue stores is a direct function of the dose.

In recent years, however, the notion that forms of B₁₂ deficiency must be circumvented by parenteral administration has been questioned and the use of oral cobalamin 500 to 1000 µg daily has been suggested as an alternative for maintenance treatment. Several studies indicate the effectiveness of this approach in elderly patients with poor B₁₂ absorption and in persons with limited diets, such as vegans, but we would express reservation regarding the use of oral replacement in the treatment of pernicious anemia with neurologic manifestations.

The most important factor influencing the response to treatment is the duration of symptoms before treatment is begun; age, gender, and the degree of anemia are relatively unimportant factors. The greatest improvement occurs in those patients whose disturbance of gait has been present for less than 3 months; recovery may be complete if therapy is instituted within a few weeks after the onset of symptoms. All neurologic symptoms and signs may improve, mostly during the first 3 to 6 months of therapy, and then

at a slower tempo, during the ensuing year or even longer. In practically all instances, there is some degree of improvement after treatment, although sometimes, in cases of longest duration, the best that can be accomplished is an arrest of progression.

Other Neurologic Disorders Due to Deficiencies in B Vitamins

Pyridoxine (Vitamin B₆) Deficiency A special type of nutritional polyneuropathy is encountered in tuberculous patients as a complication of treatment with isonicotinic acid hydrazide (INH; isoniazid). In the recent past, a similar neuropathy was observed in hypertensive patients treated with hydralazine.

The occurrence of a neuropathy due to INH was recognized in the early 1950s, soon after the introduction of this drug for the treatment of tuberculosis. The neuropathy was characterized by paresthesias and burning pain of the feet and legs, followed by weakness of these parts and loss of ankle reflexes. Rarely, with continued use of the drug, the hands were affected as well. The nature of INH-induced neuropathy was clarified by Biehl and Vilter. They found that the administration of isoniazid results in a marked excretion of pyridoxine and that the administration of pyridoxine in conjunction with INH prevented the development of neuropathy. As a result of this simple preventive measure, very few examples of INH-induced neuropathy are now observed. Hydralazine, closely related in structure to INH, causes the formation of pyridoxal-isoniazid complexes (hydrazone), which make pyridoxal (the main form of vitamin B₆) unavailable to the tissues. The neuropathy responds favorably to discontinuation of the drug and the administration of pyridoxine.

Severe pyridoxine deficiency in animals and humans also causes *seizures*. This was first observed in swine by Swank and Adams and later in infants who were maintained on a milk formula lacking in pyridoxine. A pyridoxine-responsive seizure disorder of the neonatal period is discussed on page 288.

Pyridoxine Toxicity Paradoxically, the *consumption of large amounts of pyridoxine* (by food and vitamin faddists) may also cause a sensory peripheral neuropathy or ganglionopathy (Schaumburg et al; Albin et al). There is no weakness; the symptoms, including ataxia and areflexia, are purely sensory and can be quite disabling. Symptoms may extend to the trunk, scalp, and face. Improvement is the rule when the drug is withdrawn. This disorder is probably due to the direct toxic effect of pyridoxine on dorsal root ganglion cells.

Pantothenic Acid Deficiency A predominantly sensory neuropathy has also been induced, again in swine, by Swank and Adams and later in humans by a deficiency of pantothenic acid (a constituent of coenzyme A), as reported by Bean et al. In some patients the administration of pantothenic acid has allegedly reversed the painful dysesthesias of the "burning foot" syndrome.

Riboflavin Deficiency Whether or not riboflavin deficiency leads to neurologic symptoms has been controversial. In the past, there were claims that glossitis, cheilosis, and neuropathy were due to riboflavin deficiency, but its effects were never isolated. Antozzi and coworkers have reported that a metabolic disorder similar to the Reye syndrome can be caused by riboflavin deficiency and is correctable by administration of riboflavin alone. The affected infants were hypoglycemic, hypotonic, and episodically weak and

unresponsive. Antozzi and colleagues also recorded instances of disease in older children and adults manifest as a type of lipid storage polymyopathy due to either a deficiency or malabsorption of riboflavin. Presumably a disorder of flavin metabolism had caused an impairment of both beta oxidation of fatty acids and respiratory chain I and II complexes. Serum creatine phosphate was normal in these individuals, but carnitine was reduced. The oral administration of 200 mg of riboflavin and 4 g of carnitine per day relieved the symptoms. We have had no experience with such cases.

Folate Deficiency Despite the frequency of folic acid deficiency and its hematologic effects, its role in the pathogenesis of nervous system disease has also not been established beyond doubt (see reviews by Crellin et al and by Carney). The polyneuropathy that occasionally complicates the chronic administration of phenytoin has also been attributed, on uncertain grounds, to folate deficiency. Botez and colleagues have described a group of 10 patients with sensorimotor polyneuropathy (4 also had spinal cord disease) presumably due to intestinal malabsorption; all of the patients improved over several months while receiving large doses of folic acid. This experience is unique, however. The possible role of folate deficiency in the pathogenesis of spinal cord disease has been mentioned above in relation to vitamin B₁₂ deficiency, and its putative role in psychiatric disease has been discussed by Carney. If such cases of folate deficiency, subacute combined degeneration, or mental changes do occur, they must be rare.

In summary, it has been well established that polyneuropathy may be caused by a deficiency of at least four B vitamins—thiamine (probably in concert with other vitamin deficiencies), pyridoxine, pantothenic acid, and vitamin B₁₂—and by an extreme excess of pyridoxine. That a deficiency of riboflavin causes lesions of the central or peripheral nervous system has not been proved in our opinion.

Disorders Due to Deficiencies of Fat-Soluble Vitamins

Vitamin E Deficiency This is of two types: a defect in intestinal absorption and an inherent hepatic enzyme deficiency that blocks incorporation of the vitamin into lipoprotein. A rare neurologic disorder of childhood, consisting essentially of spinocerebellar degeneration in association with polyneuropathy and pigmentary retinopathy, has been attributed to a deficiency of vitamin E consequent to prolonged intestinal fat malabsorption (Muller et al; Satya-Murti et al). The same mechanism has been proposed to explain the neurologic disorders that sometimes complicate abetalipoproteinemia (page 827), fibrocystic disease (Sokol et al), celiac sprue disease (page 977), and extensive intestinal resections (Harding et al). Vitamin E deficiency has also been observed in young children with chronic cholestatic hepatobiliary disease (Rosenblum et al). Ataxia, loss of tendon reflexes, ophthalmoparesis, proximal muscle weakness with elevated serum creatine kinase, and decreased sensation are the usual manifestations. These symptoms are referable to parts of the nervous system and musculature that are found to be diseased in animals deprived of vitamin E—degeneration of Clark's columns, spinocerebellar tracts, posterior columns, nuclei of Goll and Burdach, and sensory roots (Nelson et al). Local differences in the natural concentration of vitamin E in various parts of the nervous system and musculature are believed

to account for the distribution of the lesions. In affected children, neurologic function improves after long-term daily supplementation with high doses of vitamin E.

In recent years there have been several reports of an inherited form of spinocerebellar degeneration attributable to an inherited but conditioned vitamin E metabolism that may closely mimic the phenotype of Friedreich ataxia (“familial isolated vitamin E deficiency”). In these patients, absorption and transport of vitamin E to the liver is normal but hepatic incorporation of tocopherol (the active form of vitamin E) into very-low-density lipoproteins is defective (Traber et al). The abnormality has been traced to a mutation in the gene for the tocopherol transfer protein, located on chromosome 8q (Gotoda et al). In a sense this is a vitamin deficiency conditioned by a genetic mutation. An important feature of these cases is that chronic oral administration of large doses of vitamin E can halt and even reverse progression of the ataxia (Gabsi et al).

Vitamins A and D Disorders due to a lack or excess of these fat-soluble vitamins have been reported, but they are rare. Vitamin A deficiency sometimes occurs with malabsorption syndromes, causing impairment of vision. *Excess of vitamin A* in children or adults may result in the syndrome of *pseudotumor cerebri* (page 538). Vitamin D deficiency has been associated with hypoparathyroidism or a malabsorption state that leads to hypocalcemia, proximal muscle weakness, and rickets.

DISEASES OF THE NERVOUS SYSTEM OF PROBABLE BUT UNPROVEN NUTRITIONAL ORIGIN

The disorders comprised by this category, as the above title implies, have only an uncertain relationship to nutritional deficiency. They are found mainly in alcoholics, but their relationship to alcohol is probably not fundamental, since each has also been observed in nonalcoholic patients. The belief that these disorders are nutritional in origin is based on certain indirect evidence: (1) Usually, a prolonged period of undernutrition associated with a significant loss of weight precedes the neurologic illness. In such cases that are associated with alcoholism, the amount of alcohol consumed need not be large, but the dietary deprivation is always severe. (2) Examination at the onset of the illness frequently discloses general physical evidence of undernutrition as well as the presence of neurologic disorders of known nutritional etiology. (3) Certain attributes of the neuropathologic changes—namely their subacute evolution, symmetry, and constancy of localization—are precisely the features that characterize neurologic disorders of known nutritional etiology. (4) The same syndromes are observed occasionally in nonalcoholics under conditions of dietary depletion. (5) There is at least a partial response to correction of the nutritional impairment.

“Alcoholic” Cerebellar Degeneration

This term refers to a common and uniform type of degeneration of the vermic and anterior lobes of the cerebellum in alcoholics. Its incidence is about twice that of Wernicke disease, but unlike the latter, it is considerably more frequent in men than in women. It is characterized clinically by a wide-based stance and gait, varying degrees of instability of the trunk, and ataxia of the legs, the arms being affected to a lesser extent and often not at all. Nystagmus

Figure 41-2. CT scan from a 60-year-old alcoholic patient showing prominence of midline cerebellar sulci. A broad-based gait and ataxia of the legs had been present for many years. Death was from myocardial infarction. The cerebellum, cut in the midsagittal plane (*below*), shows folial atrophy of the anterosuperior vermis, characteristic of alcoholic cerebellar degeneration.

and dysarthria are infrequent. In addition to an ataxic (intention) tremor, there may be a tremor of the fingers or hands resembling one of the two types of parkinsonian tremor but appearing only when the limbs are placed in certain sustained postures. Mauritz and coworkers have demonstrated that the instability of the trunk in these cases consists of a specific 3-Hz rhythmic swaying in the anteroposterior direction; by contrast, patients with lesions of the cerebellar hemispheres show only slight postural instability without directional preponderance.

In most cases, the cerebellar syndrome evolves over a period of several weeks or months, after which it remains unchanged for many years. In others, it develops more rapidly or more slowly, but in these cases also the disease eventually stabilizes. Occasionally, the cerebellar disorder progresses in a saltatory manner, the symptoms worsening in relation to a severe infectious illness or an attack of delirium tremens.

The *pathologic changes* consist of a degeneration of all the neurocellular elements of the cerebellar cortex but particularly of

the Purkinje cells in the anterior and superior aspects of the vermis. The cerebellar atrophy is readily visualized by computed tomography (CT) (Fig. 41-2) and MRI.

Two particular forms of this syndrome have not been emphasized sufficiently. In one, the clinical abnormalities are limited to an instability of station and gait, individual movements of the limbs being unaffected. The pathologic changes in such cases are restricted to the anterosuperior portions of the vermis. A second type is strikingly acute but transient. Here, except for their reversibility, the cerebellar symptoms are identical to those that characterize the chronic, fixed form of the disease. In this transient type, the derangement is only one of function ("biochemical lesion") and has probably not progressed to the point of fixed structural changes. These forms of cerebellar disease, and particularly the restricted and reversible varieties, cannot be distinguished from the cerebellar manifestations of Wernicke disease either on pathologic or on clinical grounds. It is our opinion that the cerebellar ataxia of Wernicke disease and that referred to as *alcoholic cerebellar degeneration* are based on the same disease process, the former term being applicable when the cerebellar abnormalities are associated with ocular and mental signs and the latter when the cerebellar syndrome stands alone. Alcoholic cerebellar degeneration is in all likelihood due to nutritional deficiency and not to the toxic effects of alcohol or other causes, for reasons already indicated. Insofar as the cerebellar ataxia usually improves to some extent under the influence of thiamine alone (see above, under "Wernicke-Korsakoff Syndrome"), it is likely that a deficiency of this vitamin is in whole or part responsible for the cerebellar lesion, but this has not been proven.

Marchiafava-Bignami Disease (Primary Degeneration of the Corpus Callosum)

In 1903, the Italian pathologists Marchiafava and Bignami described a unique alteration of the corpus callosum in three alcoholic patients. In each case, coronal sectioning of the fixed brain disclosed a pink-gray discoloration of the central portion of the corpus callosum throughout the longitudinal extent of this structure. Microscopically, the lesion proved to be confined to the middle lamina (which makes up about two-thirds of the thickness of the corpus callosum), in which there was a loss of myelin, and to some degree, of the axis cylinders; macrophages were abundant in the altered zone, and astrocytic proliferation had followed. The clinical observations in these patients were few and incomplete. In 1907, Bignami described a case in which the corpus callosum lesion was accompanied by a similar lesion in the central portion of the anterior commissure.

These early reports were followed by a spate of articles that confirmed and amplified the original clinical and pathologic findings. By 1922 about 40 cases of this disorder had been described in the Italian literature (Mingazzini). With one exception, all the reported cases were in males, and all of these men were insatiable drinkers. They drank red wine for the most part but other forms of liquor as well. Beginning in 1936, with the report of King and Meehan, the disease came to be recognized throughout the world, and the notions that it had a predilection for drinkers of red wine and a special racial predisposition or geographic locale were abandoned.

Pathologic Features Marchiafava-Bignami disease is more readily defined by its pathologic than its clinical features. The principal alteration is in the middle portion of the corpus callosum, which on gross examination appears somewhat rarefied and sunken and reddish or gray-yellow in color, depending on its age. In the anterior portion of the corpus callosum, the lesion tends to be more severe in the midline than in its lateral parts; in the splenium, however, the opposite may pertain. The most chronic lesion takes the form of a centrally placed gray cleft or cavity, with collapse of the surrounding tissue and reduction in thickness of the corpus callosum. Microscopically, corresponding to the gross lesions, one observes clearly demarcated zones of demyelination, with variable involvement of the axis cylinders and an abundance of fatty macrophages with gliosis at the margins. Inflammatory changes are absent.

Infrequently, lesions of a similar nature are found in the central portions of the anterior and posterior commissures and the brachia pontis. These zones of myelin destruction are always surrounded by a rim of intact white matter. The predilection of this disease process for commissural fiber systems has been stressed, but it is certainly not confined to these fibers. Symmetrically placed lesions have been observed in the columns of Goll, superior cerebellar peduncles, and cerebral hemispheres, involving the centrum semiovale and extending, in some cases, into the adjacent convolutional white matter. As a rule, the internal capsule and corona radiata, subcortical arcuate fibers, and cerebellum are spared. In several cases, the lesions of deficiency amblyopia (see above) have been added; in others, the lesions of Wernicke disease.

Many of the reported cases, as first pointed out by Jequier and Wildi, have involved cortical lesions of a special type: the neurons in the third layer of the frontal and temporal lobe cortices had disappeared and were replaced by a fibrous gliosis. Morel, who first described this *cortical laminar sclerosis*, did not observe its association with Marchiafava-Bignami disease. However, when Jequier and Adams reviewed his original cases (unpublished), all had Marchiafava-Bignami disease. In a subsequent report by Delay and colleagues comprising 14 cases of cortical laminar sclerosis, the cortical lesion was also consistently associated with a corpus callosum lesion. We believe the cortical lesions are best explained as secondary to the callosal degeneration.

Clinical Features The disease affects persons in middle and late adult life. With few exceptions, the patients have been males and severe chronic alcoholics. The clinical features of the illness are otherwise quite variable, and a clear-cut syndrome of uniform type has not emerged. Many patients have presented in a state of terminal stupor or coma, precluding a detailed neurologic assessment. In others, the clinical picture was dominated by the manifestations of chronic inebriation and alcohol withdrawal—tremor, seizures, hallucinosis, and delirium tremens. In some of these patients, following the subsidence of the withdrawal symptoms, no signs of neurologic disease could be elicited, even in the end stage of the disease, which lasted for several days to weeks. In yet another group, a progressive dementia has been described, evolving slowly over a 3- to 6-year period before death. Emotional disorders leading to acts of violence, marked apathy, moral perversions, and sexual misdemeanors have been noted in these patients; dysarthria, slowing and unsteadiness of movement, transient sphincteric incontinence, hemiparesis, and apractic or aphasic disorders were superimposed in others. The last stage of the disease is characterized by physical decline, seizures, stupor, and coma. An impressive feature

of these varied neurologic deficits in some patients has been their tendency toward remission when nutrition was restored.

In two cases that have come to our attention, the clinical manifestations were essentially those of bilateral frontal lobe disease: motor and mental slowness, apathy, prominent grasping and sucking reflexes, gegenhalten, incontinence, and a slow, hesitant, wide-based gait. In both of these cases, the neurologic abnormalities evolved over a period of about 2 months, and both patients recovered from these symptoms within a few weeks of hospitalization. Death occurred several years later as a result of liver disease and subdural hematoma, respectively. In each case, autopsy disclosed an old lesion typical of Marchiafava-Bignami disease confined to the central portion of the most anterior parts of the corpus callosum, but one had to look closely to see the gray line of gliosis.

In view of the great variability of the clinical picture and the obscuration in many patients of subtle mental and neurologic abnormalities by the effects of chronic inebriation and other alcoholic neurologic disorders, the diagnosis of Marchiafava-Bignami disease is understandably difficult. In fact, it is rarely made during life, but the CT scan and MRI have disclosed some typical but unsuspected examples (see Kawamura et al). In some cases studied sequentially, MRI disclosed demyelination, swelling, and necrosis of the corpus callosum with extension toward the subcortical white matter. In rare cases these findings have reversed over time after vitamin therapy, leaving residual callosal atrophy (Gambini). The occurrence, in a chronic alcoholic, of a frontal lobe syndrome or a symptom complex that points to a diagnosis of frontal or corpus callosum tumor but in whom the symptoms remit should suggest the diagnosis of Marchiafava-Bignami disease. The image appearance may be mistaken for multiple sclerosis or gliomatosis cerebri.

Pathogenesis and Etiology Originally, Marchiafava-Bignami disease was attributed to the toxic effects of alcohol, but this is an unlikely explanation in view of the prevalence of alcoholism and the rarity of corpus callosum degeneration. Further, the distinctive callosal lesions have not been observed with other neurotoxins. Very rarely, undoubtedly examples of Marchiafava-Bignami disease have occurred in abstainers, so that alcohol cannot be an indispensable factor. A nutritional etiology has been invoked, for the reasons given earlier, but the factor that is deficient has not been determined. This view is underscored by reports of improvement in a few but not all cases following administration of thiamine. The mechanisms involved in the selective demyelination and noninflammatory necrosis of particular areas of white matter remain to be elucidated. Perhaps, when its mechanism becomes known, Marchiafava-Bignami disease, like central pontine myelinolysis (which it resembles histologically), will have to be considered in a chapter other than one on nutritional disease.

Protein-Calorie Malnutrition (PCM) and Mental Retardation

The reader might gather from the foregoing descriptions that the nervous system is rarely affected by nutritional deficiency except when subjected to the influence of chronic alcoholism, and then the essential problem is one of dietary imbalance—an inadequacy of B vitamins in the face of an adequate or near adequate caloric intake. It is true that the CNS resists the effects of starvation better than other organs. Nonetheless, there is increasing evidence that severe dietary deprivation during critical phases of brain development may result in permanent impairment of cerebral function and

Table 41-3

Vitamin-responsive inherited disorders affecting the nervous system

VITAMIN	DISORDER	THERAPEUTIC DOSE	ENZYMATIC DEFECT	NEUROLOGIC MANIFESTATIONS
Thiamine (B ₁)	Branched-chain ketoaciduria	5–20 mg	Branched-chain keto acid decarboxylase	Lethargy, coma
	Lactic acidosis	5–20 mg	Pyruvate carboxylase	Mental retardation
	Pyruvic acidemia	5–20 mg	Pyruvate dehydrogenase	Cerebellar ataxia
	Anemia	50 mg	—	Same as thiamine-deficient beriberi of infancy and childhood
Pyridoxine (B ₆)	Homocystinuria	>25 mg	Cystathione synthase	Mental retardation, cerebrovascular accidents, psychoses
	Infantile convulsions	10–50 mg	Glutamic acid decarboxylase	Seizures
Cobalamin (B ₁₂)	Xanthurenic aciduria	5–10 mg	Kynureninase	Mental retardation
	Methylmalonic aciduria	1000 g	Methylmalonyl CoA mutase apoenzyme	Lethargy, coma, psychomotor retardation
	Methylmalonic aciduria and homocystinuria	>500 g	Defects in synthesis of adenosylcobalamin and methylcobalamin	Developmental arrest, cerebellar ataxia
Folic acid	Megaloblastic anemia	<0.05 mg	Folate deficiency	Mental retardation
	Formiminotransferase deficiency	>5 mg	Intestinal malabsorption of formiminotransferase	Mental retardation
Biotin	Homocystinuria and hypomethioninemia	>10 mg	N ⁵ , N ¹⁰ -Methylenetetrahydrofolate reductase	Schizophrenic syndrome
	β-Methylcrotonylglycinuria	↑5–10 mg	β-Methylcrotonyl CoA carboxylase	Mental retardation
Nicotinamide	Propionic acidemia	↑5–10 mg	Propionyl CoA carboxylase	Lethargy, coma
	Hartnup disease	>400 mg	Intestinal malabsorption of tryptophan	Cerebellar ataxia

SOURCE: Adapted by permission from Rosenberg and from Matsui et al.

in mental retardation. Inasmuch as there are an estimated 100 million children in the world who are undernourished and suffer from varying degrees of protein, calorie, and other dietary inadequacies, this is one of the most pressing problems in medicine and society.

Two overlapping syndromes have been defined in malnourished infants and children: kwashiorkor and marasmus. *Kwashiorkor* is a syndrome of weanling children and is due to protein deficiency; it is manifest by edema (and sometimes ascites), hair changes (sparsity and depigmentation), and stunting of growth. The edema is due to hypoalbuminemia; in addition, there is an abnormal pattern of blood amino acids as well as a fatty liver. Sometimes there are skin changes suggestive of pellagra or riboflavin deficiency. *Marasmus* is characterized by an extreme degree of cachexia and growth failure in early infancy. Infants with marasmus have usually been weaned early or were never breast-fed. Common to both groups of children is an apathy and indifference to the environment combined with irritability when they are handled or moved. The children are underactive; even after an adequate diet has been instituted, their tendency is to follow with the eyes rather than to move. At one stage of early convalescence, some kwashiorkor children pass through a phase of rigidity and tremor for which there has been no explanation.

As a rule, the clinical signs of polyneuropathy or subacute combined degeneration of the cord are lacking in children with PCM. However, electrophysiologic testing may disclose a reduction of motor nerve conduction velocity and abnormalities of sen-

sory conduction (Chopra et al). In children with severe degrees of PCM, it is said that there may be evidence, in sural nerve biopsies, of retarded myelination (persistence of only the small myelinated fibers) and segmental demyelination.

Of great interest is whether the children who are rescued from these states of undernutrition by proper feeding are left with an underdeveloped or damaged brain. This subject has been studied extensively in many species of animals, as well as in humans, by clinical, biochemical, and neuropathologic methods. The literature is too large to review here, but excellent critiques have been provided by Winick, Birch and coworkers, Latham, and Dodge and colleagues.

In contrast to the devastating effect of PCM on body growth, brain weight is only slightly reduced. Nevertheless, on the basis of experiments in dogs, pigs, and rats, it is evident that prenatal and early postnatal malnutrition retards cellular proliferation in the brain. All cells are affected, including oligodendroglia, with a proportional reduction in myelin. Also, the process of dendritic branching may be retarded by early malnutrition. A limited number of studies in humans suggest that PCM has a similar effect on the brain during the first 8 months of life. In animals, varying degrees of recovery from the effects of early malnutrition are possible if normal nutrition is re-established during the vulnerable periods. Presumably this is true for humans as well, although proof is difficult to obtain. In every series of severely undernourished infants and young children who have been observed for a period of many

years, a variable proportion has been left scholastically incompetent and mentally backward to a modest degree; the majority recover, however (Galler). Unfortunately, the neurologic and intellectual consequences of PCM have defied accurate assessment because of the difficulty of isolating the effects of severe malnutrition from those of infection, social deprivation, genetic faults, and other factors. The relative importance of these various factors is still under study.

Nutritional Deficiencies Secondary to Diseases of the Gastrointestinal Tract

The vitamins known to be essential to the normal functioning of the central and peripheral nervous systems cannot be synthesized by the human organism. Each is ingested as an essential part of the normal diet and absorbed in certain regions of the gastrointestinal tract. Impairment or failure of absorption due to diseases of the gastrointestinal tract gives rise to several malabsorption syndromes, some of which have already been referred to—e.g., malabsorptive vitamin E deficiency. In these diseases, the site of the block in transport from the intestinal lumen varies; it may be at the surface of the enterocytes or at their interface with the lymphatic channels and portal capillaries.

Table 41-2, which is modified from Pallis and Lewis, lists the malabsorptive diseases and their relationships to the intestinal abnormalities. Of all these diseases, celiac sprue (gluten enteropathy) is the most common. The neurologic complications of this disorder, in our experience, have taken the form of a symmetrical, predominantly sensory polyneuropathy, as described on page 1142. However, other complications have been described, notably a progressive cerebellar syndrome with cortical, dentatal, and olivary cell loss. The cerebellar changes may be coupled with a symmetrical demyelination of the posterior columns, producing a spinocerebellar disorder similar to that of vitamin E deficiency, but in the latter case, vitamin E supplementation has no consistent effect. Others

have remarked on a high incidence of depression and other psychiatric disturbances in adult patients with celiac sprue, as also discussed in Chap. 40. Unexplained seizures are also said to occur.

Polyneuropathy and subacute combined degeneration of the spinal cord manifesting themselves many years after gastrectomy are encountered only rarely.

The neurology of gastrointestinal disease has been reviewed by Perkin and Murray-Lyon.

INHERITED VITAMIN-RESPONSIVE NEUROLOGIC DISEASES

(See Table 41-3 and Chap. 37)

Although humans lack the capacity to synthesize essential vitamin molecules, they are nonetheless able to use them in a series of complex chemical reactions involved in intestinal absorption, transport in the plasma, entry into the organelles of many organs, activation of the vitamin into coenzyme, and finally their interaction with certain specific apoenzyme proteins. This compels consideration of another aspect of nutrition wherein one or more of these steps in vitamin utilization may be defective because of a genetic abnormality. Under these circumstances, the signs of vitamin deficiency result not from vitamin deficiency in the diet but from a genetically deranged control mechanism. In some instances the defect is only quantitative, and by loading the organism with a great excess of the vitamin in question, the biochemical abnormality can be overcome. The aforementioned special type of vitamin E deficiency that results from an inherited inability to incorporate the vitamin into lipoproteins also falls into this category—the diseases of which, being of hereditary type, have already been described in Chap. 37, “The Inherited Metabolic Diseases of the Nervous System.” Rosenberg has listed the most important of these hereditary vitamin-responsive diseases, which we have simplified for the reader in Table 41-3.

CHAPTER 42

ALCOHOL AND ALCOHOLISM

Intemperance in the use of alcohol creates many problems in modern society, the importance of which can be judged by the repeated emphasis they receive in contemporary writings, both literary and scientific. These problems may be divided into three categories: psychologic, medical, and sociologic. The main psychologic issue regards why a person drinks excessively, often with full knowledge that such action will result in physical injury and even death. The medical problem embraces all aspects of alcoholic habituation as well as the diseases that result from the abuse of alcohol. The sociologic problem encompasses all of the effects of sustained drinking on the patient's work, family, and community. Some idea of the enormity of these problems can be gleaned from figures supplied by the Secretary of Health and Human Services—which indicate that up to 40 percent of medical and surgical patients have alcohol-related problems and that these patients account for 15 percent of all health-care costs, which in 1995 were estimated at 150 billion dollars.

Problems engendered by excessive drinking cannot be separated from one another; the physician must therefore be conversant with all aspects of this subject. Often, admission to a "detoxification" unit or a general hospital or to a psychiatric facility is required, according to the nature of the clinical disorder; and the physician then must depend on the aid of social agencies to help the patient or the patient's family.

The causation of alcoholism remains obscure, although environmental, cultural, and genetic factors are clearly implicated in certain groups of patients. No single personality type has been shown to predict reliably who will become addicted to alcohol. Similarly, no particular aspect of alcohol metabolism has been found to account for the development of addiction in some individuals and not in others, with the possible exception of aldehyde dehydrogenase (see later). Some persons drink excessively and become alcoholic in response to a profoundly disturbing personal or family problem, but most do not. Alcoholism may develop in response to a depressive illness, more so in women than in men, but far more often depression is a consequence of drinking. Social and cultural influences are undoubtedly important in the genesis of alcoholism, as evidenced, for example, by the remarkably high incidence of alcoholism and drinking problems in the American Indian and Eskimo populations and by the disparity in the prevalence of alcoholism, within a single community, among various ethnic groups. However, no ethnic or racial group and no social or economic class are exempt. The writings of Schuckit and of Mello, listed in the references, provide critical overviews of the many etiologic theories.

The importance of genetic factors in alcoholism has been amply identified. Goodwin and coworkers studied 55 Danish men whose biologic parents were alcoholic and 55 control subjects whose biologic parents were not alcoholic. All of the subjects had been adopted before the age of 5 weeks and had no knowledge of their biologic parentage. Twenty percent of the offspring of biologic alcoholic parents, but only 5 percent of the control subjects, had become alcoholics by the age of 25 to 29 years. A Swedish adoption study (Bohman) and one in the United States (Cadoret et al) have corroborated these findings. Family studies have disclosed

a three- to fourfold increased risk for alcoholism in sons and daughters of alcoholics, and twin studies have shown a twofold higher concordance rate for alcoholism in monozygotic than in dizygotic pairs. Details of these studies can be found in the comprehensive reviews of the genetics of alcoholism by Grove and Cadoret and by Schuckit. The search goes on for a biologic trait, or marker, that would identify those who are genetically vulnerable to the development of alcoholism, but to date none has proved to be sufficiently practical or sensitive to identify all such persons (Reich).

Several surveys have suggested a rate of alcohol dependence of 3 to 5.5 percent of adults. A minimum of 3 percent of deaths in the United States can be attributed to alcohol-related causes. More striking, but not at all surprising, is the fact that alcohol intoxication is responsible for approximately 45 percent of fatal motor vehicle accidents and 22 percent of boating accidents. It requires little imagination to conceive the havoc wrought by alcohol in terms of decreased productivity, increased incidence of suicide, accidents, crime, mental and physical disease, and disruption of family life.

PHARMACOLOGIC AND PHYSIOLOGIC CONSIDERATIONS

Ethyl alcohol, or ethanol, is the active ingredient in beer, wine, whiskey, gin, brandy, and other less common alcoholic beverages. In addition, the stronger spirits contain enanthic ethers, which provide flavor but have no important pharmacologic properties, and impurities such as amyl alcohol (fusel oil) and acetaldehyde, which act like alcohol but are more toxic. Contrary to popular opinion with regard to the prevention of Wernicke disease, the content of B vitamins in American beer and other liquors is so low as to have little nutritional value (Davidson).

Alcohol is metabolized chiefly by oxidation, less than 10 percent being excreted chemically unchanged in the urine, perspiration, and breath. The energy liberated by the oxidation of alcohol (7 kcal/g) can be utilized as completely as that derived from the metabolism of other carbohydrates. However, calories from alcohol are empty of nutrients such as proteins and vitamins and cannot be used in the repair of damaged tissue. All ingested alcohol except that metabolized by alcohol dehydrogenase in the stomach wall is carried by the portal system to the liver. Here several enzyme systems can independently oxidize alcohol to acetaldehyde. The most important of these, accounting for 80 to 90 percent of ethanol oxidation in vivo, are alcohol dehydrogenase (ADH) and its isoenzymes. This reaction leads to the formation of acetaldehyde and the reduction of NAD to NADH. A second pathway of lesser importance involves catalase, which is located in the peroxisomes and mitochondria; a third utilizes the "microsomal ethanol oxidizing system" (MEOS), located mainly in the microsomes of the endoplasmic reticulum. The details of the process by which acetaldehyde is metabolized are still not settled. Most likely it is converted by aldehyde dehydrogenase to acetate. Acetaldehyde has a number of unique biochemical effects that are not produced by alcohol alone. Persons who flush easily after ingestion of alcohol (Chinese, Japanese, and other Asians) differ from "nonflushers" with respect to the metabolism of acetaldehyde rather than to the metabolism

of alcohol. The flushing reaction has been traced to a deficiency of aldehyde dehydrogenase activity (Harada et al). The low rate of alcoholism among Asians is said to be related to the flushing reaction (which is, in effect, a modified alcohol-disulfiram reaction—see further on), but this can hardly be the case, since North American Indians, a group with a high incidence of alcoholism, show the same reaction.

For all practical purposes, once the absorption of alcohol has ended and an equilibrium has been established with the tissues, *ethanol is oxidized at a constant rate, independent of its concentration in the blood* (about 150 mg alcohol per kilogram of body weight per hour, or about 1 oz of 90-proof whiskey per hour). Actually, slightly more alcohol is metabolized per hour when the initial concentrations are very high, and repeated ingestion of alcohol may facilitate its metabolism, but these increments are of little clinical significance. In contrast, the rate of oxidation of acetaldehyde does depend on its concentration in the tissues. This fact is of importance in connection with the drug disulfiram (Antabuse), which acts by raising the tissue concentration necessary for the metabolism of a certain amount of acetaldehyde per unit of time. The patient taking both disulfiram and alcohol will accumulate an inordinate amount of acetaldehyde, resulting in nausea, vomiting, and hypotension, sometimes so pronounced in degree as to be fatal. Certain other drugs—notably the sulfonylureas, metronidazole, and furazolidone—have effects like those of disulfiram but are less potent.

Alcohol acts directly on neuronal membranes in a manner akin to that of the general anesthetics. These agents, as well as barbiturates and benzodiazepines, are lipid-soluble and are thought to dissolve in the cell membranes (in direct relation to the degree of their lipid solubility). With continued ingestion of alcohol, the neuronal membranes ostensibly “rigidify” and become resistant to the fluidizing effect of alcohol (Chin and Goldstein; Harris et al). It is unlikely, however, that these changes in the physical properties of cell membranes are in themselves sufficient to alter cell function. Probably of greater importance are the effects of alcohol on membrane receptor systems that regulate ion channels, particularly the chloride and calcium channels. One likely site that relates to the acute intoxicating effects of alcohol is a receptor for the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and its associated chloride-ion channel. Benzodiazepine antagonists appear to block the potentiation by alcohol of GABA-induced chloride flux. Like the GABA-chloride channel, the *N*-methyl-D-aspartate (NMDA) receptors, which transduce signals carried by glutamate (the major excitatory transmitter in brain), are sensitive to extremely low concentrations of alcohol. There is also evidence that alcohol selectively potentiates serotonin receptor-ion currents, and the activity of this receptor has been implicated in alcohol- and drug-seeking behavior and addiction.

The effect of chronic administration of alcohol is to increase the number of neuronal calcium channels in the cell membrane. Moreover, calcium channel blockers, given during chronic administration, prevent both the increase in neuronal calcium channels and the development of tolerance to alcohol (Dolin and Little). The significance of these findings has been demonstrated by Little and colleagues, who showed that calcium channel blockers, given to chronically intoxicated animals after withdrawal, prevent withdrawal convulsions.

The molecular mechanisms involved in the genesis of alcohol intoxication and tolerance are obviously far more complex than the foregoing remarks would indicate (see reviews by Charness and by

Samson and Harris). There is now a vast literature on this subject, much of it contradictory. A unified concept of the role of neurotransmitters and their receptors and modulators in the production of alcohol intoxication and tolerance has yet to emerge. The part played by internal cellular messengers, which have attracted much attention in the field of addiction, is also currently under investigation.

Alcohol functions as a central nervous system (CNS) depressant. Some of the early toxic effects of alcohol, such as garrulousness, aggressiveness, excessive activity, and increased electrical excitability of the cerebral cortex—all of them suggestive of cerebral stimulation—are thought to be due to the inhibition of certain subcortical structures (possibly the high brainstem reticular formation) that ordinarily modulate cerebrocortical activity. Similarly, the initial hyperactivity of tendon reflexes may represent a transitory escape of spinal motor neurons from higher inhibitory centers. With increasing amounts of alcohol, however, the depressant action involves the cortical as well as other brainstem and spinal neurons. All manner of motor functions—whether the simple maintenance of a standing posture, the control of speech and eye movements, or highly organized and complex motor skills—are adversely affected by alcohol. The movements involved in these acts are not only slower than normal but also more inaccurate and random in character and therefore less well adapted to the accomplishment of specific ends.

Alcohol also impairs the efficiency of mental function by interfering with the speed of perception and the ability to persist in mental processing. The learning process is slowed and rendered less effective. Facility in forming associations, whether of words or of figures, and the ability to focus, sustain attention, and concentrate are reduced. The subject is less versatile in directing thought along new lines appropriate to the problem at hand. Finally, alcohol impairs the faculties of judgment and discrimination and, all in all, the ability to think and reason clearly.

A scale relating various degrees of functional impairment to blood alcohol levels in *nonhabituated* persons was constructed many years ago by Miles. At a blood alcohol level of 30 mg/dL, a mild euphoria was detectable, and at 50 mg/dL, a mild incoordination. At 100 mg/dL, ataxia was obvious; at 200 mg/dL, there was confusion and a reduced level of mental activity; at 300 mg/dL, the subjects were stuporous; and a level of 400 mg/dL—accompanied by deep anesthesia—was potentially fatal. These figures are valid provided that the alcohol content in the blood rises steadily over a 2-h period.

Tolerance It should be emphasized that a scale such as the one previously described has virtually no value in the chronic alcoholic patient, for it does not take into account the adaptation of the organism to alcohol, i.e., the phenomenon of tolerance. It is common knowledge that a habituated person can drink more and show fewer effects than the moderate drinker or abstainer. This phenomenon accounts for the surprisingly large amounts of alcohol that the chronic drinker can consume without showing significant signs of drunkenness. Sober-appearing alcoholics may have blood alcohol levels of 400 to 500 mg/dL. This aspect of tolerance must always be considered in judging the significance of a single estimation of the blood alcohol concentration as an index of functional capacity.

The mechanisms that underlie tolerance and addiction are just beginning to be understood. There is little evidence that an enhanced rate of alcohol metabolism can adequately account for the degree of tolerance observed in alcoholics. An increase of neuronal adaptation to alcohol is a more likely explanation. As mentioned

earlier, theoretically the factors that are operative in this adaptation are the increasing resistance of neuronal membranes to the “fluidizing” effects of alcohol and an increase in the number of neuronal calcium channels in the cell membrane.

CLINICAL EFFECTS OF ALCOHOL ON THE NERVOUS SYSTEM

A large number of neurologic disorders are associated with alcoholism. The factor common to all of them, of course, is the abuse of alcohol, but the mechanism by which alcohol produces its effects varies widely from one group of disorders to another and in many cases, the essential problem is one of nutritional deficiency as discussed in the preceding chapter. The classification that follows is based for the most part on known mechanisms.

- I. Alcohol intoxication—drunkenness, coma, excitement (“pathologic intoxication”), “blackouts”
- II. Abstinence or withdrawal syndrome—tremulousness, hallucinosis, seizures, delirium tremens
- III. Nutritional diseases of the nervous system secondary to alcoholism (Chap. 41)
 - A. Wernicke-Korsakoff syndrome
 - B. Polyneuropathy
 - C. Optic neuropathy (“tobacco-alcohol amblyopia”)
 - D. Pellagra
- IV. Diseases of uncertain pathogenesis associated with alcoholism
 - A. Cerebellar degeneration
 - B. Marchiafava-Bignami disease
 - C. Central pontine myelinolysis
 - D. “Alcoholic” myopathy and cardiomyopathy
 - E. Alcoholic dementia
 - F. Cerebral atrophy
- V. Fetal alcohol syndrome
- VI. Neurologic disorders consequent upon cirrhosis and portal-systemic shunts (Chap. 40)
 - A. Hepatic stupor and coma
 - B. Chronic hepatocerebral degeneration
- VII. Traumatic brain lesions consequent to intoxication—subdural hematoma, cerebral contusion, etc.

Alcohol Intoxication

The usual manifestations of alcohol intoxication are so commonplace that they require little elaboration. They consist of varying degrees of exhilaration and excitement, loss of restraint, irregularity of behavior, loquacity and slurred speech, incoordination of movement and gait, irritability, drowsiness, and, in advanced cases, stupor and coma. There are several *complicated* types of alcohol intoxication, which are considered below.

Pathologic Intoxication Despite what has been said earlier, on rare occasions, alcohol has an exclusively excitatory rather than a sedative effect. This reaction has been referred to in the past as *pathologic*, or *complicated*, *intoxication* and as *acute alcoholic paranoid state*. Since all forms of intoxication are pathologic, *atypical intoxication* or *idiosyncratic alcohol intoxication* are more appropriate designations. Nevertheless, the term *pathologic intoxication* is still widely used. The boundaries of this syndrome have never been clearly drawn. In the past, variant forms of delirium

tremens and epileptic phenomena, as well as psychopathic and criminal behavior, were indiscriminately included. Now the term is generally used to designate an outburst of blind fury with assaultive and destructive behavior. Often the patient is subdued only with difficulty. The attack terminates with deep sleep, which occurs spontaneously or in response to parenteral sedation; on awakening, the patient has no memory of the episode. Lesser degrees are also known wherein the patient, after several drinks, repeatedly commits gross social indiscretions. Allegedly this reaction may follow the ingestion of a small amount of alcohol, but in the patients we have observed the amount has often been substantial. Unlike the usual forms of alcohol intoxication and withdrawal, the atypical form has not been produced in experimental subjects, and the diagnosis depends upon the aforementioned arbitrary criteria.

Pathologic intoxication has been ascribed to many factors, but there are no meaningful data to support any of them. However, an analogy may be drawn between pathologic intoxication and the paradoxical reaction that occasionally follows the administration of barbiturates or other sedative drugs. The few patients we have seen, mostly young men of college age or slightly older, have been docile and seemingly well adjusted when not drinking. Usually, they have avoided alcohol after a first episode of this sort, but there are exceptions.

The main disorders to be distinguished from pathologic intoxication are temporal lobe seizures that occasionally take the form of outbursts of rage and violence and the explosive episodes of violence that characterize the behavior of certain sociopaths. The diagnosis in these cases may be difficult and depends on eliciting the other manifestations of temporal lobe epilepsy or sociopathy. Treatment is discussed below.

Alcoholic “Blackouts” In the language of the alcoholic, the term *blackout* refers to an interval of time, during a period of severe intoxication, for which the patient, when sober, has no memory—even though the state of consciousness, as observed by others, was not grossly altered during that interval. However, a systematic assessment of mental function during the amnesic period has usually not been made. A few observations indicate that it is short-term (retentive) memory, rather than immediate or long-term memory, that is impaired; this feature and the subsequent amnesia for the episode are somewhat reminiscent of the disorder known as *transient global amnesia* (page 379) but without the incessant questioning and competence in nonmemory mental activities that characterizes the latter.

Blackouts may occur at any time in the course of alcoholism, even during the first drinking experience, and they certainly have happened in persons who never became alcoholic. The salient facts are that there is a degree of intoxication that interferes with the registration of events and the formation of memories during the period of intoxication and that the amount of alcohol consumed in moderate social drinking will rarely produce this effect.

Alcoholic Stupor and Coma As has been indicated, the symptoms of alcoholic intoxication are the result of the depressant action of alcohol on cerebral and spinal neurons. In this respect alcohol acts on nerve cells in a manner akin to the general anesthetics. Unlike the latter, however, the margin between the dose of alcohol that produces surgical anesthesia and that which dangerously depresses respiration is a narrow one, a fact that adds an element of urgency to the diagnosis and treatment of alcoholic coma. One must also be alert to the possibility that barbiturates or other sedative-

hypnotic drugs may have potentiated the depressant effects of alcohol. One of the most treacherous situations is traumatic brain injury that is complicated by intoxication, a circumstance that is prone to misinterpretation because of uncertainty as to the main cause of stupor or coma.

Treatment of Severe Alcohol Intoxication Coma due to alcohol intoxication represents a medical emergency. The main object of treatment is to prevent respiratory depression and its complications as described in Chap. 17. One would like to lower the blood alcohol level as rapidly as possible. The previously favored administration of fructose or of insulin and glucose for this purpose is of little value. Analeptic drugs such as amphetamine and various mixtures of caffeine and picrotoxin are antagonistic to alcohol only insofar as they are cerebrocortical stimulants and overall nervous system excitants; they do not hasten the oxidation of alcohol. The use of hemodialysis should be considered in comatose patients with extremely high blood alcohol concentrations (>500 mg/dL), particularly if accompanied by acidosis, and in those who have concurrently ingested methanol or ethylene glycol or some other dialyzable drug. *Pathologic intoxication* may require the use of restraints and the parenteral administration of diazepam (5 to 10 mg) or haloperidol (2 to 5 mg), repeated once after 30 to 40 min if necessary.

Methyl, Amyl, and Isopropyl Alcohols and Ethylene Glycol Poisoning with alcohols other than ethyl alcohol is a relatively rare but catastrophic occurrence. *Amyl alcohol* (fusel oil) and *isopropyl alcohol* are used as industrial solvents and in the manufacture of varnishes, lacquers, and pharmaceuticals; in addition, isopropyl alcohol is readily available as a rubbing alcohol. Intoxication may follow the ingestion of these alcohols or inhalation of their vapors. The effects of both are much like those of ethyl alcohol, but much more toxic.

Methyl alcohol (methanol, wood alcohol) is a component of antifreeze and many combustibles and is used in the manufacture of formaldehyde, as an industrial solvent, and as an adulterant of alcoholic beverages, the latter being the most common source of methyl alcohol intoxication. The oxidation of methyl alcohol to formaldehyde and formic acid proceeds relatively slowly; thus, signs of intoxication do not appear for several hours or may be delayed for a day or longer. Many of the toxic effects are like those of ethyl alcohol, but in addition severe methyl alcohol poisoning may produce serious degrees of acidosis (with an anion gap). The characteristic features of this intoxication, however, are damage to retinal ganglion cells—giving rise to scotomata and varying degrees of blindness, dilated unreactive pupils, and retinal edema—and bilateral degeneration of the putamens, readily visible on computed tomography (CT) scans. Survivors may be left blind or, less often, with putaminal necrosis and dystonia or Parkinson disease (McLean et al.). The most important aspect of treatment is the intravenous administration of large amounts of sodium bicarbonate to reverse acidosis. Hemodialysis and 4-methylpyrazole (see later) may be useful adjuncts because of the slow rate of oxidation of methanol.

Ethylene glycol, an aliphatic alcohol, is a commonly used industrial solvent and the major constituent of antifreeze. In the latter form it is sometimes consumed by skid-row alcoholics (5000 cases of poisoning annually in the United States) and in suicide attempts with disastrous results. At first the patient merely appears drunk, but after a period of 4 to 12 h, hyperventilation and severe metabolic acidosis develop, followed by confusion, convulsions, coma,

and renal failure in rapid succession. Cerebrospinal fluid lymphocytosis is a characteristic feature. The metabolic acidosis is due to the conversion of ethylene glycol by alcohol dehydrogenase into glycolic acid, thus *producing an anion gap* that reflects the presence of this additional substance in the blood. [The anion gap has been defined in different ways, but the most convenient is the difference between the positive ion Na^+ and the sum of negative ions, Cl^- plus HCO_3^- (venous CO_2 is used for the latter); a value greater than 12 is considered a gap.] The cause of the renal toxicity is less clear—probably it is due to the formation of oxalate from glycolate and the deposition of oxalate crystals in renal tubules. These crystals appear in the urine and sometimes in the CSF and aid in diagnosis. The treatment of ethylene glycol poisoning has, until relatively recently, consisted of hemodialysis and the intravenous infusion of sodium bicarbonate and ethanol, the latter serving as a competitive substrate for alcohol dehydrogenase. However, the use of ethanol in this regimen is problematic. Baud and colleagues and more recently Brent et al and Jacobsen have advocated the use of intravenous 4-methylpyrazole (fomepizole), which is a far more effective inhibitor of alcohol dehydrogenase than is alcohol. They recommend this form of treatment for methanol poisoning as well.

Some of the patients who recover from the acute renal and metabolic effects are left with multiple cranial nerve defects, particularly of the seventh and eighth nerves. The latter abnormalities develop 6 to 18 days after the ingestion of ethylene glycol and have been attributed to the deposition of oxalate crystals along the subarachnoid portions of the affected nerves (Spillane et al).

The Abstinence, or Withdrawal, Syndrome

Included under this title is the symptom complex of tremulousness, hallucinations, seizures, confusion, and psychomotor and autonomic overactivity. Although a sustained period of chronic inebriation is the most obvious factor in the causation of these symptoms, they become manifest only after a *period of relative or absolute abstinence* from alcohol—hence the designation *abstinence, or withdrawal, syndrome*. This concept is illustrated in Fig. 42-1. Each of the major manifestations of the withdrawal syndrome may occur in more or less pure form and are so described later, but usually they occur in various combinations. Major withdrawal symptoms are observed mainly in the binge, or periodic, drinker, although the steady drinker is not immune if for some reason he stops drinking. The full syndrome, depicted further on, is called *delirium tremens*.

Tremulousness and Associated Symptoms The most common single manifestation of the abstinence syndrome is tremulousness, often referred to as “the shakes” or “the jitters,” combined with general irritability and gastrointestinal symptoms, particularly nausea and vomiting. These symptoms first appear after several days of drinking, usually in the morning after a night’s abstinence. The patient “quiets his nerves” with a few drinks and is then able to drink for the rest of the day without undue distress. The symptoms return on successive mornings with increasing severity. The duration of drinking of this type varies greatly. The symptoms then become greatly augmented, reaching their peak intensity 24 to 36 h after the complete cessation of drinking. *Generalized tremor* is the most obvious feature of this illness. It is of fast frequency (6 to 8 Hz), slightly irregular, and variable in severity, tending to diminish when the patient is in quiet surroundings and to increase

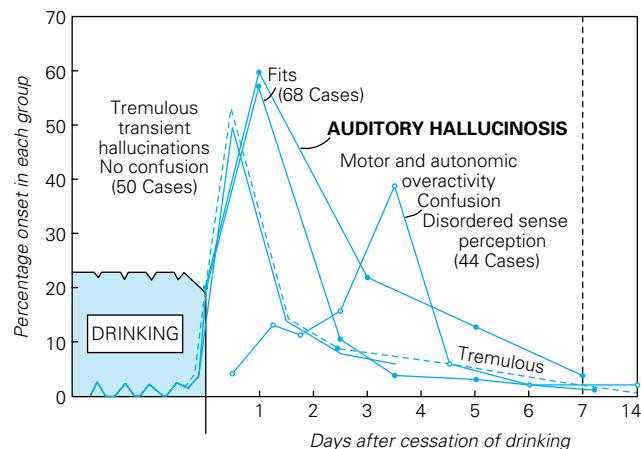

Figure 42-1. Relation of acute neurologic disturbances to cessation of drinking. The shaded drinking period is greatly foreshortened and not intended to be quantitative. The periodic notching in the baseline represents the tremulousness, nausea, and so on that occur following a night's sleep. The time relations of the various groups of symptoms to withdrawal are explained in the text. (Adapted from Victor M, Adams RD: The effect of alcohol on the nervous system. *Res Publ Assoc Res Nerv Ment Dis* 32:526, 1953, by permission.)

with motor activity or emotional stress. The tremor may be so violent that the patient cannot stand without help, speak clearly, or eat without assistance. Sometimes there is little objective evidence of tremor, and the patient complains only of being "shaky inside."

Within a few days, flushed facies, anorexia, tachycardia, and tremor characteristic of the early withdrawal syndrome subside to a large extent, but overalertness, tendency to startle easily, and jerkiness of movement may persist for a week or longer. Feelings of uneasiness may not leave the patient completely for 10 to 14 days. According to Porjesz and Begleiter, certain electrophysiologic abnormalities (diminished amplitudes of sensory evoked potentials and prolonged latencies and conduction velocities of auditory brainstem potentials) remain altered long after the clinical abnormalities have subsided.

Hallucinosis Symptoms of disordered perception occur in about one-quarter of withdrawing hospitalized tremulous patients. The patient may complain of "bad dreams"—nightmarish episodes associated with disturbed sleep—which he finds difficult to separate from real experience. Sounds and shadows may be misinterpreted, or familiar objects may be distorted and assume unreal forms (illusions). There may also be more overt hallucinations, which are purely visual in type, mixed visual and auditory, tactile, or olfactory, in this order of frequency. There is little evidence to support the popular belief that certain visual hallucinations (bugs, pink elephants) are specific to alcoholism. Actually, the hallucinations comprise the full range of visual experience. They are more often animate than inanimate; persons or animals may appear singly or in panoramas, shrunken or enlarged, natural and pleasant, or distorted, hideous, and frightening. The hallucinosis may be an isolated phenomenon lasting for a few hours, and it may later be attended by other withdrawal signs.

Acute and Chronic Auditory Hallucinosis A special type of alcoholic psychosis, consisting of a more or less pure auditory hallucinosis, has been recognized for many years. Kraepelin referred

to it as the "hallucinatory insanity of drunkards," or "alcoholic mania." A report of 75 such cases was made by Victor and Hope. The central feature of the illness, in the beginning, is the occurrence of auditory hallucinations despite an otherwise clear sensorium during the withdrawal period; i.e., the patients are not disoriented or obtunded, and they have an intact memory. The hallucinations may take the form of unstructured sounds such as buzzing, ringing, gunshots, or clicking (the elementary hallucinations of Bleuler), or they may have a musical quality, like a low-pitched hum or chant. The most common hallucinations, however, are human voices. When the voices can be identified, they are often attributed to the patient's family, friends, or neighbors—rarely to God, radio, or television. The voices may be addressed directly to the patient, but more frequently they discuss him in the third person. In the majority of cases the voices are maligning, reproachful, or threatening in nature and are disturbing to the patient; a significant proportion, however, are not unpleasant and leave the patient undisturbed. To the patient, the voices are clearly audible and intensely real, and they tend to be exteriorized; i.e., they come from behind a radiator or door, from the corridor, or through a wall, window, or floor. Another feature of auditory hallucinosis (and of visual hallucinosis as well) is that the patient's response is more or less understandable in light of the hallucinatory content. The patient may call on the police for protection or erect a barricade against invaders; he may even attempt suicide to avoid what the voices threaten. The hallucinations are most prominent during the night, and their duration varies greatly: they may be momentary, or they may recur intermittently for days on end and, in exceptional instances, for weeks or months.

While hallucinating, most patients have no appreciation of the unreality of their hallucinations. With improvement, the patient begins to question the authenticity of his hallucinations and may be reluctant to talk about them and may even question his own sanity. Full recovery is characterized by the realization that the voices were imaginary and by the ability to recall, sometimes with remarkable clarity, some of the abnormal thought content of the psychotic episode.

A unique feature of this alcoholic psychosis is its evolution, in a small proportion of the patients, to a state of *chronic auditory hallucinosis*. The chronic disorder begins like the acute one, but after a short period, perhaps a week or two, the symptomatology begins to change. The patient becomes quiet and resigned, even though the hallucinations remain threatening and derogatory. Ideas of reference and influence and other poorly systematized paranoid delusions become prominent. At this stage the illness may be mistaken for paranoid schizophrenia and indeed was so identified by Bleuler. There are, however, important differences between the two disorders: the alcoholic illness develops in close relation to a drinking bout and the past history rarely reveals schizoid personality traits. Moreover, alcoholic patients with hallucinosis are not distinguished by a high incidence of schizophrenia within their families (Schuckit and Winokur, Scott), and a large number of such patients, whom our colleagues Victor and Adams evaluated long after their acute attacks, did not show signs of schizophrenia. There is some evidence that repeated attacks of acute auditory hallucinosis render the patient more susceptible to the chronic state.

Withdrawal Seizures ("Rum Fits") In the setting of alcohol withdrawal either as relative or absolute abstinence following a period of chronic inebriation, convulsive seizures are common. More than 90 percent of withdrawal seizures occur during the 7- to 48-h period following the cessation of drinking, with a peak

incidence between 13 and 24 h. During the period of seizure activity, the electroencephalogram (EEG) is usually abnormal, but it reverts to normal in a matter of days, even though the patient may go on to develop delirium tremens. Also during the period of seizure activity, the patient is unusually sensitive to stroboscopic stimulation; almost half the patients respond with generalized myoclonus or a convulsive seizure (photoparoxysmal response).

Seizures occurring in the abstinence period have a number of other distinctive features. There may be only a single seizure, but in the majority of cases the seizures occur in bursts of two to six over a day, occasionally even more; 2 percent of patients studied by Victor developed status epilepticus. The seizures are grand mal in type, i.e., generalized, tonic-clonic convulsions with loss of consciousness. Focal seizures should always suggest the presence of a focal lesion (most often traumatic) in addition to the effects of alcohol. Twenty-eight percent of Victor's patients with generalized withdrawal seizures went on to develop delirium tremens (the percentage has been less in other series); almost invariably the seizures preceded the delirium. The postictal confusional state may blend imperceptibly with the onset of the delirium, or the postictal state may have cleared over several hours or even a day or longer before the delirium sets in. Seizures of this type typically occur in patients whose drinking history has extended over a period of many years and must be distinguished from other forms of seizures that have their onset in adult life. It is suggested that the term *rum fits*, or *whiskey fits*—i.e., the names sometimes used by alcoholics—be reserved for seizures with the attributes described here. This serves to distinguish them from seizures that occur in the interdrinking period, long after withdrawal has been accomplished.

It is important to note that the common idiopathic or post-traumatic forms of epilepsy are also influenced by alcohol. In these types of epilepsy, a seizure or seizures may be precipitated by only a short period of drinking (e.g., a weekend, or even one evening of heavy social drinking); perhaps not surprisingly, in these circumstances, the seizures occur not when the patient is intoxicated but usually the morning after, in the “sobering-up” period. Except for the transient dysrhythmia in the withdrawal period, the incidence of EEG abnormalities in patients who have had rum fits is no greater than in normal persons, in sharp contrast to the EEGs of nonalcoholic patients with recurrent seizures.

Treatment and Prevention of Withdrawal Seizures Most patients during withdrawal do not require the use of anticonvulsant drugs, since the entire episode of seizure activity—whether a single seizure or a brief flurry of seizures—may have terminated before the patient is brought to medical attention. The parenteral administration of diazepam or sodium phenobarbital early in the withdrawal period had been thought to prevent rum fits in patients with a previous history of this disorder or in those who might be expected to develop seizures on withdrawal of alcohol. This notion has been supported by the observations of D'Onofrio and colleagues that intravenous lorazepam (2 mg in 2 mL of normal saline) was highly effective in preventing *recurrent seizures* after a first seizure in the same withdrawal period. Only 3 of 100 patients so treated had a second seizure within 48 h compared to 21 of 86 untreated patients. The long-term administration of anticonvulsants is not necessary or practical: if such patients remain abstinent, they will be free of seizures; if they resume drinking, they usually abandon their medications. Furthermore, it is not certain that continued administration of anticonvulsants dependably prevents abstinence seizures. The rare instances of status epilepticus should be managed like status of any other type (page 296). In alcoholics with a history

of idiopathic or posttraumatic epilepsy, the goal of treatment should be abstinence from alcohol, because of the tendency of even short periods of drinking to precipitate seizures. Such patients need to be maintained on anticonvulsant drugs.

Delirium Tremens (“DTs”) This is the most dramatic and grave of all the alcoholic illnesses. It is characterized by profound confusion, delusions, vivid hallucinations, tremor, agitation, and sleeplessness, as well as by the signs of increased autonomic nervous system overactivity—i.e., dilated pupils, fever, tachycardia, and profuse perspiration. The clinical features of delirium are presented in detail in Chap. 20 as they relate to DTs and to other illnesses that simulate it.

Delirium tremens develops in one of several settings. The patient, an excessive and steady drinker for many years, may have been admitted to the hospital for an unrelated illness, accident, or operation and, after 2 to 4 days, occasionally even later, becomes delirious. Or, following a prolonged drinking binge, the patient may have experienced several days of tremulousness and hallucination or one or more seizures and may even be recovering from these symptoms when delirium tremens develops, rather abruptly as a rule.

As to the frequency of delirium tremens, Foy and Kay reported an incidence of 0.65 percent of all patients admitted for other reasons to a large general hospital. Among 200 consecutive alcoholics admitted to a city hospital, Ferguson et al reported that 24 percent developed delirium tremens; of these, 8 percent died—figures that are considerably higher than those recorded in our hospitals. Of course, the reported incidence of delirium tremens will vary greatly, depending on the population served by a particular hospital.

In the majority of cases delirium tremens is benign and short-lived, ending as abruptly as it begins. Consumed by relentless activity and wakefulness for several days, the patient falls into a deep sleep and then awakens lucid, quiet, and exhausted, with virtually no memory of the events of the delirious period. Somewhat less commonly, the delirious state subsides gradually with intermittent episodes of recurrence. In either event, when delirium tremens occurs as a single episode, the duration is 72 h or less in over 80 percent of cases. Less frequently still, there may be one or more relapses, several episodes of delirium of varying severity being separated by intervals of relative lucidity—the entire process lasting for several days or occasionally for as long as 4 to 5 weeks.

In the past, approximately 15 percent of cases of delirium tremens ended fatally, but the figure now is closer to 5 percent. In many of the fatal cases there is an associated infectious illness or injury, but in others no complicating illness is discernible. Many of the patients die in a state of hyperthermia; in some, death comes so suddenly that the nature of the terminal events cannot be determined. Reports of a negligible mortality rate in delirium tremens can usually be traced to a failure to distinguish between delirium tremens and the minor forms of the withdrawal syndrome, which are far more common and practically never fatal.

We make note here of our experience with delirium following the withdrawal of barbiturates, which is almost identical to the DTs, including the abrupt cessation of symptoms, as discussed on page 1022.

There are also alcohol withdrawal states, closely related to delirium tremens and about as frequent, in which one facet of the delirium tremens complex assumes prominence, to the virtual exclusion of the other symptoms. The patient may simply exhibit a transient state of quiet confusion, agitation, or peculiar behavior lasting several days or weeks. Or there may be a vivid hallucina-

tory-delusional state and abnormal behavior consistent with the patient's false beliefs. Unlike typical delirium tremens, the atypical states usually present as a single circumscribed episode without recurrences, are only rarely preceded by seizures, and do not end fatally.

Pathology *Pathologic examination* is singularly unrevealing in patients with delirium tremens. Edema and brain swelling have been absent in the authors' pathologic material except when shock or hypoxia had occurred terminally. There have been no significant light-microscopic changes in the brain, which is what one would expect in a disease that is essentially reversible. The EEG findings have been discussed in relation to withdrawal seizures.

Laboratory Findings Rarely, blood glucose is seriously depressed in the alcohol withdrawal states. Ketoacidosis with normal blood glucose is another infrequent finding. Disturbances of electrolytes are of varying frequency and significance. Serum sodium levels are altered infrequently and are more often increased than decreased. The same is true for chloride and phosphate. Serum calcium and potassium are found to be lowered in about one-quarter of patients. Most patients show some degree of hypomagnesemia, low PCO_2 , and high arterial pH—abnormalities that are probably important in the pathogenesis of withdrawal symptoms (see later). Abnormalities of the CSF occur unpredictably, as do changes on CT scanning or MRI; they may indicate the presence of some medical or surgical complication. Enlargement of the third and lateral ventricles is a common finding (see later). The MRI is normal unless there is an incipient Wernicke disease, in which case lesions in the periaqueductal region and subthalami may be evident as described on page 240.

Pathogenesis of the Tremulous-Hallucinatory-Delirious Disorders For many years prior to 1950, it was the common belief that these symptoms represented the most severe forms of alcohol intoxication—an idea that fails to satisfy the simplest clinical logic. The symptoms of toxicity—consisting of slurred speech, uninhibited behavior, staggering gait, stupor, and coma—are in themselves distinctive and, in a sense, the opposite of the symptom complex of tremor, fits, and delirium. It is evident, from observations in both humans and experimental animals, that the most important and the one obligate factor in the genesis of delirium tremens and related disorders is the withdrawal of alcohol following a period of sustained chronic intoxication. Further, the emergence of withdrawal symptoms depends on a rapid *decline* in the blood alcohol level from a previously higher level and not necessarily upon the complete disappearance of alcohol from the blood.

The mechanisms by which the withdrawal of alcohol produces symptoms are incompletely understood. In all but the mildest cases, the early phase of alcohol withdrawal is attended by a drop in serum magnesium concentration and a rise in arterial pH—the latter on the basis of respiratory alkalosis (Wolfe and Victor). Possibly the compounded effect of these two factors, both of which are associated with hyperexcitability of the nervous system, is responsible in part for seizures and for other symptoms that characterize the early phase of withdrawal. However, these factors alone are not explanatory. The molecular mechanisms that are thought to be operative in the genesis of alcohol tolerance and withdrawal have been mentioned earlier. The GABA-nergic system has been most strongly implicated, in part because the receptors for this inhibitory transmitter are downregulated by chronic alcohol use, but the situation is not nearly so simple, insofar as the excitatory glutamatergic system is also inhibited by alcohol.

Treatment of Delirium Tremens and Minor Withdrawal Symptoms

The general aspects of management of the delirious and confused patient have been described on page 973. More specifically, the treatment of delirium tremens begins with a careful search for associated injuries (particularly head injury with cerebral lacerations or subdural hematoma), infections (pneumonia or meningitis), pancreatitis, and liver disease. Because of the frequency and seriousness of these complications, chest films and a CT scan should be obtained in most instances, and lumbar puncture should be performed if there is suspicion of meningitis. In severe forms of delirium tremens, the temperature, pulse, and blood pressure should be measured at frequent intervals in anticipation of peripheral circulatory collapse and hyperthermia, which, added to the effects of injury and infection, are the usual causes of death in this disease. In the case of hypotension, one must act quickly, utilizing intravenous fluids and, if called for, vasopressor drugs. The occurrence of hyperthermia demands the use of a cooling mattress or evaporative cooling in addition to specific treatment for any infection that may be present.

An additional important element in treatment is the correction of fluid and electrolyte imbalance, particularly hypokalemia and severe hypomagnesemia. Severe degrees of agitation and perspiration may require the administration of up to 5 L of fluid daily, of which at least 1500 to 2000 mL should be normal saline. The specific electrolytes and the amounts that must be administered are governed by the laboratory values for these electrolytes. If the serum sodium is extremely low, one must be cautious in raising the level lest a central pontine myelinolysis be induced (see page 973). In the rare case of hypoglycemia, the administration of glucose is an urgent matter. Patients who present with severe alcoholic ketoacidosis and normal or only slightly elevated blood glucose concentrations usually recover promptly, without the use of insulin.

It must be emphasized that a *special danger attends the use of glucose solutions in alcoholic patients*. The administration of intravenous glucose may serve to consume the last available reserves of thiamine and precipitate Wernicke disease, as discussed in Chap. 41. Typically, these patients have subsisted on a diet disproportionately high in carbohydrate (in addition to alcohol, which is metabolized entirely as carbohydrate) and low in thiamine, and their body stores of B vitamins may have been further reduced by gastroenteritis and diarrhea. For this reason it is good practice to add B vitamins, specifically thiamine (which may also be supplemented by intramuscular injection), in all cases requiring parenterally administered glucose—even though the alcoholic disorder under treatment, e.g., delirium tremens, is not primarily due to vitamin deficiency.

With respect to the use of medications, it is important to distinguish between mild withdrawal symptoms, which are essentially benign and responsive to practically any sedative drug, and full-blown delirium tremens. There is no certain way to predict whether a patient with the early signs of withdrawal will progress to a state of delirium tremens. In the latter state, the object of drug therapy is to blunt the psychomotor overactivity, prevent exhaustion, and facilitate the administration of parenteral fluid and nursing care; one should not attempt to suppress agitation at all costs, since doing so requires an amount of drug that might seriously depress respiration.

A wide variety of drugs are effective in controlling withdrawal symptoms. The more popular ones have been chlordiazepoxide (Librium), diazepam (Valium), meprobamate, hydroxyzine (Vistaril) and the ancillary medications, clonidine and beta-adrenergic

blockers, and both older and newer anticonvulsant drugs such as gabapentin, which may reduce the requirement for sedative drugs. There is little to choose among the primary drugs in respect to their therapeutic efficacy. More importantly, there are few data to indicate that any one of them can prevent hallucinosis or delirium tremens or shorten the duration or alter the mortality rate of the latter disorder (Kaim et al). In general, phenothiazine drugs should be avoided because they reduce the threshold to seizures. Probably, the use of any of the diazepine medications is as effective as a single dose of lorazepam in prophylactically suppressing seizures (see earlier discussion).

If parenteral medication is necessary, we prefer 10 mg of diazepam or chlordiazepoxide given intravenously and repeated once or twice at 20- to 30-min intervals until the patient is calm but awake; we have also favored midazolam in closely controlled circumstances. Beta-blocking agents, such as propranolol and atenolol, are helpful in reducing heart rate, blood pressure, and the tremor to some extent. Lofexidine, an alpha₂ agonist that blocks autonomic outflow centrally, and clonidine are similarly effective in reducing the severity of most of the withdrawal symptoms, but they are not recommended as the sole treatments. Corticosteroids have no place in the treatment of the withdrawal syndrome.

Nutritional Diseases of the Nervous System

(See Chap. 41)

Alcoholism provides the ideal setting for the development of nutritional diseases of the nervous system. Although only a small proportion of alcoholics develop nutritional diseases, the overall number of these diseases is substantial because of the frequency of alcoholism. The importance of the alcohol-induced deficiency diseases relates to the fact that they are preventable and, if neglected, may lead to permanent disability. These illnesses are discussed fully in the preceding chapter, "Diseases of the Nervous System Due to Nutritional Deficiency."

Disorders of Uncertain Pathogenesis Associated with Alcoholism

Also discussed in Chap. 41 are so-called *alcoholic cerebellar degeneration* and *Marchiafava-Bignami disease*. The former is almost certainly of nutritional origin; in the latter a nutritional-metabolic etiology seems likely but has not been established. Central pontine myelinolysis, though frequently observed in alcoholics, is more appropriately considered with the acquired metabolic disorders (Chap. 40). Certain disorders of skeletal and cardiac muscle associated with alcoholism (*acute alcoholic myopathy* and *cardiomyopathy*) are described in Chap. 51, with the myopathies due to drugs and toxins. There remain to be discussed several diverse disorders that have been attributed to alcoholism but whose causal relationship to alcohol abuse, nutritional deficiency, or some other factor is not clear.

Alcoholic Dementia and Cerebral Atrophy The term *alcoholic dementia* is used widely and often indiscriminately to designate a presumably distinctive form of dementia that is attributable to the chronic, direct effects of alcohol on the brain. Unfortunately, a syndrome subsumed under the title of *alcoholic dementia* and its many synonyms that appear in the older literature (*alcoholic deteriorated state*, *chronic alcoholic psychosis*, *chronic or organic brain syndrome due to alcohol*) has never been delineated satisfac-

tory, either clinically or pathologically. In the *Comprehensive Textbook of Psychiatry*, it has been defined as "a gradual disintegration of personality structure, with emotional lability, loss of control, and dementia" (Sadock and Sadock). Purported examples of this state show a remarkably diverse group of symptoms, including jealousy and suspiciousness; coarsening of moral fiber and other personality and behavioral disorders; deterioration of work performance, personal care, and living habits; and disorientation, impaired judgment, and defects of intellectual function, particularly of memory.

In recent years, there have been attempts to redefine alcoholic dementia. Cutting and also Lishman have expressed the view that the term *Korsakoff psychosis* should be limited to patients with a fairly pure disorder of memory of acute onset and that patients with more global symptoms of intellectual deterioration, of gradual evolution, be considered to have alcoholic dementia. These are rather weak diagnostic criteria. As pointed out in Chap. 41, *Korsakoff psychosis* may have an insidious onset and gradual progression, and patients with this disorder, in addition to an amnesic defect, characteristically show disturbances of cognitive functions that depend little or not at all on memory. More importantly, in none of the patients designated by these authors as having alcoholic dementia was there a neuropathologic examination, without which the clinical assessment must remain arbitrary and imprecise.

The pathologic changes that purportedly underlie primary alcoholic dementia are even less precisely defined than the clinical syndrome. Courville, whose writings have been quoted most frequently in this respect, described a series of cerebral cortical changes that he attributed to the toxic effects of alcohol. Some of them turn out on close inspection to be quite nonspecific, reflecting nothing more than the effects of aging or the insignificant artifacts of tissue fixation and staining. More recently, Harper and colleagues have reported that the mean brain weight is decreased in alcoholics and the pericerebral space is increased in volume—findings that do no more than confirm the brain shrinkage that is demonstrable by CT scans in many alcoholics and is to some extent reversible with sustained abstinence (see later). Also, using an automated cell-counting method, these authors reported a reduction in the number of neurons in the superior frontal cortex. Other investigators, using more accurate (stereologic) counting methods, have not duplicated these findings (Hansen et al; Jensen and Pakkenberg), nor have experimental studies in animals settled the problem.

In our experience, the majority of cases that come to autopsy with the label of *alcoholic dementia* prove simply to have the lesions of the Wernicke-Korsakoff syndrome. Traumatic lesions of varying degrees of severity are commonly added. Other cases show the lesions of Marchiafava-Bignami disease, hepatic encephalopathy, or an unrelated communicating hydrocephalus, Alzheimer disease, ischemic necrosis, or some other disease quite unrelated to alcoholism. Practically always in our material, the clinical state can be accounted for by one or a combination of these disease processes, and there has been no need to invoke a hypothetical toxic effect of alcohol on the brain. This has also been the experience of Torvik and associates; with a few exceptions, such as coincidental Alzheimer disease, all their cases that had been diagnosed as having alcoholic dementia turned out, on neuropathologic examination, to have the chronic lesions of Wernicke-Korsakoff disease.

In brief, the most serious flaw in the concept of a primary alcoholic dementia is that it lacks a distinctive, well-defined pathology. Until such time as the morphologic basis is established,

its status must remain ambiguous. A more detailed discussion of this subject and of so-called alcoholic cerebral atrophy (see later) can be found in the review by Victor (1994), listed in the References.

Cerebral atrophy, like the "alcoholic deteriorated state," does not constitute a well-defined entity. The concept of alcoholic cerebral atrophy was the product originally of pneumoencephalographic studies. Relatively young alcoholics, some with and some without symptoms of cerebral disease, were often found to have enlarged cerebral ventricles and widened sulci, mainly of the frontal lobes (see, for example, reports of Brewer and Perrett and of Haug). Similar findings have been reported in chronic alcoholics examined by CT scanning and MRI (see review by Carlen et al).

The clinical correlates of these radiologic findings are quite unclear. Most often, the finding of large ventricles comes as a surprise, no symptoms or signs of neuropsychiatric disease having been noted in the course of the usual neurologic testing. In this connection, the findings of Wilkinson are of particular importance. He demonstrated that in clinically normal alcoholics, the radiologic measures of "brain atrophy" were age-related; once the age factor was removed, the CT findings in these subjects did not differ significantly from those in nonalcoholic controls.

The term *alcoholic cerebral atrophy* implies that chronic exposure of the brain to alcohol causes an irreversible loss of cerebral tissue. From the study by Harper and colleagues this may indeed be true, but it requires confirmation. The idea of alcoholic atrophy is open to criticism mainly on the grounds that dilated ventricles have in fact been reversible to a considerable extent when abstinence is maintained (Carlen et al, Lishman, Zipursky et al, Schruth et al). Until this matter has been studied further, it would be preferable to refer to this condition as an asymptomatic ventricular enlargement and sulcal widening in alcoholics, rather than as cerebral atrophy.

Fetal Alcohol Syndrome

That parental alcoholism may have an adverse effect on the offspring has been a recurrent theme in medical writings. Probably the first allusion to such a relationship was that of Sullivan (1899), who reported that the mortality among the children of drunken mothers was more than two times greater than that among children of nondrinking women of "similar stock." This increased mortality was attributed by Sullivan and later by Haggard and Jellinek to postnatal influences such as poor nutrition and a chaotic home environment rather than to the intrauterine effects of alcohol. The idea that maternal alcoholism could damage the fetus was generally rejected and relegated to the category of superstitions about alcoholism or the claims of temperance ideologues.

In the late 1960s, the effects of alcohol abuse on the fetus were rediscovered, so to speak. Lemoine and associates in France and then Ulleland and Jones and Smith in the United States described a distinctive pattern of abnormalities in infants born of severely alcoholic mothers. They stated that the affected infants are small in length in comparison to weight, and most of them fall below the third percentile for head circumference. They are distinguished also by the presence of short palpebral fissures (shortened distance between inner and outer canthi) and epicanthal folds; maxillary hypoplasia, micrognathia, indistinct philtrum, and thin upper lip; and longitudinally oriented palmar creases, flexion deformities of the fingers, and a limited range of motion of other joints. Minor anomalies (usually spontaneously closing cardiac septal defects),

anomalous external genitalia, and cleft lip and palate are much more frequent than in the general population. All of these features have similarities to the syndrome described in a proportion of infants whose mothers had taken anticonvulsants during pregnancy; the "fetal anticonvulsant syndrome" (page 296). The newborn infants suck and sleep poorly, and many of them are irritable, restless, hyperactive, and tremulous; these last symptoms resemble those of alcohol withdrawal except that they persist.

The first long-term study of children with what has come to be called *fetal alcohol syndrome* (FAS) was reported by Jones and coworkers. Among 23 infants born to alcoholic mothers, there was a neonatal mortality of 17 percent; among the infants who survived the neonatal period, almost half failed to achieve normal weight, length, and head circumference or remained backward mentally to a varying degree, even under optimal environmental conditions. Several large groups of severely affected FAS children have now been observed for 20 years or longer (see Streissguth). Distractibility, inattentiveness, hyperactivity, and impairment of fine motor coordination are prominent features in early childhood. Most such children fall into the category of attention-deficit hyperactivity disorder. Slow growth of head circumference is a consistent finding throughout infancy and childhood. The physical stigmata of the syndrome become less distinctive after puberty, but practically all adolescents are left with some degree of mental retardation and behavioral abnormalities.

The pathologic changes that underlie the FAS have been studied in a small number of cases and no uniform change has emerged. Of some interest are observations such as those of Ikonomidou and coworkers that demonstrate a profound effect of alcohol exposure on the deletion of millions of neurons in the developing rat brain by a mechanism of apoptosis. The main vulnerability occurs during periods of synaptogenesis, which in humans extends from the sixth month of gestation onward.

It is noteworthy that infants born to nonalcoholic mothers who had been subjected to severe dietary deprivation during pregnancy (during World War II) were small and often premature, but these infants did not show the pattern of malformations that characterizes FAS. Alcohol readily crosses the placenta in humans and animals; in the mouse, rat, chick, miniature swine, and beagle dog, alcohol has been shown to have both embryotoxic and teratogenic effects. Thus, the evidence to date favors a toxic effect of alcohol, although a possible toxic effect of acetaldehyde and smoking and a possible contributory role for nutritional deficiency have not been totally excluded.

Unequivocal cases of FAS observed to date have occurred only in infants born to severely alcoholic mothers (many of them with delirium tremens and liver disease) who continued to drink heavily throughout pregnancy. It is important to state that a relationship to lesser degrees of alcohol intake is far less secure. Data derived from the collaborative study sponsored by the National Institutes of Health indicate that about one-third of the offspring of women who are heavy drinkers have the FAS. Abel and Sokol have estimated that the worldwide incidence of the FAS is 1.9 per 1000 live births and have pronounced it to be the leading known cause of mental retardation in the western world. The degree of maternal alcoholism that is necessary to produce the syndrome and the critical stage in gestation during which it occurs are still vague. The various teratogenic effects described earlier are estimated to occur in the embryonic period, i.e., in the first 2 months of fetal life. Other nonteratogenic effects appear to be related to periods during gestation when the fetus is exposed to particularly high alcohol levels.

A comprehensive account of alcohol-related birth defects and the controversial issues surrounding this subject is contained in a special issue of *Alcohol Health and Research World*, published by the National Institutes of Health (Vol. 18, 1994).

Neurologic Complications of Alcoholic Cirrhosis and Portal-Systemic Shunts

This category of alcoholic disease is discussed in Chap. 40, in connection with the acquired metabolic disorders of the nervous system.

Treatment of Alcohol Addiction

Following recovery from the acute medical and neurologic complications of alcoholism, the patient still must face the underlying problem of alcohol dependence. To treat only the medical complications and leave the management of the drinking problem to the patient alone is shortsighted. Almost always, drinking is resumed, with a predictable recurrence of medical illness. For this reason the physician must be prepared to deal with the addiction or at least to initiate treatment.

The problem of excessive drinking is formidable but not nearly as hopeless as it is generally made out to be (see review of O'Connor and Schottenfeld). A common misconception among physicians is that specialized training in psychiatry and an inordinately large amount of time are required to deal with the addictive drinker. Actually, a successful program of treatment can be initiated by any interested physician, using the standard techniques of history taking, establishing rapport with the patient, and setting up a schedule of frequent visits, though not necessarily for prolonged periods. Our position on this matter was reinforced by a controlled study of problem drinkers in whom treatment was equally successful whether carried out by general practitioners or by specialists (Drummond et al.). The various approaches to the patient who has a drinking problem but is not yet alcohol dependent are summarized by O'Connor and Schottenfeld. They favor brief and focused interventions that point out the problem in unambiguous terms and offer empathetic advice; the physician is often the central person in this interaction.

The requisite for successful treatment is total abstinence from alcohol; for all practical purposes, this represents the only permanent solution. It is generally agreed that any attempts to curb the drinking habit will fail if the patient continues to drink. There are said to be alcohol addicts who have been able to reduce their intake of alcohol and eventually to drink in moderation, but they must represent only a small proportion of the addicted population. Alcoholic patients must be made fully aware of the medical and social consequences of continued drinking. They must also be made to understand that because of some constitutional peculiarity (like that of the diabetic, who cannot handle sugar) they are incapable of drinking in moderation. These facts should be presented in much the same way as one would explain the essential features of any other disease; there is nothing to be gained from adopting a punitive or moralizing attitude. Yet patients should not be given the idea that they are in no way to blame for their illness; there appears to be an advantage in making them feel that they are responsible for doing something about their drinking.

A number of methods have proved valuable in the short- and long-term management of alcoholic patients. The more important of these are admission to a detoxification or special hospital unit,

rehabilitative therapy, aversion treatment, the use of disulfiram (Antabuse), and the participation in self-help organizations for recovery from alcoholism. Detoxification clinics and special hospital units for the treatment of alcoholism are now widely available. The physician should be fully aware of all the community resources available for the management of this problem and should be prepared to take advantage of them in appropriate cases. Most inpatient programs include individual and group counseling, didactics about the illness and recovery, and family intervention. Outpatient treatment (of individuals or groups) is widely available, either from specialized facilities or from specialized therapists in general mental health facilities; family counseling is usually offered as well and is often beneficial. Most professional alcoholism treatment in the United States includes an introduction to the methods and utilization of Alcoholics Anonymous (AA, see later).

Disulfiram interferes with the metabolism of alcohol, so that a patient who takes both alcohol and disulfiram accumulates an inordinate amount of acetaldehyde in the tissues, resulting in nausea, vomiting, and hypotension, sometimes pronounced in degree. It is no longer considered necessary to demonstrate these effects to patients; it is sufficient to warn them of the severe reactions that may result if they drink while they have the drug in their bodies. Treatment with disulfiram is instituted only after the patient has been sober for several days, preferably longer. It should never be given to patients with cardiac or advanced liver disease. Should the patient drink while taking disulfiram, the ensuing reaction is usually severe enough to require medical attention, and a protracted spree can thus be prevented. Disulfiram may cause a polyneuropathy if continued over months or years, but this is a rare complication.

Several other drugs have recently become popular in maintaining abstinence. The opioid antagonist naltrexone (50 mg/day) has been used for this purpose, with mixed but overall favorable results. In Europe, a modicum of success has been achieved with the GABA and glutamate modulator acamprosate (2000 mg daily), but this drug is not yet available in the United States. Putatively, a novel approach has been to block the addicting effects of alcohol on the mesolimbic dopaminergic system by the use of anticonvulsants such as topiramate. Johnson and colleagues were able to demonstrate a reduction in alcoholic intake in patients taking this drug, in comparison to placebo, albeit over only a 12-week period. The use of these medications and the possible reasons for conflicting results between studies are given in a thorough review by Swift.

Alcoholics Anonymous, an informal fellowship of recovering alcoholics, has proved to be the single most effective force in the rehabilitation of alcoholic patients. The philosophy of this organization is embodied in its "12 Steps," a series of principles for sober living that guide the patient to recovery. The AA philosophy stresses in particular the practice of making restitution, the necessity to help other alcoholics, trust in a higher power, the group confessional, and the belief that the alcoholic alone is powerless over alcohol. Although accurate statistics are lacking, it is said that about one-third of the members who express more than a passing interest in the program attain a state of long-sustained or permanent sobriety. The methods used by AA are not acceptable to every patient, but most who persist in its activities appear to benefit; in particular, the physician should not accept a patient's initial negative reaction as reason to abandon AA as a mode of treatment.

Finally, it should be noted that alcoholism is frequently associated with psychiatric disease of other types, particularly socio-

pathy and affective illness (the term "dual diagnosis" is used by psychiatrists to denote this combination of psychopathologies). In the latter case, the prevailing mood is far more often one of depression than of mania and is more often encountered in women, who are more apt to drink under these conditions than are men. In

these circumstances, expert psychiatric help should be sought, preferably from someone who is also familiar with addictive diseases.

The role of physicians in caring for patients with alcohol problems has been outlined by several governmental agencies and are summarized in the review article by O'Connor and Schottenfeld.

CHAPTER 43

DISORDERS OF THE NERVOUS SYSTEM DUE TO DRUGS, TOXINS, AND OTHER CHEMICAL AGENTS

Subsumed under this title is a diverse group of disorders of the nervous system that result from the introduction into the body of drugs and other injurious or poisonous substances. A drug can be broadly defined as any chemical agent that affects living processes, but for purposes of this chapter, the discussion is limited to such drugs in modern use for the prevention and treatment of diseases. In addition, the neurologist must be concerned with the myriad of chemical agents that have no therapeutic utility but may adversely affect the nervous system; they abound in the environment as household products, insecticides, industrial solvents, and other poisons, the toxic neurological effects of which must be recognized and treated. Also included among neurotoxins are those generated by bacteria and other infectious agents, as well as several found in nature, such as marine toxins and agents elaborated by living animals. These are designated as *endogenous* if they arise within the body and *exogenous* if introduced from outside. Such a division cannot always be sharply drawn, as in the case of toxins produced by certain bacteria after being introduced from the outside (e.g., tetanus).

It would hardly be possible within the confines of this chapter to discuss with any degree of completeness the innumerable drugs and toxins that affect the nervous system. The interested reader is referred to a number of comprehensive monographs and references listed at the end of this chapter. In addition, an up-to-date handbook of pharmacology and toxicology should be part of the library of every physician.

The scope of this chapter is also limited because the therapeutic and adverse effects of many drugs are considered elsewhere in this volume in relation to particular symptoms and diseases. Thus, the toxic effects of ethyl, methyl, amyl, and isopropyl alcohol, as well as ethylene and diethylene glycol, are discussed in Chap. 42, on alcohol. The adverse effects of antibiotics on cochlear and vestibular function and on neuromuscular transmission are discussed in Chaps. 15 and 53, respectively. Many of the undesirable side effects of the common drugs used in the treatment of extra-pyramidal motor symptoms, pain, headache, convulsive seizures, sleep disorders, psychiatric illnesses, and so forth are also considered in the chapters dealing with each of these disorders and in the chapters that cover psychiatric diseases. Cyanide and carbon monoxide poisoning are discussed in relation to anoxic encephalopathy (Chap. 40). A number of therapeutic agents that damage the peripheral nerves (e.g., cisplatin, disulfiram, vincristine, dapsone, etc.) are mentioned in this chapter but are discussed further in Chap. 46 on peripheral neuropathy, and those affecting muscle, in Chap. 51.

Of necessity, the presentation of this subject must be introduced by some general remarks on the action of drugs on the nervous system and on the selective ways in which the more common categories of drugs and chemical agents affect the nervous system.

The references at the end of the chapter are listed in relation to each of these categories:

1. The general principles guiding the action of drugs on the nervous system
2. The addicting drugs: opiates and synthetic analgesics
3. Sedative-hypnotic drugs
4. Antipsychotic drugs
5. Antidepressant drugs
6. Stimulants
7. Psychoactive drugs
8. Bacterial toxins
9. Plant poisons, venoms, bites, and stings
10. Heavy metals
11. Industrial toxins
12. Antineoplastic and immunosuppressive agents
13. Antibiotics of various classes
14. Cardioactive agents (beta blockers, digitalis derivatives, amiodarone)

NEUROPHARMACOLOGY: GENERAL PRINCIPLES

Of primary importance is the manner in which a therapeutic agent, specifically its chemical structure, affects the biochemistry and physiology of neurons and their supporting elements (*pharmacodynamics*). The rational use of any drug requires a knowledge of the best route of administration, the drug's absorption characteristics, its distribution in the nervous system and other organs, and its biotransformations and excretion (*pharmacokinetics*). Since every drug, if given in excess, has some adverse effects, therapeutics and toxicology are inseparable.

Drug–Nervous System Interactions

In no other field of neurology is it more apparent that all systems of neurons are not identical. Each has its own vulnerabilities to particular drugs and toxic agents. This principle, originally enunciated by O. and C. Vogt in their theory termed *pathoclasis*, has been elegantly confirmed by tracing chemical molecules to specific aggregates of neurons. Thus, pathoclasis explains the preferential effects of anesthetics on the neurons of the upper brainstem reticular formation, which, with its diffuse cortical connections, underlies consciousness. There are examples not only of certain groups of nerve cells being selectively destroyed by a particular agent but also of their function and particular parts of their structure being altered. Drugs may actually be targeted even to the terminal axons, dendrites, neurofilaments, or receptors on pre- and postsynaptic surfaces of neurons or to certain of their metabolic activities,

whereby they synthesize and release neurotransmitters or maintain their cellular integrity by the synthesis of ribonucleic acid (RNA), deoxyribonucleic acid (DNA), and other proteins. The production of parkinsonism by the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is an excellent example of pathoclisis, in which a disease process and a synthetic toxin effect a progressive loss of melanin-bearing nigral neurons and a depletion of their neurotransmitter, dopamine. An intriguing but not yet fully established extension of this pathoclisis relates to the manner in which certain toxins affect only individuals with a genetic disposition to a degenerative neurologic disease.

Evidence is also accumulating regarding the mechanisms by which drugs and toxins can act on particular steps in the formation, storage in presynaptic vesicles, release, uptake, catabolism, and resynthesis of neurotransmitters such as dopamine, serotonin, norepinephrine, acetylcholine, and other catecholamines. Johnston and Silverstein have summarized current views of how these transmitters and modulating agents, by attaching to receptors at neuronal synapses, are able to increase or decrease the permeability of ion channels and stimulate or inhibit second cytoplasmic messengers. Many examples can be given. Drugs such as L-dopa, tryptophan, and choline enhance the synthesis of dopamine, serotonin, and acetylcholine, respectively. Baclofen modulates the release of gamma-aminobutyric acid (GABA), the main inhibitory transmitter in the central nervous system (CNS). Bretylium prevents the release of norepinephrine; botulinum toxin has a similar effect on acetylcholine in the neuromuscular junction, and tetanus toxin on GABA in Renshaw cells of the spinal cord. Amantadine, an antiviral agent, is thought to promote the release of dopamine, guanidine, and acetylcholine. Benzodiazepines, bromocriptine, and methylphenidate are viewed as receptor agonists; the phenothiazines and anticholinergics act as receptor antagonists. Certain drugs enhance the activity of neurotransmitters by inhibiting their reuptake, as, for example, the class of antidepressant drugs that has a relatively selective influence on the reuptake of serotonin. One must not assume that these are the exclusive modes of action of each of these drugs, but these data are instructive and indicate the future direction of neuropharmacology.

Lacking still is information about the precise mechanisms of even the most common inhalational anesthetics. It has been assumed that by their lipid solubility they alter the physicochemical properties of the cell membrane and thus impair the activities of the membrane receptor systems that regulate ion channels, particularly the chloride and calcium channels. A discussion of the clinical effects of general anesthesia can be found on page 309.

Bioavailability

A majority of drugs that act on the nervous system are ingested; factors that govern their intestinal absorption must, therefore, be taken into account. Small molecules usually enter the plasma by diffusion, larger ones by pinocytosis. The substances with which the drugs are mixed (excipients); the presence of food, other drugs, or intestinal diseases; and the age of the patient all influence the rate of absorption and blood concentrations. Different calculations are necessary for intramuscular, subcutaneous, and intrathecal routes of administration. To some extent, the solubilities of drugs (in lipid or water) determine the routes by which they can be given; some drugs, such as morphine, can be administered by manifold routes. Carried in the blood, the drug (or toxin) reaches many tissues, including the nervous system; protein binding in the plasma

has an important influence on distribution. Many drugs and toxic substances bind to serum albumin and other serum proteins, limiting the availability of the ionized form. The common drug and toxin transformations involve hydroxylation, deamination, oxidation, and dealkylation, which enhance their solubility and elimination by the kidney. Most of these catalytic processes occur in liver cells and utilize multiple enzymes.

To enter the extracellular compartment of the nervous system, a drug or toxic agent must transgress the tight capillary endothelial barrier (blood-brain barrier) and the barrier between the blood and cerebrospinal fluid (blood-CSF barrier). Intrathecal injection circumvents these barriers, but then the agent tends to concentrate in the immediate subpial and subependymal regions. The process of movement from plasma to brain is by diffusion through capillaries or by facilitated transport. The solubility characteristics of the drug determine its rate of diffusion.

In the following discussion on neurotoxins, the reader will appreciate a number of novel phenomena: *tolerance* (lessening effect of increasing dose), *dependence* and *addiction* (insatiable need), *habituation*, *drug-seeking behaviors*, and *abstinence* with its associated *withdrawal effects*. These were described in Chap. 42 on alcoholism and are further elaborated in sections below. Particularly difficult in reference to drugs such as nicotine is the separation of habituation from addiction, i.e., of psychologic dependence from physical dependence (see further on).

To make intelligent use of the pharmacologic agents described later, the neurologist must know about their pharmacodynamic and pharmacokinetic properties. The few examples given earlier are intended to provide a glimpse of the complex interactions between chemical agents and the cells of the nervous system. For more specific information, the reader is referred to *The Biochemical Basis of Neuropharmacology* by Cooper, Bloom, and Roth, an excellent text that we have consulted through its many editions and to *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, now in its tenth edition, edited by Hardman and colleagues. The continued elucidation of the modes of action of the several hundred drugs and toxins that act on the nervous system promises to yield important information about the biochemical physiology of neurons and opens for study an inviting field of experimental neuropharmacology and neuropathology.

OPIATES AND SYNTHETIC ANALGESIC DRUGS

The opiates, strictly speaking, include all the naturally occurring alkaloids in opium, which is prepared from the seed capsules of the poppy *Papaver somniferum*. For clinical purposes, the term *opiate* refers only to the alkaloids that have a high degree of analgesic activity, i.e., morphine and codeine. The terms *opioid* and *narcotic-analgesic* designate drugs with actions similar to those of morphine. Compounds that are chemical modifications of morphine include diacetylmorphine, or heroin (still the most commonly abused opioid), hydromorphone (Dilaudid), codeine, hydrocodone, oxymorphone, and oxycodone (Percodan, Oxycontin). A second class of opioids comprises the purely synthetic analgesics: meperidine (Demerol) and its congeners, notably fentanyl (Sublimaze), methadone (Dolophine), levorphanol (Levo-Dromoran), propoxyphene (Darvon), pentazocine (Talwin), diphenoxylate (the main component of Lomotil), and phenazocine (Prinadol). The synthetic analgesics are similar to the opiates, in both their pharmacologic effects and patterns of abuse, the differences being mainly quantitative.

The clinical effects of the opioids are considered from two points of view: (1) acute poisoning and (2) addiction.

Opioid Overdose

Because of the common and particularly the illicit use of opioids, poisoning is a frequent occurrence. This happens also as a result of ingestion or injection with suicidal intent, errors in the calculation of dosage, the use of a substitute or contaminated street product, or unusual sensitivity. Children exhibit an increased susceptibility to opioids, so that relatively small doses may prove toxic. This is true also of adults with myxedema, Addison disease, chronic liver disease, and pneumonia. Acute poisoning may also occur in addicts who are unaware that available opioids vary greatly in potency and that tolerance for opioids declines quickly after the withdrawal of the drug; upon resumption of the habit, a formerly well-tolerated dose can be fatal.

Varying degrees of unresponsiveness, shallow respirations, slow respiratory rate (e.g., two to four per minute) or periodic breathing, pinpoint pupils, bradycardia, and hypothermia are the well-recognized clinical manifestations of acute opioid poisoning. In the most advanced stage, the pupils dilate, the skin and mucous membranes become cyanotic, and the circulation fails. The immediate cause of death is usually respiratory depression, with consequent asphyxia. Patients who suffer a cardiorespiratory arrest are sometimes left with all the known residua of anoxic encephalopathy. Mild degrees of intoxication are revealed by anorexia, nausea, vomiting, constipation, and loss of sexual interest.

Treatment of Overdose This consists of the administration of naloxone (Narcan), or the longer acting nalmefene, both specific antidotes to the opiates and also to the synthetic analgesics. The dose of naloxone is 0.7 mg/70 kg body weight *intravenously*, repeated if necessary once or twice at 5-min intervals. In cases of opioid poisoning, the improvements in circulation and respiration and reversal of miosis are usually dramatic. In fact, failure of naloxone to produce such a response should cast doubt on the diagnosis of opioid intoxication. If an adequate respiratory and pupillary response to naloxone is obtained, the patient should nonetheless be observed for up to 24 h and further doses of naloxone (50 percent higher than the ones previously found effective) can be given *intramuscularly* as often as necessary. Naloxone has less direct effect on consciousness, however, and the patient may remain drowsy for many hours. This is not harmful provided respiration is well maintained. Although nalmefene has a plasma half-life of 11 h, compared to 60-90 min for naloxone, it has no clear advantage in emergency practice. Gastric lavage is a useful measure if the drug was taken orally. This procedure may be efficacious many hours after ingestion, since one of the toxic effects of opioids is pylorospasm and ileus, which causes much of the drug to be retained in the stomach.

Once the patient regains consciousness, complaints such as pruritus, sneezing, tearing, piloerection, diffuse body pains, yawning, and diarrhea may appear. These are the recognizable symptoms of the opioid abstinence, or withdrawal, syndrome, described later. An antidote therefore must be used with great caution in an addict who has taken an overdose of opioid, because in this circumstance it may precipitate withdrawal phenomena. Nausea and severe abdominal pain, due presumably to pancreatitis (from spasm of the sphincter of Oddi), are other troublesome symptoms of opiate use or withdrawal. Seizures are rare.

Opioid Addiction

Just 50 years ago there were an estimated 60,000 persons addicted to narcotic drugs in the United States, exclusive of those who were receiving drugs because of incurable painful diseases. This represented a relatively small public health problem in comparison with the abuse of alcohol and barbiturates. Moreover, opioid addiction was of serious proportions in only a few cities—New York, Chicago, Los Angeles, Washington, and Detroit. Since the late 1960s, a remarkable increase in opioid (mainly heroin) addiction has taken place. The precise number of opioid addicts is not known but is currently estimated by the Drug Enforcement Administration to be well more than 500,000 (a disproportionate number in New York and a few other large cities). The problem assumes enormous importance when one recognizes that one-quarter of addicts are seropositive for human immunodeficiency virus (HIV) and are the chief source of transmission of AIDS to newborns and to the heterosexual nonaddicted population. The prevalence and patterns of opioid abuse have been reviewed by Brust.

Etiology and Pathogenesis A number of factors—socioeconomic, psychologic, and pharmacologic—contribute to the genesis of opioid addiction. In our culture, the most susceptible subjects are young men or delinquent youths living in the economically depressed areas of large cities, but significant numbers are now found in suburbs and in small cities as well. The onset of opioid use is usually in adolescence, with a peak at 17 to 18 years; fully two-thirds of addicts start using the drugs before the age of 21. Almost 90 percent of addicts engage in criminal activity, often to obtain their daily ration of drugs, but most of them have a history of arrests or convictions antedating their addiction. Also, many of them have psychiatric disturbances, conduct disorder and sociopathy being the most common ("dual-diagnosis," in psychiatric jargon). Monroe and colleagues, using the Lexington Personality Inventory, examined a group of 837 opioid addicts and found evidence of antisocial personality in 42 percent, emotional disturbance in 29 percent, and thinking disorder in 22 percent; only 7 percent were free of such disorders. Obviously, vulnerability to addiction is not confined to one personality type.

Association with addicts is the apparent explanation for beginning addiction. One addict recruits another person into addiction, and the new recruit does likewise. In this sense opioid addiction is contagious, and partly as a result of this pattern, heroin addiction has attained epidemic proportions. A small, almost insignificant proportion of addicts are introduced to drugs by physicians in the course of an illness. Therefore, there has been a regrettable tendency not to prescribe opiates to patients with acute or chronic pain (e.g., cancer pain) because of the risk of addiction.

Opioid addiction consists of three recognizable phases: (1) episodic intoxication, or "euphoria," (2) pharmacogenic dependence or drug-seeking behavior (addiction), and (3) the propensity to relapse after a period of abstinence.

Some of the symptoms of opioid intoxication have already been considered. In patients with severe pain or pain-anticipatory anxiety, the administration of opioids produces a sense of unusual well-being, a state that has traditionally been referred to as *morphine euphoria*. It should be emphasized that only a negligible proportion of such persons continue to use opioids habitually after their pain has subsided. The vast majority of potential addicts are not suffering from painful illnesses at the time they initiate opioid use, and the term *euphoria* is probably not an apt description of

the initial effects. These persons, after several repetitions, recognize a "high," despite the subsequent recurrence of unpleasant, or *dysphoric*, symptoms (nausea, vomiting, and faintness as the drug effect wanes). One of our patients described the initial effect as "dying and going to heaven." The repeated self-administration of the drug is the most important factor in the genesis of *addiction*. Regardless of how one characterizes the state of mind that is produced by episodic injection of the drug, the individual quickly discovers the need to increase the dose in order to obtain the original effects (*tolerance*). Although the initial effects may not be fully recaptured, the progressively increasing dose of the drug does relieve the discomfort that arises as the effects of each injection wear off. In this way a new *pharmacogenetically induced* need is developed, and the use of opioids becomes self-perpetuating. At the same time a marked degree of *tolerance* is produced, so that enormous amounts of drugs, e.g., 5000 mg of morphine daily, can eventually be administered without the development of toxic symptoms.

The pharmacologic criteria of addiction, as indicated in the chapter on alcoholism, are *tolerance* and *physical dependence*. The latter refers to the symptoms and signs that become manifest when the drug is withdrawn following a period of continued use. These symptoms and signs constitute a specific clinical state, termed *the abstinence or withdrawal syndrome* (see later). The mechanisms that underlie the development of tolerance and physical dependence are not fully understood. However, it is known that opioids activate an opioid antinociceptive system (enkephalins, dynorphins, endorphins), which are opioid receptors and are located at many different levels of the nervous system (these are described in Chap. 8, on pain; see also the review of Fields).

The Opioid Abstinence Syndrome The intensity of the *abstinence* or *withdrawal* syndrome depends on the dose of the drug and the duration of addiction. The onset of abstinence symptoms in relation to the last exposure to the drug, however, is related to the pharmacologic half-life of the agent. With morphine, the majority of individuals receiving 240 mg daily for 30 days or more will show moderately severe abstinence symptoms following withdrawal. Mild signs of opiate abstinence can be precipitated by narcotic antagonists in persons who have taken as little as 15 mg of morphine or an equivalent dose of methadone or heroin three times daily for 3 days.

The abstinence syndrome that occurs in the morphine addict may be taken as the prototype. The first 8 to 16 h of abstinence usually pass asymptotically. At the end of this period, yawning, rhinorrhea, sweating, piloerection, and lacrimation become manifest. Mild at first, these symptoms increase in severity over a period of several hours and then remain constant for several days. The patient may be able to sleep during the early abstinence period but is restless, and thereafter insomnia remains a prominent feature. Dilatation of the pupils, recurring waves of "gooseflesh," and twitchings of the muscles appear. The patient complains of aching in the back, abdomen, and legs and of "hot and cold flashes"; he frequently asks for blankets. At about 36 h the restlessness becomes more severe, and nausea, vomiting, and diarrhea usually develop. Temperature, respiratory rate, and blood pressure are slightly elevated. All these symptoms reach their peak intensity 48 to 72 h after withdrawal and then gradually subside. The opioid abstinence syndrome is rarely fatal (it is life-threatening only in infants). After 7 to 10 days, the clinical signs of abstinence are no longer evident, although the patient may complain of insomnia, nervousness, weakness, and muscle aches for several more weeks, and small

deviations of a number of physiologic variables can be detected with refined techniques for up to 10 months (protracted abstinence).

Habituation, the equivalent of emotional or psychologic *dependence*, refers to the substitution of drug-seeking activities for all other aims and objectives in life. It is this feature that fosters relapse to the use of the drug long after the physiologic ("nonpurposive") abstinence changes seem to have disappeared. The cause for relapse is not fully understood. Theoretically, fragments of the abstinence syndrome may remain as a conditioned response, and these abstinence signs may be evoked by the appropriate environmental stimuli. Thus, when a "cured" addict returns to a situation where narcotic drugs are readily available or in a setting that was associated with the initial use of drugs, the incompletely extinguished drug-seeking behavior may reassert itself.

The characteristics of addiction and of abstinence are qualitatively similar with all drugs of the opiate group as well as the related synthetic analgesics. The differences are quantitative and are related to the differences in dosage, potency, and length of action. Heroin is two to three times more potent than morphine, but the heroin withdrawal syndrome encountered in hospital practice is usually mild in degree because of the low dosage of the drug in the street product. Dilaudid (hydromorphone) is more potent than morphine and has a shorter duration of action; hence the addict requires more doses per day, and the abstinence syndrome comes on and subsides more rapidly. Abstinence symptoms from codeine, while definite, are less severe than those from morphine. The addiction liabilities of propoxyphene are negligible. Abstinence symptoms from methadone are less intense than those from morphine and do not become evident until 3 or 4 days after withdrawal; for these reasons methadone can be used in the treatment of morphine and heroin dependency (see further on). Meperidine addiction is of particular importance because of its high incidence among physicians and nurses. Tolerance to the drug's toxic effects is not complete, so that the addict may show tremors, twitching of muscles, confusion, hallucinations, and sometimes convulsions. Signs of abstinence appear 3 to 4 h after the last dose and reach their maximum intensity in 8 to 12 h, at which time they may be worse than those of morphine abstinence.

As to the biologic basis of addiction, tolerance, and physical dependence, our understanding is still very limited. Experiments in animals have provided the first insights into the neurotransmitter and neuronal systems involved. As a result of microdialyzing opiates and their antagonists into the central brain structures of animals, it has been tentatively concluded that mesolimbic structures, particularly the nucleus accumbens, ventral tegmentum of the midbrain, and locus ceruleus are activated or depressed under conditions of repeated opiate exposure. Thus, chronic opiate usage increases the levels of certain intracellular messengers (possibly G proteins) that drive cyclic-AMP activity in the locus ceruleus and in the nucleus accumbens; blocking the expression of these proteins markedly increases the self-administration of opiates by addicted rats. As in alcoholism, certain subtypes of the serotonin and dopamine receptors in limbic structures have been implicated in the psychic aspects of addiction and habituation. These same structures are conceived as a common pathway for the impulse to human drives such as sex, hunger, and psychic fulfillment. The neurochemical mechanism of addiction has been reviewed by Camí and Farré.

The *diagnosis* of addiction is usually made when the patient admits to using and needing drugs. Should the patient conceal this fact, one relies on collateral evidence such as miosis, needle marks, emaciation, abscess scars, or chemical analyses. Meperidine ad-

dicts are likely to have dilated pupils and twitching of muscles. The finding of morphine or opiate derivatives (heroin is excreted as morphine) in the urine is confirmatory evidence that the patient has taken or has been given a dose of such drugs within 24 h of the test. The diagnosis of opiate addiction is also at once apparent when the treatment of acute opiate intoxication precipitates a characteristic abstinence syndrome.

Treatment of the Opioid Abstinence Syndrome (Physical Dependence) One approach that has achieved some degree of success over the past 30 years has been the substitution of methadone for opioid, in the ratio of 1 mg methadone for 3 mg morphine, 1 mg heroin, or 20 mg meperidine. Since methadone is long-acting and effective orally, it need be given only twice daily by mouth—10 to 20 mg per dose being sufficient to suppress abstinence symptoms. After a stabilization period of 3 to 5 days, this dosage of methadone is reduced and the drug is withdrawn over a similar period. An alternative but probably less effective method has been the use of clonidine (0.2 to 0.6 mg twice a day for a week), a drug that counteracts most of the noradrenergic withdrawal symptoms; however, the hypotension that is induced by this drug may be a problem (Jasinski et al).

Recently, a rapid detoxification regimen that is conducted under general anesthesia has become popular in a number of centers as a means of treating opiate addiction. The technique consists of administering increasing doses of opioid receptor antagonists (naltrexone or naltrexone) over several hours while the autonomic and other features of the withdrawal syndrome are suppressed by the infusion of propofol or a similar anesthetic, supplemented by intravenous fluids. Medications such as clonidine and sedatives are also given in the immediate postanesthetic period. The addict is instructed to continue taking naltrexone for several days or weeks, a practice adopted by one of the outpatient treatment centers for addiction described later. There are substantial risks involved in this procedure, and several deaths have occurred for which reason it has been all but abandoned in our hospitals. Furthermore, a number of patients continue to manifest signs of withdrawal after the procedure and require continued hospitalization. There are as yet few careful studies of the efficacy and overall safety of this procedure.

Treatment of Opiate Habituation (Psychologic Dependence) This is in some ways far more demanding than the treatment of opioid withdrawal and can be best accomplished in special facilities and programs that are devoted wholly to the problem. These are available in most communities. The most effective ones have been the ambulatory methadone maintenance clinics, where more than 100,000 former heroin addicts are participating in rehabilitation programs approved by the Food and Drug Administration. Methadone, in a dosage of 60 to 100 mg daily (sufficient to suppress the craving for heroin), is given under supervision day by day (less often with long-acting methadone) for months or years. Various forms of psychotherapy and social service counseling often administered by former heroin addicts are integral parts of the program.

The results of methadone treatment are difficult to assess and vary considerably from one program to another. Even the most successful programs suffer an attrition rate of about 25 percent when they are evaluated after several years. Of the patients who remain, the majority achieve a high degree of social rehabilitation, i.e., they are gainfully employed and no longer engage in criminal behavior or prostitution.

The usual practice of methadone programs is to accept only addicts over the age of 16 years with a history of heroin addiction

for at least 1 year. This leaves many adolescent addicts untreated. The number of addicts who can fully withdraw from methadone and maintain a drug-free existence is very small. This means that the large majority of addicts now enrolled in methadone programs are committed to an indefinite period of methadone maintenance, and the effects of such a regimen are uncertain.

An alternative method of ambulatory treatment of the opiate addict involves the use of narcotic antagonists, of which naloxone and naltrexone are the best known. The physical effects of abusing narcotics are thereby partially blocked, and there may be some degree of aversive conditioning if withdrawal symptoms are produced. Naltrexone is favored because it has a longer effect than naloxone, is almost free of agonist effects, and can be administered orally. Similar results have also been achieved with cyclazocine in a small number of highly motivated patients; this drug is administered orally in increasing amounts until a dosage of 2 mg/70 kg body weight is attained. The drug is taken twice daily (for 2 to 6 weeks) and is then withdrawn slowly.

More recently, interest has centered on the use of buprenorphine for the treatment of heroin (and cocaine) abuse. Buprenorphine is unique in that it has both opioid agonist and antagonist properties; it therefore mutes the effect of withdrawal and serves also as an aversive agent, like naltrexone. In addition, there is evidence, based on animal experiments and experience with small numbers of addicts, that it may be useful for the treatment of dual dependence on cocaine and opiates (see Mello and Mendelson). Buprenorphine has the additional advantage of being administered as a sublingual tablet. The FDA has recently approved its use.

Medical and Neurologic Complications of Opioid Use In addition to the toxic effects of the opioid itself, the addict may suffer a variety of neurologic and infectious complications resulting from the injection of contaminated adulterants (quinine, talc, lactose, powdered milk, and fruit sugars) and of various infectious agents (injections administered by unsterile methods). The most important of these is HIV infection, but septicemia and endocarditis and viral hepatitis may also occur. Particulate matter that is injected with heroin or a vasculitis that is induced by chronic heroin abuse may cause stroke by an incompletely understood *occlusion of cerebral arteries*, with hemiplegia or other focal cerebral signs. *Amblyopia*, due probably to the toxic effects of quinine in the heroin mixtures, has been reported, as well as *transverse myelopathy* and several types of *peripheral neuropathy*. The spinal cord disorder expresses itself clinically by the abrupt onset of paraplegia with a level on the trunk below which motor function and sensation are lost or impaired and by urinary retention. Pathologically, there is an acute necrotizing lesion involving both gray and white matter over a considerable vertical extent of the thoracic and occasionally the cervical cord. In some cases a myelopathy has followed the first intravenous injection of heroin after a prolonged period of abstinence. We have also seen two cases of cervical myelopathy from heroin-induced stupor and a prolonged period of immobility with the neck hyperextended over the back of a chair or sofa.

In addition, we have observed several instances of a subacute progressive cerebral leukoencephalopathy after heroin use, similar to ones that occurred in Amsterdam in the 1980s, the result of inhalation of heroin pyrolysate or an adulterant (Wolters et al and Tan et al). In our cases the white matter changes were concentrated in the posterior regions of the hemispheres and in the internal capsules and, in one striking case, in the cerebellar white matter

(Ropper and Blair). A similar leukoencephalopathy has also been reported in cocaine users, although a hypertensive encephalopathy or an adrenergic-induced vasculopathy may have played a role in these cases.

Damage to single peripheral nerves at the site of injection of heroin and from compression is a relatively common occurrence. However, bilateral compression of the sciatic nerves, the result of sitting or lying for a prolonged period in a stuporous state or in the lotus position while “stoned,” has occurred in several of our patients. In sciatic compression of this type, the peroneal branch has been more affected than the tibial, causing foot drop with less weakness of plantar flexion. More difficult to understand in heroin abusers is the involvement of other individual nerves, particularly the radial nerve, and painful affection of the brachial plexus, apparently unrelated to compression and remote from the sites of injection. Possibly in some instances there was a vasculitis affecting peripheral nerves.

An acute generalized *myonecrosis* with myoglobinuria and renal failure has been ascribed to the intravenous injection of adulterated heroin. Brawny edema and fibrosing myopathy (Volkmann contracture) are the sequelae of venous thrombosis resulting from the administration of heroin and its adulterants by the intramuscular and subcutaneous routes. Occasionally there may be massive swelling of an extremity into which heroin had been injected subcutaneously or intramuscularly; infection and venous thrombosis appear to be involved in its causation.

The diagnosis of drug addiction or the suspicion of this diagnosis should always raise the possibility of an assortment of infectious complications: AIDS, syphilis, abscesses and cellulitis at injection sites, septic thrombophlebitis, hepatitis, and periarteritis. Tetanus, endocarditis (due mainly to *Staphylococcus aureus*), spinal epidural abscess, meningitis, brain abscess, and tuberculosis have occurred less frequently.

SEDATIVE-HYPNOTIC DRUGS

This class of drugs, also referred to as depressants, consists of two main groups. The first includes the barbiturates, meprobamate, and chloral hydrate. These drugs are now little used, having been largely replaced by a second group, the *benzodiazepines*, the most important of which are chlordiazepoxide (Librium), lorazepam (Ativan), alprazolam (Xanax), clonazepam (Klonipin), and diazepam (Valium). Closely related are the nonbenzodiazepine hypnotics, typified by zolpidem (Ambien). The advantages of the benzodiazepine drugs are their *relatively* low toxicity and addictive potential and their minimal interactions with other drugs.

Barbiturates

Despite the marked reduction in the medical use of barbiturates during the past three decades, the improper use of these drugs—particularly their nonmedical and illicit use—is still responsible for a sizeable number of suicides, accidental deaths, and addiction. In the past, about 50 barbiturates were marketed for clinical use, but only a few are now encountered with any regularity: pentobarbital (Nembutal), secobarbital (Seconal), amobarbital (Amytal), thiopental (Pentothal), and phenobarbital (Luminal). The first three are the ones most commonly abused. Barbiturates are also a component of combination preparations for the treatment of migraine (e.g., butalbital in Fiorinal).

Mechanism of Action All the common barbiturates are derived from barbituric acid; the differences between them depend on variations in the side chains of the parent molecule. The potency of each drug is a function of the ionization constant and lipid solubility. The higher its lipid solubility, the greater the drug's potency and the quicker and briefer its action. The lowering of plasma pH increases the rate of entry of the ionized form into the brain. The action of barbiturates is to suppress neuronal transmission, presumably by enhancing GABA inhibition at pre- and postsynaptic receptor sites, and to reduce excitatory postsynaptic potentials. The major points of action in the CNS are similar to those of alcohol and other coma-producing drugs; impaired consciousness or coma relates to inactivation of neurons in the reticular formation of the upper brainstem. The liver is the main locus of drug metabolism, and the kidney is the method of elimination of the metabolites. All the barbiturates are similar pharmacologically and differ only in the speed of onset and duration of their action. The clinical problems posed by the barbiturates are different, however, depending on whether the intoxication is acute or chronic.

Acute Barbiturate Intoxication This results from the ingestion of large amounts of the drug, either accidentally or with suicidal intent. The latter is most frequently the act of a depressed person. The hysteric or sociopath may take an overdose as a suicidal gesture and become seriously intoxicated because of miscalculation or ignorance of the toxic dosage. Often the drug is taken while the individual is inebriated—a dangerous situation, since alcohol and barbiturate have an additive effect.

The symptoms and signs vary with the type and amount of drug as well as with the length of time that has elapsed since it was ingested. Pentobarbital and secobarbital produce their effects quickly, and recovery is relatively rapid. Phenobarbital induces coma more slowly, and its effects tend to be prolonged. In the case of long-acting barbiturates, such as phenobarbital and barbital, the hypnotic-sedative effect lasts 6 h or more after an average oral dose; with the intermediate-acting drugs such as amobarbital, 3 to 6 h; and with the short-acting drugs, secobarbital and pentobarbital, less than 3 h. Most fatalities follow the ingestion of secobarbital, amobarbital, or pentobarbital. The ingestion by adults of more than 3.0 g of these drugs at one time will prove fatal unless intensive treatment is applied promptly. The potentially fatal dose of phenobarbital is 6 to 10 g. The lowest plasma concentration associated with lethal overdosage of phenobarbital or barbital has been approximately 60 mg/mL and that of amobarbital and pentobarbital, 10 mg/mL.

In regard to prognosis and treatment, it is useful to recognize three grades of severity of acute barbiturate intoxication. *Mild intoxication* follows the ingestion of approximately 0.3 g pentobarbital (the hypnotic dose in an unhabituated patient is 100 mg) or its equivalent. The patient is drowsy or asleep, although readily roused if called or shaken. The symptoms resemble those of alcohol intoxication. The patient thinks slowly, and there may be mild disorientation, lability of mood, impairment of judgment, slurred speech, drunken gait, and nystagmus. *Moderate intoxication* follows the ingestion of 5 to 10 times the oral hypnotic dose. The patient is stuporous, tendon reflexes are usually depressed or absent, and respirations are slow but not shallow. Corneal and pupillary reflexes are retained, with occasional exceptions. Usually the patient can be roused by vigorous manual stimulation; when awakened, he is confused and dysarthric and, after a few moments, drifts back into stupor.

Severe intoxication occurs with the ingestion of 10 to 20 times the oral hypnotic dose. The patient cannot be roused by any means, i.e., is comatose. Respiration is slow and shallow or irregular, and pulmonary edema and cyanosis may be present. The tendon reflexes are usually but not invariably absent. Most patients show no response to plantar stimulation, but in those who do, the responses are extensor. With deep coma, the corneal and gag reflexes may also be abolished. Ordinarily the pupillary light reflex is retained in severe intoxication and is lost only if the patient is asphyxiated; but in advanced cases, the pupils become miotic and poorly reactive, simulating opiate intoxication. At this point respiration is greatly depressed and oculocephalic and oculovestibular reflex responses are usually abolished. In the early hours of coma, there may be a phase of flexor or extensor posturing or rigidity of the limbs, hyperactive reflexes, ankle clonus, and extensor plantar signs; persistence of these signs indicates that anoxic damage has been added. The temperature may be subnormal, the pulse is thready and rapid, and the blood pressure is at shock levels. Failure of respiration to quicken on painful stimulation is an ominous sign.

There are few conditions other than barbiturate intoxication that cause a flaccid coma with small reactive pupils, hypothermia, and hypotension. A pontine hemorrhage may do so, but a hysterical trance or catatonic stupor do not present a problem in differential diagnosis. The use of gas and high-pressure liquid chromatography provides a reliable means of identifying the type and amount of barbiturate in the blood. A patient who has also ingested alcohol may be comatose with relatively low blood barbiturate concentrations. Contrariwise, the barbiturate addict may show only mild signs of intoxication with very high blood barbiturate concentrations.

In mild intoxication, the normal electroencephalogram (EEG) activity is replaced by fast (beta) activity, in the range of 20 to 30 cycles per second, and is most prominent in the frontal regions. In more severe intoxication, the fast waves become less regular and interspersed with 3- to 4-per-second slow activity; in still more advanced cases, there are short periods of suppression of all activity, separated by bursts of slow (delta) waves of variable frequency. In extreme overdosage, all electrical activity ceases. This is one instance in which a "flat" (isoelectric) EEG cannot be equated with brain death, and the effects are fully reversible unless anoxic damage has supervened.

Management In mild or moderate intoxication, recovery is the rule and special treatment is not required except to prevent aspiration. If the patient is unresponsive, special measures must be taken to maintain respiration and prevent infection. An endotracheal tube should be inserted, with suctioning as necessary. Any risk of respiratory depression or underventilation requires the use of a positive-pressure respirator.

Hemodialysis or hemofiltration with charcoal may be used in comatose patients who have ingested long-acting barbiturates and these treatments are particularly advisable if anuria or uremia has developed. Treatment with analeptic drugs (e.g., picrotoxin, pentylenetetrazol), which enjoyed a brief period of popularity, has been generally abandoned, since these drugs do not affect the rate of metabolism or the excretion of barbiturates.

Occasionally, in the case of a barbiturate addict who has taken an overdose of the drug, recovery from coma is followed by the development of abstinence symptoms, as described later.

Barbiturate Addiction (Chronic Barbiturate Intoxication)

Chronic barbiturate intoxication, like other drug addictions, tends to develop on a background of some psychiatric disorder, most

commonly a depressive illness with symptoms of anxiety and insomnia. Alcoholics find that barbiturates effectively relieve their nervousness and tremor. As with other drug addictions, the incidence of barbiturism is particularly high in individuals with ready access to drugs, such as physicians, pharmacists, and nurses. The easy availability through the internet of medications that contain barbituates may increase dependence on these drugs (Romero et al).

The manifestations of barbiturism are much the same as those of alcohol intoxication. The barbiturate addict thinks slowly, exhibits increased emotional lability, and becomes untidy in dress and personal habits. The neurologic signs include dysarthria, nystagmus, and cerebellar incoordination. If the dosage is elevated rapidly, the signs of moderate or severe intoxication, as described earlier, become manifest.

A characteristic feature of chronic barbiturate intoxication is the development of a striking degree of tolerance. The average addict ingests about 1.5 g of a potent barbiturate daily and does not manifest signs of severe intoxication unless this amount is exceeded. However, tolerance to barbiturates does not develop as rapidly as to opiates. Most persons can ingest up to 0.4 g daily for as long as 3 months and then cease taking the drug without developing major withdrawal signs (seizures or delirium). With a dosage of 0.8 g daily for a period of 2 weeks to 2 months, abrupt withdrawal will result in serious symptoms in the majority of patients (see later).

Barbiturate Abstinence, or Withdrawal, Syndrome Immediately following withdrawal, the patient seemingly improves over a period of 8 to 12 h, as the symptoms of intoxication diminish. Then a new group of symptoms develops, consisting of nervousness, tremor, insomnia, postural hypotension, and weakness. With chronic phenobarbital or barbital intoxication, withdrawal symptoms may not become apparent until 48 to 72 h after the final dose. Generalized seizures with loss of consciousness may occur, usually between the second and fourth days of abstinence but occasionally as long as 6 or 7 days after withdrawal. There may be a single seizure, several seizures, or, rarely, status epilepticus. Characteristically, in the withdrawal period, there is a greatly heightened sensitivity to photic stimulation, to which the patient responds with myoclonus or a seizure accompanied by paroxysmal changes in the EEG. The convulsive phase may be followed directly by a delusional-hallucinatory state or, as occurred in one of our cases (Romero et al), a full-blown delirium indistinguishable from delirium tremens, or a varying degree of improvement may follow the seizures before the delirium becomes manifest. Death has been reported under these circumstances. The abstinence syndrome may occur in varying degrees of completeness; some patients have seizures and recover without developing delirium, and others have a delirium without preceding seizures.

Treatment of Chronic Barbiturate Intoxication and Abstinence This should be carried out in the hospital. If the diagnosis of addiction is made before signs of abstinence have appeared, the "stabilization dosage" should first be determined. This is the amount of short-acting barbiturate required to produce mild symptoms of intoxication (nystagmus, slight ataxia, and dysarthria). Usually 0.2 g of pentobarbital given orally every 6 h is sufficient for this purpose. Then a gradual withdrawal of the drug is undertaken, 0.1 g daily, the reduction being stopped for several days if abstinence symptoms appear. In this way, a severely addicted person can be

withdrawn in 14 to 21 days. The patient who presents with severe withdrawal symptoms, such as seizures, is generally given 0.3 to 0.5 g of phenobarbital intramuscularly and then enough to maintain a state of mild intoxication. Most other anticonvulsant medicines are ineffective against barbiturate withdrawal convulsions, and diazepines are only partially effective in our experience. Withdrawal should then be carried out as indicated earlier. If the abstinence symptoms are not severe, it is not necessary to re intoxicate the patient, but treatment can proceed along the lines laid down for other forms of delirium and confusion. After recovery has taken place, whether from acute or chronic intoxication, the psychiatric problem requires evaluation and an appropriate plan of therapy.

Chloral Hydrate

This is the oldest and one of the safest, most effective, and most inexpensive of the sedative-hypnotic drugs. After oral administration, chloral hydrate is reduced rapidly to trichloroethanol, which is responsible for the depressant effects on the CNS. A significant portion of the trichloroethanol is excreted in the urine as the glucuronide, which may give a false-positive test for glucose.

Tolerance and addiction to chloral hydrate develop only rarely; for this reason it is an appropriate medication for the management of insomnia. Poisoning with chloral hydrate is a rare occurrence and resembles acute barbiturate intoxication except for the finding of miosis, which is said to characterize the former. Treatment follows along the same lines as for barbiturate poisoning. Death from poisoning is due to respiratory depression and hypotension; patients who survive may show signs of liver and kidney disease.

Paraldehyde, another member of this group of sedative drugs, is no longer being manufactured in the United States, and chloral hydrate is now available mainly as an elixir for pediatric use.

Benzodiazepines

With the introduction of chlordiazepoxide in 1960 and the benzodiazepine drugs that followed (particularly diazepam), the older sedative drugs (barbiturates, paraldehyde, chloral hydrate) have become virtually obsolete. Indeed, the benzodiazepines are among the most commonly prescribed drugs in the world today. According to Hollister, 15 percent of all adults in the United States use a benzodiazepine at least once yearly and about half this number use the drug for a month or longer. As mentioned earlier, these drugs, compared with the older sedatives, have *relatively* minor hypnotic effects and low abuse potential and are *relatively* safe when taken in overdose.

The benzodiazepines have been prescribed frequently for the treatment of anxiety and insomnia, and they are especially effective when the anxiety symptoms are severe. Also, they have been used to control overactivity and destructive behavior in children and the symptoms of alcohol withdrawal in adults. Diazepam is particularly useful in the treatment of delirious patients who require parenteral medication. The benzodiazepines possess anticonvulsant properties, and the intravenous use of diazepam, lorazepam, and midazolam is an effective means of controlling status epilepticus, as described on page 297. Diazepam in massive doses has been used with considerable success in the management of muscle spasm in tetanus and in the "stiff man" syndrome (page 1279). Diazepam has been far less successful in the treatment of extrapyramidal movement disorders and dystonic spasms. Alprazolam (Xanax) has

a central place in the treatment of panic attacks and other anxiety states, as an adjunct in some depressive illnesses, and in the behavioral disturbances in Alzheimer disease. It seems, however, to create more dependence than some of the others in its class.

Other important benzodiazepine drugs are flurazepam (Dalmane), triazolam (Halcion), chlorazepate (Tranxene), temazepam (Restoril), and other newer varieties, all widely used in the treatment of insomnia (page 340), and clonazepam (Klonipin), which is useful in the treatment of myoclonic seizures (page 274) and intention myoclonus (page 89). Midazolam (Versed), a short-acting parenteral agent, is given frequently to achieve the brief sedation required for procedures such as MRI or endoscopy and is useful in the treatment of status epilepticus, however, it is known to cause respiratory arrest on occasion. Lorazepam (Ativan) and oxazepam (Serax) are said to be preferable to other benzodiazepines in treating the elderly and those with impaired liver function. Many other benzodiazepine compounds have appeared in recent years, but a clear advantage over the original ones remains to be demonstrated (Hollister; Pirosky and Cohn).

The popularly used sleeping medication, Zolpidem (Ambien) differs from the benzodiazepines structurally but is pharmacologically similar.

The benzodiazepine drugs, like barbiturates, have a depressant action on the CNS by binding to specific receptors on GABA inhibitory systems. The benzodiazepines act in concert with GABA to open chloride ion channels and hyperpolarize postsynaptic neurons and reduce their firing rate. The primary sites of their action are the cerebral cortex and limbic system, which accounts for their anticonvulsive and anxiolytic effects. While quite safe in the recommended dosages, they are far from ideal. They frequently cause unsteadiness of gait and drowsiness and at times syncope, confusion, and impairment of memory, especially in the elderly. If taken in large doses, the benzodiazepines can depress the state of consciousness, resembling that of other sedative-hypnotic drugs but with less respiratory suppression and hypotension. Flumazenil, a specific pharmacologic antagonist of the CNS effects of benzodiazepines, rapidly but briefly reverses most of the symptoms and signs of benzodiazepine overdose. It acts by binding to CNS diazepine receptors and thereby blocking the activation of inhibitory GABA-ergic synapses. Flumazenil may also have diagnostic utility in cases of coma of unknown etiology and in hepatic encephalopathy (see page 968).

Signs of physical dependence and true addiction, though relatively rare, undoubtedly occur in chronic benzodiazepine users, even in those taking therapeutic doses. The withdrawal symptoms are much the same as those that follow the chronic use of other sedative drugs (anxiety, jitteriness, insomnia, seizures) but may not appear until the third day after the cessation of the drug and may not reach their peak of severity until the fifth day (Hollister). In chronic benzodiazepine users, the gradual tapering of dosage over a period of 1 to 2 weeks minimizes the withdrawal effects. However, we have observed numerous cases over the years in which the cessation of moderate doses of chronically used diazepines has resulted in one or more seizures. This is likely to happen when the patient is hospitalized for other reasons and the accustomed sleeping medication is omitted.

Carbonic Acid Derivatives

These drugs are capable of modest depressant action and are effective in relieving mild degrees of nervousness, anxiety, and mus-

cle tension. Meprobamate (Equanil, Miltown) is the best-known member of this group. It was the first of the “new” (postbarbiturate) antianxiety drugs, a chemical variant of the weak and ineffective muscle relaxant mephenesin. With average doses (400 mg three or four times a day), the patient is able to function quite effectively; larger doses cause ataxia, drowsiness, stupor, coma, and vasomotor collapse.

Meprobamate has turned out to have the same disadvantages as the barbiturates, including death from overdosage. Addiction to meprobamate may occur, and if four or more times the daily recommended dose is taken over a period of weeks to months, withdrawal symptoms (including convulsions) may appear. Because of this tendency to produce physical dependence and other disadvantages (serious toxic reactions and a high degree of sedation), meprobamate and its congeners are now seldom used except illicitly.

Buspirone A new class of antianxiety agents, exemplified by the selective 5-HT₂ serotonergic agent buspirone (BuSpar), is chemically and pharmacologically different from the benzodiazepines, barbiturates, or other sedatives. Its distinctive nature is confirmed by the observation that it does not block the withdrawal syndrome of other sedative-hypnotic drugs. Because of its apparently reduced potential for abuse and tolerance, it is not included in the list of controlled pharmaceutical substances in the United States, but adverse interactions with MAO inhibitors are known. Its use with other psychotropic drugs is still under investigation.

ANTIPSYCHOSIS DRUGS

In the mid-1950s, a large series of pharmacologic agents, originally referred to as tranquilizers (later, as psychotropic or neuroleptic drugs), came into prominent use—mainly for the control of schizophrenia, psychotic states associated with “organic brain syndromes,” and affective disorders (depression and manic-depressive disease). The mechanisms by which these drugs ameliorate disturbances of thought and affect in psychotic states are not fully understood, but presumably they act by blocking the postsynaptic mesolimbic dopamine receptors of which there are four subtypes, termed D₁ through D₄ on neuronal membranes (see Table 4-2 and discussion of dopamine receptor subtypes on page 60). The D₂ receptors are located mainly in the frontal cortex, hippocampus, and limbic cortex, and the D₁ receptors, in the striatum as discussed in Chap. 4. The blockade of dopamine receptors in the striatum is probably responsible for the parkinsonian side effects of this entire class of drugs, and the blockade of another dopaminergic (tuberoinfundibular) system, for the increased prolactin secretion by the pituitary. These drugs also produce some adrenergic blocking effect. The newer “atypical” antipsychotic drugs, typified by clozapine (Clozaril), apparently achieve the same degree of D₂ and D₃ blockade in the temporal and limbic lobes while exhibiting substantially less antagonistic activity in the striatum—accounting also for their lesser parkinsonian side effects. These drugs also block subsets of serotonin receptors.

Since the introduction in the 1950s of the phenothiazine chlorpromazine as an anesthetic agent and the serendipitous discovery of its antipsychotic effect on schizophrenia, a large number of antipsychotic drugs have been marketed for clinical use. No attempt is made here to describe or even list all of them. Some have had only an evanescent popularity, and others have yet to prove their

value. Chemically, these compounds form a heterogeneous group. Eight classes of them are of particular clinical importance: (1) the phenothiazines; (2) the thioxanthines; (3) the butyrophenones; (4) the rauwolfa alkaloids; (5) an indole derivative, loxapine (Loxitane), and a unique dihydroindalone, molindone (Molan); (6) a diphenylbutylpiperidine, pimozide (Orap); (7) dibenzodiazepines, typified by clozapine (Clozaril) and olanzapine (Zyprexa); and (8) a benzisoxazole derivative, risperidone (Risperdal). The last four of these drugs were introduced more recently than the others and hence have had a more limited trial. Molindone and loxapine are about as effective as the phenothiazines in the management of schizophrenia, and their side effects are similar although claims have been made that they are less likely to induce tardive dyskinésias and seizures. Their main use is in patients who are not responsive to the older drugs or who suffer intolerable side effects from them. The antipsychotic agents in the class of clozapine have attracted great interest, since—as already mentioned—they are associated with relatively fewer extrapyramidal side effects. For this reason, they are particularly favored in controlling the confusion and psychosis of parkinsonian patients. The other new class of drugs, of which risperidone is the main example, also has fewer extrapyramidal side effects than the phenothiazines and a more rapid onset of action than the traditional antipsychotic medications. Pimozide may be useful in the treatment of haloperidol-refractory cases of Gilles de la Tourette syndrome (page 95); its main danger is its tendency to produce cardiac arrhythmias.

Phenothiazines

This group comprises some of the most widely used tranquilizers, such as the phenothiazines chlorpromazine (Thorazine), promazine (Sparine), trifluopromazine (Vesprin), prochlorperazine (Compa-zine), perphenazine (Trilafon), fluphenazine (Permitil, Prolixin), thioridazine (Mellaril), mesoridazine (Serentil), and trifluoperazine (Stelazine). In addition to their psychotherapeutic effects, these drugs have a number of other actions, so that certain members of this group are used as antiemetics (prochlorperazine) and antihistamines (promethazine).

The phenothiazines have had their widest application in the treatment of the major psychoses, namely schizophrenia and, to a lesser extent, manic-depressive psychosis. Under the influence of these drugs, many patients who would otherwise be hospitalized are able to live at home and even work productively. In the hospital, the use of these drugs has greatly facilitated the care of hyperactive and combative patients (see Chaps. 57 and 58 for details of this clinical use).

Side effects of the phenothiazines are frequent and often serious. All of them may cause a cholestatic type of jaundice, agranulocytosis, convulsive seizures, orthostatic hypotension, skin sensitivity reactions, mental depression, and, most importantly, immediate or delayed extrapyramidal motor disorders. The neuroleptic malignant syndrome is the most extreme complication and is discussed separately further on. The following types of extrapyramidal symptoms, also discussed on page 94, have been noted in association with all of the phenothiazines as well as the butyrophenones and, to a lesser extent, metoclopramide (Reglan) and pimozide, which block dopaminergic receptors:

1. A *parkinsonian syndrome* is the most common complication—masked facies, slight symmetric tremor, reduced blinking, generalized rigidity, shuffling gait, and slowness of

movement. These symptoms may appear after several days of drug therapy but more often after several weeks. Suppression of dopamine in the striatum (similar to the effect of loss of dopaminergic nigral cells that project to the striatum) is presumably the basis of the parkinsonian signs.

2. *Acute dyskinetic and dystonic reactions*, taking the form of involuntary movements of lower facial muscles (mainly around the mouth) and protrusion of the tongue (buccolingual or oral-masticatory syndrome), dysphagia, torticollis and retrocollis, oculogyric crises, and tonic spasms of a limb. These complications usually occur early in the course of administration of the drug, sometimes after the initial dose, in which case they recede dramatically upon immediate discontinuation of the drug and the intravenous administration of diphenhydramine hydrochloride (Benadryl) or benztrapine (Cogentin).
3. *Akathisia*—an inner restlessness reflected by a persistent shifting of the body and feet and an inability to sit still, such that the patient paces the floor or jiggles the legs constantly (see page 97). Of all the phenothiazines, molindone has a special tendency to cause akathisia. This disorder often responds to oral propranolol.
4. *Tardive dyskinetias*—A group of *late and persistent complications* of neuroleptic therapy, which may continue after removal of the offending drug, comprises lingual-facial-buccal-cervical dyskinetias, choreoathetotic and dystonic movements of the trunk and limbs, diffuse myoclonus (rare), perioral tremor (“rabbit” syndrome), and dysarthria or anarthria. Snyder has postulated that the movements are due to hypersensitivity of dopamine receptors in the basal ganglia, secondary to prolonged blockade of the receptors by antipsychotic medication. Baldessarini estimates that as many as 40 percent of patients receiving long-term antipsychotic medication develop tardive dyskinetia of some degree. A pathology has never been ascertained and the effect is likely due to subcellular pathophysiologic alterations in the basal ganglia. Treatment is discussed later.
5. The *neuroleptic malignant syndrome* is discussed separately later because of its gravity and requirement for specific treatment.

Butyrophenones

Haloperidol (Haldol) is the only member of this group approved for use as an antipsychotic in the United States. It has much the same therapeutic effects as the phenothiazines in the management of acute psychoses and shares the same side effects as the phenothiazines, but exhibits little or no adrenergic blocking action. It is an effective substitute for the phenothiazines in patients who are intolerant of the latter drugs, particularly of their autonomic effects. It is also one of the main drugs for the treatment of Gilles de la Tourette syndrome (the other being pimozide; see page 95) and the movement disorder of Huntington chorea.

Treatment of Neuroleptic Side Effects

As indicated earlier, acute dystonic spasms usually respond to diphenhydramine (Benadryl). Administration of antiparkinsonian drugs of the anticholinergic type (trihexyphenidyl, procyclidine, and benztrapine) may hasten recovery from some of the acute symptoms. The purely parkinsonian syndrome usually improves as

well, but the tardive dyskinetias stand apart because they may persist for months or years and may be permanent.

Oral, lingual, and laryngeal dyskinetias of the tardive type are affected relatively little by any antiparkinsonian drugs. Amantadine (Symmetrel) in doses of 50 to 100 mg tid has been useful in a few of the cases of postphenothiazine dyskinetia. Other drugs such as benztropine have been tried in the treatment of regional and more generalized tardive dyskinetia, with uncertain results. Nevertheless, there is a tendency for most of the obstinate forms to subside slowly even after several years of unsuccessful therapy. Once a tardive syndrome has been identified, several authoritative clinicians recommend a gradual reduction in the dose of the antipsychosis medication to the minimum necessary for the control of psychotic symptoms. Some reports favor the substitution of one of the newer “atypical” antipsychotic medications but no systematic study of their effectiveness has been undertaken.

For severe and recalcitrant cases, particularly those involving axial dystonias and similar disabling features, Fahn recommends administration of the dopamine depleting drug tetrabenazine (similar but faster in action and less toxic than reserpine). This medication is given in doses of 75 to 300 mg per day. Jankovic and Beach report an 83 percent success rate using this approach for tardive dyskinetias. The medication is not easily available in the United States but can be obtained from Canada at this time. The use of low doses of antipsychotic drugs and frequent drug holidays, especially in the more susceptible older patients, may help to prevent the development of tardive dyskinetia.

Neuroleptic Malignant Syndrome

This is the most dreaded complication of phenothiazine and haloperidol use; rare instances have been reported after the institution or the withdrawal of L-dopa and similar dopaminergic agents. Its incidence has been calculated to be only 0.2 percent of all patients receiving neuroleptics (Caroff and Mann), but its seriousness is underscored by a mortality rate of 15 to 30 percent if not recognized and treated promptly. It may occur days, weeks, or months after neuroleptic treatment is begun. The syndrome consists of rigidity, stupor, unstable blood pressure, variable hyperthermia, diaphoresis and other signs of autonomic dysfunction, high serum creatine kinase (CK) values (up to 60,000 units), and, in some cases, renal failure due to myoglobinuria. The syndrome was first observed in patients treated with haloperidol, and since then other neuroleptic drugs have been incriminated, particularly the highly potent thioxanthine derivatives and the phenothiazines—chlorpromazine, fluphenazine, and thioridazine—but also, on rare occasions, the less potent drugs that are used to control nausea, such as promethazine. It has become evident that the newer antipsychotic drugs, and specifically olanzapine, are also capable of inducing the syndrome but the risk in comparison to the first generation of antipsychotic drugs has not been established.

If treatment of the neuroleptic malignant syndrome is started early, when consciousness is first altered and the temperature is rising, bromocriptine in oral doses of 5 mg tid (up to 20 mg tid) will terminate the condition in a few hours. If oral medication can no longer be taken because of the patient’s condition, dantrolene, 0.25 to 3.0 mg intravenously, may be lifesaving. Once coma has supervened, shock and anuria may prove fatal or leave the patient in a vegetative state. The rigors during high fever may cause muscle damage and myoglobinuria, and the circulatory collapse may lead to hypoxic-ischemic brain injury.

Meningitis, heat stroke, lithium intoxication, catatonia, and acute dystonic reactions figure in the differential diagnosis. Of course, neuroleptic medication must be discontinued as soon as any of the severe extrapyramidal reactions are recognized. It has been common practice to avoid future administration of the offending neuroleptic, but the risk of using another class of antipsychotic agents has not been fully addressed.

The neuroleptic malignant syndrome bears an uncertain relationship to *malignant hyperthermia* by way of its clinical aspects but also in its response to bromocriptine and dantrolene (see later). Malignant hyperthermia is an inherited disorder that, in susceptible individuals, is triggered by inhalation anesthetics and skeletal muscle relaxants (page 1272). This disorder was described before the introduction of neuroleptic drugs and in a small proportion of cases has been related to a mutation of the ryanodine receptor gene on chromosome 19q. A genetic factor is also suspected to underlie the neuroleptic malignant syndrome (a polymorphism in the D₂ receptor gene; see Suzuki et al), possibly provoked by fatigue and dehydration. There is no evidence that the occurrence of one of these syndromes confers a susceptibility to the other.

It hardly needs to be pointed out that the antipsychotic drugs have been much overused. This would be suspected just from the frequency with which they are being prescribed. These medications have specific indications, noted earlier and in Chaps. 56, 57, and 58, and the physician should be certain of the diagnosis and the indication for their use. That the neuroleptic drugs can produce tardive dyskinesia in nonpsychotic patients is reason enough not to prescribe them for nervousness, apprehension, anxiety, mild depression, insomnia, and the many normal psychologic reactions to trying environmental circumstances. These drugs are not curative but only suppress or partially alleviate symptoms, and they should not serve as a substitute for, or divert the physician from, the use of other measures for the relief of abnormal mental states.

ANTIDEPRESSION MEDICATIONS

Four classes of drugs—the monoamine oxidase (MAO) inhibitors, the tricyclic compounds, the serotoninergic drugs, and lithium—are particularly useful in the treatment of depressive illnesses. The adjective *antidepressant* refers to their therapeutic effect and is employed here in deference to common clinical practice. *Antidepressive* or *antidepression* drugs would be preferable, since the term *depressant* still has a pharmacologic connotation that does not necessarily equate with the therapeutic effect. For example, barbiturates and chloral hydrate are depressants in the pharmacologic sense and mood elevators or antidepressants in the clinical sense.

Monoamine Oxidase Inhibitors

The observation that iproniazid, an inhibitor of MAO, had a mood-elevating effect in tuberculous patients initiated a great deal of interest in compounds of this type and led quickly to their exploitation in the treatment of depression. Iproniazid proved exceedingly toxic to the liver and was soon taken off the market, as were several subsequently developed MAO inhibitors; but other drugs in this class, much better tolerated, are still available. These include isocarboxazid (Marplan), phenelzine (Nardil), and tranylcypromine (Parnate), the latter two being the more frequently used. Tranylcypromine, which bears a close chemical resemblance to dextroamphetamine, may produce unwanted stimulation, but the most common adverse effect of all the MAO inhibitors is postural hy-

potension. Also, interactions with a wide array of other drugs and ingested substances may induce severe hypertension.

Monoamine oxidase is located on the outer surface of the mitochondria in neurons and is utilized in the catabolism of catecholamines (Coyle). In the gut and liver, this enzyme normally serves to deaminate phenethylamine, tyramine, and tryptamine—the products of protein catabolism. Inhibition of MAO allows these dietary amines, which have an amphetamine-like action, to enter the systemic circulation in increased quantities, thus releasing norepinephrine from sympathetic nerve endings and increasing heart rate and blood pressure. Probably more relevant to their action as antidepressants, the MAO inhibitors also have in common the ability to block the intraneuronal oxidative deamination of naturally occurring amines (norepinephrine, epinephrine, and serotonin), and it has been suggested that the accumulation of these substances is responsible for the antidepressant effect. However, many enzymes other than monoamine oxidase are inhibited by MAO inhibitors, and the latter drugs have numerous actions unrelated to enzyme inhibition. Furthermore, many agents with antidepressant effects like those of the MAO inhibitors do not inhibit MAO. Therefore, one cannot assume that the therapeutic effect of these drugs has a direct relation to MAO inhibition in the brain.

The MAO inhibitors must be dispensed with great caution and constant awareness of their potentially serious side effects. They may at times cause excitement, restlessness, agitation, insomnia, and anxiety, occasionally with the usual dose but more often with an overdose. Mania and convulsions may occur (especially in epileptic patients). Other side effects are muscle twitching and involuntary movements, urinary retention, skin rashes, tachycardia, jaundice, visual impairment, enhancement of glaucoma, impotence, sweating, muscle spasms, paresthesias, and a serious degree of orthostatic hypotension.

Patients taking MAO inhibitors must be warned against the use of phenothiazines, CNS stimulants, tricyclic and serotoninergic antidepressants (see later), and also sympathomimetic amines and tyramine. The combination of an MAO inhibitor and any of these drugs or amines may induce severe hypertension, atrial and ventricular arrhythmia, pulmonary edema, stroke, and even death. Sympathomimetic amines are contained in some commonly used cold remedies, nasal sprays, nose drops, and certain foods—aged cheese, beer, red wine, pickled herring, sardines, sausages, and preserved meat or fish. Exaggerated responses to the usual dose of meperidine (Demerol) and other narcotic drugs have also been observed sporadically; in these cases, respiratory function may be depressed to a serious degree, and hyperpyrexia, agitation, and pronounced hypotension may occur as well, sometimes with fatal issue. Unpredictable side effects may also accompany the simultaneous administration of barbiturates and MAO inhibitors. The abrupt occurrence of severe occipital headache, nausea, vomiting, pupillary dilation, or visual blurring should suggest a hypertensive crisis. Treatment is with intravenous phentolamine 5 mg, nitroprusside, labetalol, or a calcium channel blocker administered slowly to prevent hypotension. Overdosage may lead to coma, for which there is no treatment other than supportive care.

The therapeutic use of MAO inhibitors is discussed in Chaps. 56 and 57.

Tricyclic Antidepressants

Soon after the first successes with MAO inhibitors, a new class of tricyclic compounds appeared. The first was imipramine (Tofranil),

soon followed by amitriptyline (Elavil) and then by desipramine (Norpramin) and nortriptyline (Pamelor). Another important dibenzazepine derivative is carbamazepine (Tegretol), which is widely used in the control of seizures but has also found a place in the treatment of lancinating neuropathic and myelopathic pain and possibly of depression and mood instability. Subsequently, a number of additional antidepressant drugs were introduced. Included here are variants of the conventional tricyclic drugs (amoxapine, protriptyline, trimipramine, doxepin), tetracyclines (maprotiline), bicyclines (zimeldine), and others (trazodone, bupropion). A full account of these drugs, which will not be attempted here, can be found in the monographs of Hollister and of Pirodsky and Cohn.

The mode of action of these agents is not fully understood, but there is evidence that they block the reuptake of amine neurotransmitters, both norepinephrine and serotonin. Blocking this amine pump mechanism (called the presynaptic plasma transporter), which ordinarily terminates synaptic transmission, permits the persistence of neurotransmitter substances in the synaptic cleft and does no more than support the hypothesis that endogenous depression is associated with a deficiency of noradrenergic or serotonergic transmission.

The tricyclic antidepressants and the serotonergic drugs discussed in the next section, are presently the most effective drugs for the treatment of patients with depressive illnesses, the former being particularly useful for those with anergic depressions associated with hypersomnia, early morning awakening, and decreased appetite and libido. The side effects of the tricyclic drugs are less frequent and far less serious than those of the MAO inhibitors.

The tricyclic (dibenzazepine) compounds are potent anticholinergic agents, which accounts for their most prominent and serious side effects—orthostatic hypotension and urinary bladder weakness. They may also occasionally produce CNS excitation—leading to insomnia, agitation, and restlessness—but usually these effects are readily controlled by small doses of benzodiazepines given concurrently or in the evenings. Rarely, they may cause ataxia and blood dyscrasias. As indicated earlier, the tricyclic drugs should not be given with an MAO inhibitor; serious reactions have occurred when small doses of imipramine were given to patients who had discontinued the MAO in the previous days or week. It must be repeated that both the MAO inhibitors and the tricyclic antidepressants are dangerous drugs when taken in excess.

Tricyclic compounds are a frequent cause of accidental poisoning and a favored suicidal instrument of depressed patients. It is common for the intoxicated patient to have taken several drugs, in which case chemical analyses of the blood and urine are particularly helpful in determining the drugs involved and in sorting out therapeutic and toxic concentrations. Mortality from overdose is mostly due to cardiac disturbances, particularly tachyarrhythmias and impaired conduction (atrioventricular block). Treatment consists of gastric aspiration and instillation of activated charcoal and the addition of physostigmine to reverse serious arrhythmias; the short duration of action of physostigmine requires that frequent doses be given. Dialysis is of no value because of the low plasma concentrations of the drug.

Serotonin Reuptake Inhibitors and Related Drugs

The selective serotonin reuptake inhibitors (SSRIs) constitute a newer class of antidepressants; paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft) are the ones most often used, but others

are being developed at a rapid pace. They act presumably by inhibiting the reuptake of serotonin and to a lesser extent of norepinephrine, somewhat like the effect of a tricyclic antidepressant. This results in a potentiation of the actions of these neurotransmitters. Because they do not bind as avidly as tricyclic drugs to the muscarinic and adrenergic receptors in the brain, they produce fewer side effects, but some patients complain of anxiety or insomnia when they are first introduced. *As with the tricyclic agents, the concomitant administration of MAO inhibitors is hazardous.* There should be a period of at least 1 week between the administration of these two classes of drugs to allow for the washout of the last agent used. Of the several related drugs such as venlafaxine (Effexor), nefazodone (Serzone), citalopram (Celexa), and bupropion (Wellbutrin), each has a novel structure that is not analogous to that of the other categories of antidepressants. They are believed to act similarly to the SSRI class by inhibiting the reuptake of serotonin and norepinephrine. These newer drugs share most of the side effects of the SSRI drugs, including the danger of concomitant MAO inhibitor administration.

The symptoms of a “serotonin syndrome” that results from excessive intake or from the concurrent use of MAO inhibitors include confusion, restlessness, myoclonus, shivering, and diaphoresis, as summarized by Sternbach.

The risk of seizures related to the taking of certain of these medications has been much discussed. For the most part, the risk is quite small but there is little information to guide their use in known epileptics. Several studies suggest that the frequency of convulsions may increase in such patients. Bupropion has been particularly associated with seizures in about 0.5 percent of patients treated at higher dose levels (over 400 mg per day) and this drug should not be used in individuals with a history of seizures.

The SSRI drugs are well tolerated, may be effective in a shorter time than the tricyclic agents, and are very popular at the moment, but their long-term therapeutic usefulness in comparison with their predecessors remains to be determined (see review of Richelson). Fluoxetine has also been used with benefit in a group of autistic children (page 890). Constipation, dry mouth, and reduced sexual potency are to be expected to some, but varying degrees. Hyponatremia is a rare complication.

Lithium

The discovery of the therapeutic effects of lithium salts in mania has led to its widespread use in the treatment of manic-depressive disease (bipolar disorder). The drug has proved relatively safe, and blood levels are easily monitored. Its value is much more certain in treatment of the manic phase of bipolar disorder and prevention of recurrences of cyclic mood shifts than it is in treatment of anxiety and depression. Guidelines for the clinical use of lithium are given in Chap. 57. Its mechanism of action is unclear, but there is experimental evidence that lithium blocks the stimulus-induced release of norepinephrine and enhances the reuptake of this amine—the opposite, in a sense, of what occurs with the other classes of antidepressants.

With blood levels of lithium in the upper therapeutic range, it is not uncommon to observe a fast-frequency action tremor or asterixis, together with nausea, loose stools, fatigue, polydipsia, and polyuria. These symptoms usually subside with time. Above a level of 1.5 to 2 meq/L, particularly in patients with impaired renal function or in those taking a thiazide diuretic, serious intoxication becomes manifest—clouding of consciousness, confusion, delirium,

dizziness, nystagmus, ataxia, stammering, diffuse myoclonic twitching, and nephrogenic diabetes insipidus. Vertical (down-beating) nystagmus and opsoclonus may also be prominent. This clinical state, particularly confusion and myoclonus associated with sharp waves in the EEG, may mimic Creutzfeldt-Jakob disease (page 653), but there should be no problem in diagnosis if the setting of the illness and the administration of lithium are known. At a blood lithium concentration of 3.5 meq/L, these symptoms are replaced by stupor and coma, sometimes with convulsions, and may prove fatal.

Discontinuing lithium in the intoxicated patient, which is the initial step in therapy, does not result in immediate disappearance of toxic symptoms. This may be delayed by a week or two, and the diabetes insipidus may persist even longer. Fluids, sodium chloride, aminophylline, and acetazolamide promote the excretion of lithium. Lithium coma may require hemodialysis, which has proved to be the most rapid means of reducing the blood lithium concentration.

STIMULANTS

Drugs that act primarily as CNS stimulants have a relatively limited therapeutic use but assume clinical importance for other reasons. Some members of this group, e.g., the amphetamines, are much abused, and others are not infrequent causes of poisoning.

Amphetamines (Benzedrine, Adderall) These drugs and dextroamphetamine, its D-isomer, are powerful analeptics (CNS stimulants) and in addition have significant hypertensive, respiratory-stimulant, and appetite-depressant effects. They are effective in the management of narcolepsy but have been much more widely and sometimes indiscriminately used for the control of obesity, the abolition of fatigue, and the treatment of hyperactivity in children. Undoubtedly, they are able to reverse fatigue, postpone the need for sleep, and elevate mood, but these effects are not entirely predictable, and the user must pay for the period of wakefulness with even greater fatigue and often with depression that may follow. The intravenous use of a high dose of amphetamine produces an immediate feeling of ecstasy, the “flash.”

Because of the popularity of the amphetamines and the ease with which they can be procured, instances of acute and chronic intoxication are observed frequently. The toxic signs are essentially an exaggeration of the analeptic effects—restlessness, excessive speech and motor activity, tremor, and insomnia. Severe intoxication may give rise to hallucinations, delusions, and changes in affect and thought processes—a state that may be indistinguishable from paranoid schizophrenia. An amphetamine associated vasculitis and intracerebral and subarachnoid hemorrhage are well-recognized but rare complications of chronic intoxication (Harrington et al), and they may occur after acute use as well. Similar cerebrovascular complications may appear with sympathomimetic agents contained in over-the-counter cold medications and in dieting aids. Phenylpropanolamine has been implicated most often, but ephedrine and similar agents rarely have the same effects and induce a vasculopathy. The pathogenesis of the vascular lesion is unknown (both vasospasm and arteritis have been reported), and the same state occurs with cocaine, as described below.

Chronic use of amphetamines can lead to a high degree of tolerance and psychologic dependence. Withdrawal of the drug after sustained oral or intravenous use is regularly followed by a period of prolonged sleep (a disproportionate amount of which is REM sleep), from which the patient awakens with a ravenous appetite, muscle pains, and feelings of profound fatigue and depre-

sion. Treatment consists of discontinuing the use of amphetamine and administering antipsychotic drugs. Nitrites may be useful if the blood pressure is markedly elevated.

Methylphenidate (Ritalin) This drug has much the same type of action as dextroamphetamine and is effective in the treatment of narcolepsy. Paradoxically, like amphetamine, it is useful in the management of attention-deficit hyperactivity disorder in children, and its chronic usage in moderate doses results in no deleterious effects (see page 511).

HALLUCINOGENS

Included in this category is a heterogeneous group of drugs, the primary effect of which is to alter perception, mood, and thinking out of proportion to other aspects of cognitive function and consciousness. This group of drugs comprises *cocaine*, *lysergic acid derivatives* [e.g., *lysergic acid diethylamide (LSD)*], *phenylethylamine derivatives* (*mescaline* or *peyote*), *psilocybin*, *certain indolic derivatives*, *cannabis* (*marijuana*), *phencyclidine (PCP)*, and a number of less important compounds. They are also referred to as psychoactive or psychotomimetic drugs or as hallucinogens and psychedelics—but none of these names is entirely suitable. The problems raised by the nontherapeutic use of these drugs, which has declined somewhat but is still of serious proportions, have been reviewed by Nicholi and by Verebey and their associates.

Cocaine

The conventional use of cocaine as a local anesthetic has for many years been overshadowed by its illicit and widespread use as a stimulant and mood elevator. Originally, cocaine was sold as a white, lactose-adulterated powder that was administered intranasally (“snorted”); less often, it was smoked or injected intravenously or intramuscularly. Since 1985 there has been an alarming escalation in the use of cocaine, mainly because a relatively pure and inexpensive form of the free alkaloid base (“crack”) became readily available at that time. This form of cocaine is heat-stable and therefore suitable for smoking. According to the National Household Survey on Drug Abuse, there are an estimated 600,000 frequent cocaine users in the United States. (Frequent use was arbitrarily defined as use on 51 or more days during the preceding year.) The number of occasional users (less than 12 days in the preceding year) was 2.4 million. These figures are probably subject to significant underreporting.

A sense of well-being, euphoria, loquacity, and restlessness are the familiar effects. Pharmacologically, cocaine is thought to act like the tricyclic antidepressants; i.e., it blocks the presynaptic reuptake of biogenic amines, thus producing vasoconstriction, hypertension, and tachycardia and predisposing to generalized tremor, myoclonus, seizures, and psychotic behavior. These actions as well as its immediate mood-elevating and euphoric effects are much the same as those of dextroamphetamine (see earlier). The cocaine abuser readily develops psychologic dependence and habituation, i.e., an inability to abstain from frequent compulsive use (“craving”). The manifestations of physical dependence are more subtle and difficult to recognize. Nevertheless, abstinence from cocaine following a period of chronic abuse is regularly attended by insomnia, restlessness, anorexia, depression, hyperprolactinemia, and signs of dopaminergic hypersensitivity—a symptom complex that constitutes an identifiable withdrawal syndrome.

With the increasingly widespread use of cocaine, a variety of

new complications continues to emerge. The symptoms of severe intoxication (overdose), noted above, may lead to coma and death and require emergency treatment in an intensive care unit, along the lines indicated for the management of other forms of coma. Seizures often occur in this setting and are treated more effectively with benzodiazepines than with standard anticonvulsant drugs. Spontaneous subarachnoid or intracerebral hemorrhage and cerebral infarction have rarely followed the intranasal use and smoking of cocaine (Levine et al). These complications are presumably the result of vasospasm induced by the sympathomimetic actions of cocaine. Cocaine and amphetamines also, on occasion, produce a state of generalized vasospasm leading to multiple cortical infarctions and posterior white matter changes that are evident on imaging studies, not unlike those seen with hypertensive encephalopathy (page 728). Several cases of a pathologically verified vasculitis and instances of “beading” of cerebral vessels on the arteriogram have also been noted. We have seen several instances of vasospasm but have no experience with the vasculitis; however, it would seem that these two different types of vasculopathy can result from cocaine and amphetamine use (page 733). Roth and colleagues have described 39 patients who developed acute rhabdomyolysis after cocaine use; 13 of these had acute renal failure, severe liver dysfunction, and disseminated intravascular coagulation and 6 of them died. Some reports indicate that cocaine use during pregnancy may cause fetal damage, abortion, or persistent signs of toxicity in the newborn infant.

Anxiety, paranoia, and other manifestations of psychosis may develop within several hours of cocaine use. These complications are best treated with haloperidol.

Marijuana

During the past three decades the prevalence of marijuana use in the United States has declined by about half, but it is still the most commonly used illicit drug in the United States. The effects, when taken by inhaling the smoke from cigarettes or pipe, are prompt in onset and evanescent. With low doses, the symptoms are like those of mild alcohol intoxication (drowsiness, euphoria, dulling of the senses, and perceptual distortions). With increasing amounts, the effects are similar to those of LSD, mescaline, and psilocybin (see later); they may be quite disabling for many hours. With even larger doses, severe depression and stupor may occur, but death is rare (for a full account, see Hollister, 1988). No damage to the nervous system has been found after chronic use.

Reverse tolerance to marijuana (i.e., increasing sensitization) may be observed initially, but on continued use, tolerance to the euphoriant effects develops. In one of the few experimental studies of chronic marijuana use, the subjects reported feeling “jittery” during the first 24 h after abrupt cessation of smoking marijuana, although no objective withdrawal signs could be detected.

The mild antiemetic and antinauseant effects of marijuana coupled with euphoria have led to its use as an agent to ameliorate the effects of cancer chemotherapies, and this purported therapeutic effect is the mainstay of the movement for its legalization.

Mescaline, LSD, and Psilocybin

These drugs produce much the same clinical effects if given in comparable amounts. The perceptual changes are the most dramatic: the user describes vivid visual hallucinations, alterations in the shape and color of objects, unusual dreams, and feelings of depersonalization. An increase in auditory acuity has been de-

scribed, but auditory hallucinations are rare. Cognitive functions are difficult to assess because of inattention, drowsiness, and inability to cooperate in mental testing. The somatic symptoms consist of dizziness, nausea, paresthesias, and blurring of vision. Sympathomimetic effects—pupillary dilation, piloerection, hyperthermia, and tachycardia—are prominent, and the user may also show hyperreflexia, incoordination of the limbs, and ataxia.

Tolerance to LSD, mescaline, and psilocybin develops rapidly, even on a once-daily dosage. Furthermore, subjects tolerant to any one of these three drugs are cross-tolerant to the other two. Tolerance is lost rapidly when the drugs are discontinued abruptly, but no characteristic signs of physical dependence (abstinence syndrome) ensue. In this sense, addiction does not develop, although users may become dependent upon the drugs for emotional support (psychologic dependence or habituation).

Although LSD has no therapeutic value and the use of marijuana is governed by the federal narcotic laws, these drugs are taken by narcotic addicts as a substitute for more potent drugs, by “drug-heads” (i.e., individuals who use any agent that alters consciousness), and by many troubled, unhappy college and high school students for social conformity or for reasons that even they cannot ascertain. Their use is attended by a number of serious adverse reactions taking the form of acute panic attacks, long-lasting psychotic states resembling paranoid schizophrenia, and flashbacks (spontaneous recurrences of the original LSD experience, sometimes precipitated by smoking marijuana and accompanied by panic attacks). Serious physical injury may follow upon impairment of the user’s critical faculties. Whether prolonged usage leads to permanent damage to the nervous system is uncertain; there are some data to suggest that this may happen, but there is little doubt that the mental state of some psychologically predisposed individuals is permanently altered. The reports claiming that LSD may cause chromosomal damage remain to be validated. Numerous claims have been made that LSD and related drugs are effective in the treatment of mental disease and a wide variety of social ills and that they have the capacity to increase one’s intellectual performance, creativity, and self-understanding. To date there have been no acceptable studies that validate any of these claims.

Phencyclidine (“Angel Dust”) and “Ecstasy”

During the early 1970s, the abuse of PCP and its analogues was a significant problem. The popularity of these drugs has dropped sharply, but some illicit use continues because they are relatively cheap, easily available, and quite potent. (Their manufacture as a veterinary anesthetic was stopped in 1979.) Phencyclidine is taken illicitly in the form of a granular powder, frequently mixed with other drugs, and is smoked or snorted. It is usually classified as a hallucinogen, although it also has stimulant and depressant properties. The effects of intoxication are like those of LSD and other hallucinogens and resemble those of an acute schizophrenic episode, which may last several days to a week or more. After the ingestion of a large amount (10 mg or more) of phencyclidine, it is present in the blood and urine for only a few hours.

Toxicity from the illicit use of “ecstasy” (NMDA) during all-night dance parties (“raves”) has increased as a result of its ill-founded reputation for safety. It appears to cause a release of both serotonin and dopamine in the brain and produces an elated state similar to the effects of cocaine. Seizures, cerebral hemorrhages, and psychosis have been reported in previously healthy individuals (Verebey et al).

A discussion of the legal implications of the illicit use of the aforementioned drugs and their social impact is beyond the scope of this chapter but can be found in the appended references.

DISORDERS DUE TO BACTERIAL TOXINS

The most important diseases in this category are *tetanus*, *botulism*, and *diphtheria*. Each is caused by an extraordinarily powerful bacterial toxin that acts primarily on the nervous system.

Tetanus

The cause of this disease is the anaerobic, spore-forming rod *Clostridium tetani*. The organisms are found in the feces of some humans and many animals, particularly horses, from which they readily contaminate the soil. The spores may remain dormant for many months or years, but when they are introduced into a wound, especially if a foreign body or suppurative bacteria are present, they are converted into their vegetative forms, which produce the exotoxin tetanospasmin. In developing countries, tetanus is still a common disease, particularly in newborns, in whom the spores are introduced via the umbilical cord (*tetanus neonatorum*). In the United States, the incidence rate of tetanus is about one per million per year. Injection of contaminated heroin is a significant cause. About two-thirds of all injuries leading to tetanus occur from deep scratches and puncture wounds in the home and about 20 percent in gardens and on farms.

Since 1903, when Morax and Marie proposed their theory of centripetal migration of the tetanus toxin, it has been taught that spread to the nervous system occurs via the peripheral nerves, the toxin ascending in the axis cylinders or the perineurial sheaths. Modern studies, utilizing fluorescein-labeled tetanus antitoxin, have disclosed that the toxin is also widely disseminated via blood or lymphatics, probably accounting for the generalized form of the disease. However, in local tetanus, the likely mode of spread to the CNS is indeed by retrograde axonal transport.

Mode of Action of Tetanus Toxin Like botulinum toxin, the tetanus toxin is a zinc-dependent protease. It blocks neurotransmitter release by cleaving surface proteins of the synaptic vesicles, thus preventing the normal exocytosis of neurotransmitter. The toxin interferes with the function of the reflex arc by the blockade of inhibitory transmitters, mainly GABA, at presynaptic sites in the spinal cord and brainstem. Elicitation of the jaw jerk, for example, is normally followed by the abrupt suppression of motor neuron activity, manifested in the electromyogram (EMG) as a “silent period” (see further on). In the patient with tetanus, there is a failure of this inhibitory mechanism, with a resulting increase in activation of the neurons that innervate the masseter muscles (*trismus* or lockjaw). Of all neuromuscular systems, the masseter innervation seems to be the most sensitive to the toxin. Not only do afferent stimuli produce an exaggerated effect, but they also abolish reciprocal innervation; both agonists and antagonists contract, giving rise to the characteristic muscular spasm as discussed on page 40. In addition to its generalized effects on the motor neurons of the spinal cord and brainstem, there is evidence that the toxin acts directly on skeletal muscle at the point where the axon forms the end plate (accounting perhaps for localized tetanus) and also upon the cerebral cortex and the sympathetic nervous system, in the hypothalamus.

The incubation period varies greatly, from a day or two to a month or even longer. Long incubation periods are associated with mild and localized types of the disease.

Clinical Features There are several clinical types of tetanus, usually designated as local, cephalic, and generalized.

Generalized Tetanus This is the most common form. It may begin as local tetanus that becomes generalized after a few days, or it may be diffuse from the beginning. Trismus is frequently the first manifestation. In some cases this is preceded by a feeling of stiffness in the jaw or neck, slight fever, and other general symptoms of infection. The localized muscle stiffness and spasms spread quickly to other bulbar muscles as well as those of the neck, trunk, and limbs. A state of unremitting rigidity develops in all the involved muscles: the abdomen is board-like, the legs are rigidly extended, and the lips are pursed or retracted (*risus sardonicus*); the eyes are partially closed by contraction of the orbicularis oculi, or the eyebrows are elevated by spasm of the frontalis. Superimposed on this persistent state of enhanced muscle activity are paroxysms of tonic contraction or spasm of muscles (tetanic seizures or convulsions), which occur spontaneously or in response to the slightest external stimulus. They are agonizingly painful. Consciousness is not lost during these paroxysms. The tonic contraction of groups of muscles results in opisthotonus or in forward flexion of the trunk, flexion and adduction of the arms, clenching of the fists, and extension of the legs. Spasms of the pharyngeal, laryngeal, or respiratory muscles carry the constant threat of apnea or suffocation. Fever and pneumonia are common complications. Large swings in blood pressure and pulse as well as profuse diaphoresis are typical, mainly in response to the intense muscular contractions but may also be related to the action of the toxin on the CNS. Death is usually attributable to asphyxia from laryngospasm, to heart failure, or to shock, the latter resulting from the action of the toxin on the hypothalamus and sympathetic nervous system.

Generalized spasms and rigidity of trunk and limbs developing in a neonate a few days after birth should always suggest the diagnosis of tetanus. This form of tetanus occurs when there has been inadequate sterile treatment of the umbilical cord stump in a neonate born to an unimmunized mother.

Local Tetanus This is the most benign form. The initial symptoms are stiffness, tightness, and pain in the muscles in the neighborhood of a wound, followed by twitchings and brief spasms of the affected muscles. Local tetanus occurs most often in relation to a wound of the hand or forearm, rarely in the abdominal or paravertebral muscles. Gradually, some degree of continuous involuntary spasm becomes evident. This is referred to as *rigidity*, *hypertonic contractions*, or *tetanic spasticity*, terms that denote the sustained tautness of the affected muscles and resistance of the part to passive movement. Superimposed on this background of more or less continuous motor activity are brief, intense spasms, lasting from a few seconds to minutes and occurring “spontaneously” or in response to all variety of stimulation (Strupp and Adams). Early in the course of the illness there may be periods when the affected muscles are palpably soft and appear to be relaxed. A useful diagnostic maneuver at this stage is to have the patient perform some repetitive voluntary movements, such as opening and closing the hand, in response to which there occurs a gradual increase in the tonic contraction and spasms of the affected muscles, followed by spread to neighboring muscle groups (recruitment spasm). The phenomenon resembles paradoxical myotonia (page

1268). Even with mild localized tetanus there may be a slight trismus, a useful diagnostic sign.

Symptoms may persist in localized form for several weeks or months. Gradually the spasms become less frequent and more difficult to evoke, and they finally disappear without residue. Complete recovery is to be expected, since there are no pathologic changes in muscles, nerves, spinal cord, or brain, even in the most severe generalized forms of tetanus.

Cephalic Tetanus This form of tetanus follows wounds of the face and head. The incubation period is short, 1 or 2 days as a rule. The affected muscles (most often facial) are weak or paralyzed. Nevertheless, during accessions of tetanic spasm, the palsied muscles are seen to contract. Apparently the disturbance in the facial motoneurons is sufficient to prevent voluntary movement but insufficient to prevent the strong reflex impulses that elicit facial spasm. The spasms may involve the tongue and throat, with persistent dysarthria, dysphonia, and dysphagia. Ophthalmoparesis is known to occur but is difficult to verify because of severe blepharospasm. In a strict sense these cephalic forms of tetanus are examples of local tetanus that frequently becomes generalized. Many cases prove fatal.

Diagnosis This is made from the clinical features and a history of preceding injury. The latter is sometimes disclosed only after careful questioning, the injury having been trivial and forgotten. The organisms may or may not be recovered from the wound by the time the patient receives medical attention; other laboratory tests, apart from the EMG, are of little value. Serum CK may be moderately elevated if the rigidity is generalized. The EMG recorded from muscles in spasm shows continuous discharges of normal motor units like those recorded from a forceful voluntary muscle contraction. Most characteristic of tetanus, as mentioned earlier, is a loss of the physiologic silent period that occurs 50 to 100 ms after reflex contraction. This pause, normally effected by the recurrent inhibition of Renshaw cells, is blocked by tetanus toxin. In generalized tetanus the loss of the silent period can almost always be demonstrated in the masseter, and it is found in a muscle affected by local tetanus. Interestingly, the silent period is preserved in the stiff man syndrome (page 1279). Tetany due to hypocalcemia, the spasms of strychnine poisoning or black widow spider bite, trismus due to painful conditions in and around the jaw, the dysphagia of rabies, hysterical spasms, rigidity and dystonic spasms caused by neuroleptic drugs, and the spasms of the stiff-man syndrome all resemble the spasms of tetanus but should not be difficult to distinguish when all aspects of these disorders are considered.

The death rate from tetanus is about 50 percent overall; it is highest in newborns, heroin addicts, and patients with the cephalic form of the disease. The patient usually recovers if there are no severe generalized muscle spasms during the course of the illness or if the spasms remain localized.

Treatment This must be directed along several lines. At the outset, a single dose of antitoxin (3000 to 6000 U of tetanus immune human globulin) should be given along with a 10-day course of penicillin (1.2 million U of procaine penicillin daily), metronidazole (500 mg every 6 h intravenously or 400 mg rectally), or tetracycline (2 g daily). These drugs are effective against the vegetative forms of *C. tetani*. Immediate surgical treatment of the wound (excision or debridement) is imperative, and the tissue around the wound should be infiltrated with antitoxin.

Survival depends on expert and constant nursing in an intensive care unit and may be necessary for weeks. Tracheostomy is a requisite in all patients with recurrent generalized tonic spasms and should not be delayed until apnea or cyanosis has occurred. The patient must be kept as quiet as possible to avoid stimulus-induced spasms. This requires a darkened, quiet room and the judicious use of sedation. The benzodiazepines are the most useful drugs; diazepam 120 mg/day or more can be given in frequent divided doses if ventilatory support is available; alternatively midazolam or propofol can be used in a continuous intravenous infusion. Short-acting barbiturates (secobarbital or pentobarbital) and chlorpromazine may also be useful, as is morphine. Intrathecal baclofen and continuous atropine infusions have been used with success in severe cases, and intramuscular injections of botulinus toxin may be used for trismus and local spasm. The aim of therapy is to suppress muscle spasms and to keep the patient drowsy but arousable. All treatments and manipulations should be kept to a minimum; they should be carefully planned and coordinated, and the patient should be sedated beforehand.

Failure of these measures to control the tetanic paroxysms demands that intravenous administration of neuromuscular blocking agents such as pancuronium or vecuronium be used to abolish all muscle activity; appropriate sedative medication is instituted for as long as necessary, breathing being maintained entirely by a positive-pressure respirator. Many intensive care units favor the use of neuromuscular paralytic drugs in all but the mildest cases. Further details concerning treatment can be found in the review by Farrar et al.

All persons at risk of infection should be immunized against tetanus and receive a booster dose of toxoid every 10 years—a practice that is frequently neglected in the elderly. Injuries that carry a threat of tetanus should be treated by an injection of toxoid if the patient has not received a booster injection in the preceding year, and a second dose of toxoid is needed 6 weeks later. If the injured person has not received a booster injection since the original immunization, he or she should receive an injection of both toxoid and human antitoxin; the same applies to the injured person who has never been immunized. An attack of tetanus does not confer permanent immunity, and persons who recover should be actively immunized.

Diphtheria

Diphtheria, an acute infectious disease caused by *Corynebacterium diphtheriae*, is now quite rare in the United States and western Europe. The faecal-pharyngeal form of the disease, which is the most common clinical type, is characterized by the formation of an inflammatory exudate of the throat and trachea; at this site, the bacteria elaborate an exotoxin, which affects the heart and nervous system in about 20 percent of cases.

The involvement of the nervous system follows a predictable pattern (Fisher and Adams). It begins locally, with *palatal paralysis* (nasal voice, regurgitation, and dysphagia) between the fifth and twelfth days of illness. At this time or shortly afterward, other cranial nerves (trigeminal, facial, vagus, and hypoglossal) may also be affected. *Ciliary paralysis* with loss of accommodation and blurring of vision, but with preserved light reaction, appears usually in the second or third week. Rarely the extraocular muscles are weakened. The cranial nerve signs may clear without further involvement of the nervous system, or a delayed sensorimotor polyneuropathy may develop between the fifth and eighth weeks of the disease. The latter varies in severity from a mild, predominantly

distal affection of the limbs to a rapidly evolving, ascending paralysis, like that of the Guillain-Barré syndrome; CSF findings are similar as well (acellular fluid with elevated protein). The neurologic symptoms progress for a week or two, and if the patient does not succumb to respiratory paralysis or cardiac failure (cardiomyopathy), these conditions stabilize and then improve slowly and more or less completely.

The early oropharyngeal symptoms, the unique ciliary paralysis with relatively retained pupillary response to light, and the subacute evolution of a delayed symmetrical sensorimotor peripheral neuropathy distinguish diphtheria from all other forms of polyneuropathy. The long latency between the initial infection and the involvement of the nervous system has no clear explanation. In experimental animals, Waksman and colleagues demonstrated that the toxin reaches the Schwann cells in the most vascular parts of the peripheral nervous system within 24 to 48 h of infection, but its metabolic effect on cell membranes extends over a period of weeks. As in humans, the toxin produces demyelination in the proximal parts of spinal nerves, in dorsal root ganglia, and in spinal roots. The cardiac musculature and the conducting system of the heart undergoes mild focal necrosis.

The source of diphtheritic infection may be extrafacial—a penetrating wound, skin ulcer, or umbilicus. The systemic and neurologic complications of faecal diphtheria can also be observed in the extrafacial form of the disease, after a similar latent period. It is probable, therefore, that the toxin reaches its neural site via the bloodstream; but, in addition, some action is exerted locally, as evidenced by palatal paralysis in faecal cases and by initial weakness and sensory impairment in the neighborhood of the infected wound.

There is no specific treatment for any of the neurologic complications of diphtheria. It is generally agreed that the administration of antitoxin within 48 h of the earliest symptoms of the primary diphtheritic infection lessens the incidence and severity of the peripheral nerve complications.

The polyneuropathy of diphtheria is discussed further in Chap. 46 (page 1128).

Botulism

Botulism is a rare form of food-borne illness caused by the exotoxin of *C. botulinum*. Outbreaks of poisoning are most often due to ingested bacteria contained in home-preserved than to commercially canned products, and vegetables and home-cured ham are incriminated more commonly than are other food products. Very rarely, a contaminated wound is the source of infection. Although the disease is ubiquitous, five western states (California, Washington, Colorado, New Mexico, and Oregon) account for more than half of all reported outbreaks in the United States. *Neonatal and infantile forms* of the disease have been reported. These are due to absorption of the toxin formed by germination of ingested spores (rather than ingestion of preformed toxin), an important source of which is contaminated natural (raw) honey. A few adult cases may have a similar source.

It is now well established, on the basis of observations in both animals and humans, that the primary site of action of botulinus toxin is at the neuromuscular junction, more specifically on the presynaptic endings. The toxin interferes with the release of acetylcholine from peripheral motor nerves by a mechanism like that of tetanus toxin on the spinal interneurons (see previous discussion). The physiologic defect is similar to the one that characterizes

the myasthenic syndrome of Lambert-Eaton (page 1259) but different from that of myasthenia gravis.

Symptoms usually appear within 12 to 36 h of ingestion of the tainted food. Anorexia, nausea, and vomiting occur in most patients. As a rule, blurred vision and diplopia are the initial neural symptoms; their association with ptosis, strabismus, and extraocular muscle palsies, particularly of the sixth nerve, may at first suggest a diagnosis of myasthenia gravis. In botulism, however, the pupils are often unreactive. Other symptoms of bulbar involvement—nasality of the voice and hoarseness, dysarthria, dysphagia, and an inability to phonate—follow in quick succession, and these, in turn, are followed by progressive weakness of muscles of the face, neck, trunk, and limbs and by respiratory insufficiency. Despite the oropharyngeal weakness, it is not unusual for the gag reflex to be retained. Tendon reflexes are lost in cases of severe generalized weakness. These symptoms and signs evolve rapidly, over 2 to 4 days as a rule, and may be mistaken for those of the Guillain-Barré syndrome. Sensation remains intact, however, and the spinal fluid usually shows no abnormalities. Severe constipation is characteristic of botulism, due perhaps to paresis of smooth muscle of the intestine. Consciousness is retained throughout the illness unless severe degrees of anoxia develop. In the past, the mortality was consistently above 60 percent, but it has declined in recent decades, with improvements in the intensive care of acute respiratory failure and the effectiveness of *C. botulinum* antitoxins.

The clinical diagnosis can be confirmed by electrophysiologic studies. Specifically, there is reduced amplitude of evoked muscle potentials and an increase in amplitude with rapid repetitive nerve stimulation (the opposite of what is found in myasthenia gravis). In patients who recover, improvement begins within a few weeks, first in ocular movement, then in other cranial nerve function. Complete recovery of paralyzed limb and trunk musculature may take many months.

The three types of botulinus toxin, A, B, and E, cannot be distinguished by their clinical effects alone, so that the patient should receive the trivalent antiserum as soon as the clinical diagnosis is made. This antitoxin can be obtained from the Centers for Disease Control and Prevention, Atlanta. An initial dose of 10,000 U is given intravenously after intradermal testing for sensitivity to horse serum, followed by daily doses of 50,000 U intramuscularly until improvement begins.

Guanidine hydrochloride (50 mg/kg) has been somewhat useful in reversing the weakness of limb and extraocular muscles. Antitoxin and guanidine probably change the course of the illness relatively little, and recovery, in the final analysis, depends on the effectiveness of respiratory care, maintenance of fluid and electrolyte balance, prevention of infection, and so on.

The skilled injection of small quantities of botulinus toxin into a muscle will weaken or paralyze it for weeks to months. Advantage is taken of this phenomenon in the treatment of the localized dystonias (page 93).

POISONING DUE TO PLANTS, VENOMS, BITES, AND STINGS

Ergotism

Ergotism is the name applied to poisoning with ergot, a drug derived from the rye fungus *Claviceps purpurea*. Ergot is used therapeutically to control postpartum hemorrhage due to uterine atony; one of its alkaloids, ergotamine, is used in the treatment of

migraine, and a class of dopamine agonists used in the treatment of Parkinson disease has ergot activity. Chronic overdosage of the drug is the usual cause of ergotism; acute overdosage in the postpartum state or in the treatment of migraine may cause an alarming rise in blood pressure.

Two types of ergotism are recognized: *gangrenous*, due to a vasospastic, occlusive process in the small arteries of the extremities, and *convulsive*, or *neurogenic* ergotism. The latter is characterized by fasciculations, myoclonus, and spasms of muscles, followed by seizures. In nonfatal cases, a tabes-like neurologic syndrome may develop, with loss of knee and ankle jerks, ataxia, and impairment of deep and superficial sensation. The pathologic changes are said to consist of degeneration of the posterior columns, dorsal roots, and peripheral nerves, but they have been poorly described. The relation of these changes to ergot poisoning is not clear, since most of the cases have occurred in areas where malnutrition was endemic. The authors have had no experience with this condition.

Lathyrism

Lathyrism is a neurologic syndrome characterized by the relatively acute onset of pain, paresthesias, and weakness in the lower extremities, progressing to a permanent spastic paraparesis. It is a serious medical problem in India and in some North African countries and is probably due to a toxin contained in the chickling vetch, *Lathyrus*, a legume that is consumed in excess quantities during periods of famine. This disorder is discussed further with the spinal cord diseases (page 1083).

Mushroom Poisoning

The gathering of wild mushrooms, a popular pastime in late summer and early fall, always carries with it the danger of poisoning. As many as 100 species of mushrooms are poisonous. Most of them cause only transient gastrointestinal symptoms, but some elaborate toxins that can be fatal. The most important of these toxins are the cyclopeptides, which are contained in several species of *Amanita phalloides* and *muscaria* and account for more than 90 percent of fatal mushroom poisonings. These toxins disrupt RNA metabolism, causing hepatic and renal necrosis. Symptoms of poisoning with *Amanita* usually appear between 10 and 14 h after ingestion and consist of nausea, vomiting, colicky pain, and diarrhea, followed by irritability, restlessness, ataxia, hallucinations, convulsions, and coma. There may be added evidence of a polymyopathy presenting as flaccid areflexic paralysis, high serum CK, diminished EMG potentials, and fiber necrosis.

Other important toxins are methylhydrazine (contained in the *cyromitra* species) and muscarine (*inocybe* and *clitocybe* species). The former gives rise to a clinical picture much like that caused by the cyclopeptides. The symptoms of muscarine poisoning, which appear within 30 to 60 min of ingestion, are essentially those of parasympathetic stimulation—miosis, lacrimation, salivation, nausea, vomiting, diarrhea, perspiration, bradycardia, and hypotension. Tremor, seizures, and delirium occur in cases of severe poisoning.

The mushroom toxins have no effective antidotes. If vomiting has not occurred, it should be induced with ipecac, following which activated charcoal should be administered orally in order to bind what toxin remains in the gastrointestinal tract. A local poison control center may help identify the poisonous mushroom and its toxin. Even more important, the gathering and ingestion of field varieties

of mushrooms should be left to those absolutely certain of their identity.

Buckthorn Poisoning

A rapidly progressive and sometimes fatal paralysis follows the ingestion of the small fruit of the buckthorn shrub that is indigenous to northern Mexico and the neighboring southwestern parts of the United States. The responsible toxin causes a predominantly motor polyneuropathy, probably of axonal type. Except for a normal spinal fluid protein concentration, the disorder closely resembles Guillain-Barré syndrome and tick paralysis (see below), and its recognition depends on awareness of ingestion of the fruit in endemic areas.

Neurotoxin Fish Poisoning (Ciguatera)

Ingestion of marine toxins that block neural sodium channels is a common form of poisoning throughout coastal areas and islands of the world. It results from eating fish that have fed on toxin-containing microscopic dinoflagellates. Reef fish and shellfish are exposed to high concentrations of these organisms during periodic upswings in the population of the dinoflagellates. They may be so profuse as to color the surrounding water (red tide). Although the toxins differ (tetrodotoxin—pufferfish; ciguatoxin—snails; saxitoxin and brevitoxin—shellfish), the neurologic and gastrointestinal symptoms that follow the ingestion of poisoned fish are similar. The initial symptoms are diarrhea, vomiting, or abdominal cramps coming on minutes to hours after the ingestion. These are followed by paresthesias that begin periorally and then involve the limbs distally. Hot and cold sensory stimuli (e.g., ice cream) are characteristically associated with electrical-like or burning paresthesias. Muscle aches and shooting pains are also mentioned by most patients. In pufferfish poisoning and in advanced stages of poisoning from other fish, weakness occurs, and there have been a few reports of coma and of respiratory failure. The recognition of this type of fish poisoning is straightforward in endemic areas, in some of which there is a seasonal clustering of cases. In tourists returning home from endemic areas or in persons consuming imported fish, the illness may be mistaken for the Guillain-Barré syndrome. Prominent perioral paresthesias should suggest the correct diagnosis. Supportive treatment is all that is required, but treatment with intravenous mannitol is said to hasten recovery.

Pearn reviews the biochemistry and physiologic and clinical effects of the various marine toxins and points out a form of chronic intoxication unknown to us but apparently endemic in certain island communities. The ostensible main chronic effects are severe fatigue and asthenic weakness. The problem of distinguishing this syndrome from depression is acknowledged by the author and the cases on which we have consulted locally almost always fall into the psychiatric category.

Venoms, Bites, and Stings

These are relatively rare but nonetheless important causes of mortality in the United States. The venoms of certain species of snakes, lizards, spiders (especially the black widow spider, page 1280), and scorpions contain neurotoxins that may cause a fatal depression of respiration and curare-like paralysis of neuromuscular transmission. In the United States, there are about 8000 poisonous snake bites per year. Some, such as the coral snake envenomation, are

neurotoxic, producing pupillary dilatation, ptosis, ocular palsies, ataxia, and respiratory paralysis. Others (rattlesnakes, water moccasin snakes) cause tissue necrosis and circulatory collapse. These are reviewed by Gold and colleagues. The serious effects of *Hymenoptera* stings (bees, wasps, hornets, and fire ants) are due mainly to hypersensitivity and anaphylaxis. Several instances of cerebral or myocardial infarction have been reported after bee and wasp stings (Crawley et al). All of these disorders are discussed in detail in *Harrison's Principles of Internal Medicine*.

TICK PARALYSIS

This rare condition is the result of a toxin secreted by the gravid tick. In Canada and the northwestern United States, the wood tick *Dermacentor andersoni* is mainly responsible; in the southeastern United States it is *Dermacentor variabilis*, a dog tick (the tick in Australia is the *Ixodes holocyclus*), but various other ticks may occasionally have the same effect. The illness is more common and is generally more severe in cases on the Australian Continent than it is in North America. Most cases occur in children because their small body mass renders them susceptible to the effects of relatively small amounts of the toxin. The illness arises almost exclusively in the spring, when the mature gravid ticks are most plentiful. Clinical manifestations require that the tick be attached to the skin for several days.

The neurotoxin causes a generalized, flaccid, areflexic paralysis, appearing over 1 or 2 days thereby mimicking the Guillain-Barré syndrome. In a few cases, several days of ataxia and areflexia precede the paralysis, but sensory loss tends to be minimal. External ophthalmoplegia, which occurred in 5 of the 6 children described by Grattan-Smith et al, is exceptional judging by other reports; internal ophthalmoplegia and pharyngeal weakness are also known to occur, and while not typical, raise the possibility of botulism or diphtheria. The CSF is normal and electrophysiologic studies show reduction in the amplitude of the muscle action potentials but normal or only slightly slowed nerve conduction. Prominent ptosis and neck weakness may also raise the question of a neuromuscular process, but repetitive stimulation testing is normal or evokes only a slight decrement or increment in some cases.

The ticks tend to attach to the hairlines or in the matted hair of the scalp, neck, and pubis, where a careful search will reveal them (for which reason nurses and electroencephalography technicians often are most likely to find them; see Felz et al). The diagnosis is much in the awareness of clinicians in endemic areas during the tick season, for they are gratified with rapid and dramatic improvement when the tick is removed. The paralysis is reported to become transiently worse after tick removal in some of the Australian cases.

From a neurologic point of view, the frequent disorder that follows tick bite is what has come to be known as *Lyme disease*—so named for the Connecticut community in which it was discovered. The causative agent is *Borrelia burgdorferi*, a spirochetal organism. The disorder is discussed fully with other infectious diseases in Chap. 32 and in Chap. 46, with the neuropathies.

HEAVY METALS

Lead

The causes and clinical manifestations of lead poisoning are quite different in children and adults.

Lead Poisoning in Children In the United States, this disease has been identified most often in 1- to 3-year-old children who inhabit urban slum areas where old, deteriorated housing prevails. (Lead paint was used in most houses built before 1940 and in many built before 1960.) The chewing of lead paint is promoted by compulsive ingestion (pica) from windowsills and painted plaster walls. The development of an acute encephalopathy is the most serious complication, resulting in death in 5 to 20 percent of cases and in permanent neurologic and mental deficits in more than 25 percent of survivors.

Clinical Manifestations These develop over a period of 3 to 6 weeks. The child becomes anorectic, less playful and less alert, and more irritable. These symptoms may be misinterpreted as a behavior disorder or a manifestation of mental retardation. Intermittent vomiting, vague abdominal pain, clumsiness, and ataxia may be added. If these early signs of intoxication are not recognized and the child continues to ingest lead, more flagrant signs of acute encephalopathy may develop—most frequently in the summer months, for reasons that are not understood. Vomiting becomes more persistent, apathy progresses to drowsiness and stupor interspersed with periods of hyperirritability, and finally, seizures and coma supervene. This syndrome may evolve in a period of a week or less, most rapidly in children under 2 years of age; in older children, it is more likely to develop in recurrent and less severe episodes. This clinical syndrome must be distinguished from tuberculous meningitis, viral meningoencephalitis, and the various conditions causing acute increased intracranial pressure. Usually, in lead encephalopathy, the CSF is under increased pressure with manifest papilledema, and there may be a slight lymphocytic pleocytosis and elevated protein, but normal glucose values. It follows that lumbar puncture should be done with caution and only if it is essential for diagnosis.

Diagnosis Since the symptoms of plumbism are nonspecific, the diagnosis depends on an appreciation of the causative factors, a high index of suspicion, and the results of certain laboratory tests. The presence of lead lines at the metaphyses of long bones and basophilic stippling of red cells are too inconstant to be relied on, but basophilic stippling of bone marrow normoblasts is uniformly increased. Impairment of heme synthesis, which is exquisitely sensitive to the toxic effects of lead, results in the increased excretion of urinary coproporphyrin (UCP) and of δ -aminolevulinic acid (ALA). These urinary indices and the lead concentrations in the serum bear an imperfect relationship to the clinical manifestations. In the test for UCP, which is readily performed in the clinic and emergency department, a few milliliters of urine are acidified with acetic acid and shaken with an equal volume of ether; if coproporphyrin is present, the ether layer will reveal a reddish fluorescence under a Wood's lamp. This test is strongly positive when the whole blood concentration of lead exceeds 80 mg/dL. The diagnosis can be confirmed by promoting lead excretion with calcium disodium edetate (CaNa_2EDTA), given in three doses (25 mg/kg) at 8-h intervals. Excretion of over 500 mg in 24 h is indicative of plumbism. The measurement of zinc protoporphyrin (ZPP) in the blood is another reliable means of determining the presence and degree of lead exposure. The binding of erythrocyte protoporphyrin to zinc occurs when lead impairs the normal binding of erythrocyte protoporphyrin to iron. Elevated ZPP can also be induced when access to iron is limited by other conditions, such as iron deficiency anemia.

Pathology In children who die of acute lead encephalopathy, the brain is massively swollen, with herniation of the temporal lobes

and cerebellum, multiple microscopic ischemic foci in the cerebrum and cerebellum, and endothelial damage and deposition of proteinaceous material and mononuclear inflammatory cells around many of the small blood vessels. There are also hyperplastic changes in arteries and arterioles, and in some places, perivascular infiltrates of lymphocytes and mononuclear cells. In the territories of some of these vessels there are foci of ischemic necrosis with surrounding glial reaction appropriate for the age of the lesion. Similar changes are present in the kidney.

At blood lead concentrations of 70 mg/dL symptoms may be minimal, but acute encephalopathy may occur abruptly and unpredictably, for which reason the child should be hospitalized for chelation therapy. Some children with a blood lead level of 50 mg/dL may have symptoms of severe encephalopathy, whereas others may be asymptomatic. In the latter case, an attempt should be made to discover and remove the source of lead intoxication and the child should be reexamined at frequent intervals. The seriousness of lead encephalopathy is indicated by the fact that most of the children who become stuporous or comatose remain mentally retarded despite treatment. The physician's aim, therefore, is to institute treatment before the severe symptoms of encephalopathy have become manifest.

Treatment The plan of therapy includes the following:

1. Establishment of urinary flow, following which intravenous fluid therapy is restricted to basal water and electrolyte requirements.
2. In cases of acute encephalopathy, combined chelation therapy with 2,3-dimercaptopropanol (BAL, 12 to 24 mg/kg) and CaNa₂ EDTA (0.5 to 1.5 g/m² body surface area) for 5 to 7 days. This is followed by a course of oral penicillamine (40 mg/kg, not exceeding 1 g/day). In acute cases the goal is to reduce the serum lead levels below 40 mg/dL. Once the absorption of lead has ceased, chelating agents remove lead only from soft tissues and not from bone, where most of the lead is stored. Any intercurrent illness may result in a further mobilization of lead from bones and soft tissues and an exacerbation of symptoms of lead intoxication.
3. Repeated doses of mannitol for relief of cerebral edema.
4. Microcytic hypochromic anemia is treated with iron once the chelating agents have been discontinued.
5. Seizures are best controlled with intravenous diazepam or midazolam.

Prevention The prevention of reintoxication (or initial intoxication) demands that the child be removed from the source of lead. Although this is axiomatic, it is often difficult to accomplish, despite the best efforts of local health departments and hospital and city social workers. Nevertheless, an attempt to eliminate the environmental factor must be made in each case. Such attempts, among other things, have resulted in a marked decrease in the incidence of acute lead encephalopathy in the past two decades. Although florid examples of this encephalopathy are now uncommon, undue exposure to lead (blood levels > 30 mg/dL) remains inordinately prevalent and a continuing source of concern to public health authorities. As to the levels that pose a danger to the child, there is still some uncertainty. Rutter, who reviewed all of the evidence up to 1980, concluded that persistent blood levels above 40 mg/dL may cause slight cognitive impairment and, less certainly, an increased risk of behavioral difficulties. More recently, Canfield and colleagues have reported, from a prospective study of

172 children, that even lower levels may induce a decline in IQ at 3 and 5 years of age. These data require confirmation before general acceptance. Further compounding the problem of interpreting low-level lead exposure in children with blood lead concentrations below 45 g/dL is the observation by Rogan and colleagues that treatment with succimer, while successful in reducing lead levels, did not improve cognitive or behavioral function. The oral lead chelator succimer is approved for outpatient treatment of asymptomatic children with blood lead levels higher than 45 mg/dL. A 3-week course of treatment is given, with weekly monitoring of blood lead levels to identify lead mobilization from bones and soft tissues (Jorgensen).

In 1988, on the basis of epidemiologic and experimental studies in the United States, Europe, and Australia, the Agency for Toxic Substances and Disease Registry set a much lower threshold for neurobehavioral toxicity (10 to 15 mg/dL). They estimated that 3 to 4 million American children have blood levels in excess of this amount. Needleman et al studied the long-term effects of low doses of lead in asymptomatic children, 132 of whom had demonstrable levels of lead in the dentin of shed teeth (average 24 mg/dL). Eleven years later, the children were found to have behavioral abnormalities proportionate to their early lead levels. In comparison to a normal population, more had dropped out of school and more had lower vocabulary and grammatical reasoning scores, more reading difficulty, poorer hand-eye coordination performance, slower finger-tapping rates, and longer reaction times. The authors claimed to have eliminated other confounding variables such as lower social class and genetic factors. These findings are similar to those of the long-term studies of Baghurst et al (see also Mahaffey). There are no adequate pathologic or MRI studies of such cases.

Lead Intoxication in Adults Lead intoxication in adults is much less common than in children. The hazards to adults are the result of inhaling the dust of inorganic lead salts and the fumes from the burning of objects containing lead or involvement in processes that require the remelting of lead. Painting, printing, pottery glazing, lead smelting, welding, and storage battery manufacturing are the industries in which these hazards are likeliest to occur. In the past, miners and brass foundry and garage workers (during automobile radiator repair, when soldered joints were heated) were the ones most at risk. Currently, other, sometimes idiosyncratic, sources are more common. For example, the authors have encountered a striking case of lead encephalopathy in a man of Indian origin who was taking large amounts of an Aruvedic herbal remedy for arthritis. The first manifestation was a series of generalized seizures followed by a fluctuating encephalopathy. His serum lead level was 70 mg/dL, and 24-h urine collection contained 1550 mg of lead (normal being < 400 mg). There was a T2-weighted hyperintensity in the cerebral cortex. Whitfield and colleagues reviewed 23 instances of lead encephalopathy in adults. At the time of their report most cases were due to moonshine (homemade whiskey from lead-lined stills). More recently most cases have been from various herbal medications as already mentioned. Combined lead and arsenic poisoning from herbal compounds is also known.

The usual manifestations of lead poisoning in adults are colic, anemia, and peripheral neuropathy. Encephalopathy of the type described above is decidedly rare. Lead colic, frequently precipitated by an intercurrent infection or by alcohol intoxication, is characterized by severe, poorly localized abdominal pain, often with rigidity of abdominal muscles but without fever or leukocytosis. The

pain responds to the intravenous injection of calcium salts, at least temporarily, but responds poorly to morphine. Mild anemia is common. A black line of lead sulfide may develop along the gingival margins. Peripheral neuropathy, usually a bilateral wrist drop, is a rare manifestation and is discussed on page 1132.

The diagnostic tests for plumbism in children are generally applicable to adults, with the exception of bone films, which are of no value in the latter. Also, the treatment of adults with chelating agents follows the same principles as in children.

Intoxication with tetraethyl and tetramethyl (organic) lead, used as additives in gasoline, is caused by inhalation of gasoline fumes. It occurs most often in workers who clean gasoline storage tanks. Insomnia, irritability, delusions, and hallucinations are the usual clinical manifestations, and a maniacal state may develop. The hematologic abnormalities of inorganic lead poisoning are not found, and chelating agents are of no value in treatment. Organic lead poisoning is usually reversible, but fatalities have been reported. The pathologic changes have not been well described.

Arsenic

In the past, medications such as Fowler's solution (potassium arsenite) and the arsphenamines, used in the treatment of syphilis, were frequent causes of intoxication, but now the most common cause is the suicidal or accidental ingestion of herbicides, insecticides, or rodenticides containing copper acetoarsenate (Paris green) or calcium or lead arsenate. In rural areas, arsenic-containing insecticide sprays are a common source of poisoning. Arsenic is used also in the manufacture of paints, enamels, and metals; as a disinfectant for skins and furs; and also in galvanizing, soldering, etching, and lead plating. Occasional cases of poisoning are reported in relation to these occupations. Arsenic is still contained in some topical creams and oral solutions that are used in the treatment of psoriasis and other skin disorders and in some herbal remedies.

Arsenic exerts its toxic effects by reacting with the sulphydryl radicals of certain enzymes necessary for cellular metabolism. The effects on the nervous system are those of an encephalopathy or peripheral neuropathy. The latter may be the product of chronic poisoning or may become manifest between 1 and 2 weeks after recovery from the effects of acute poisoning. It takes the form of a distal axonopathy that is described on page 1132. In cases of arsenical polyneuropathy we have cared for, a distal sensorimotor areflexic syndrome developed subacutely. At autopsy there was a dying back pattern of myelin and axons with macrophage and Schwann cell reactions and chromatolysis of motor neurons and sensory ganglion cells. The CNS appeared normal.

The symptoms of encephalopathy (headache, drowsiness, mental confusion, delirium, and convulsive seizures) may also occur as part of acute or chronic intoxication. In the latter case, they are accompanied by weakness and muscular aching, hemolysis, chills and fever, mucosal irritation (in patients exposed to arsine gas), diffuse scaly desquamation, and transverse white lines, 1 to 2 mm in width, above the lunula of each fingernail (Mees lines). Acute poisoning by the oral route is associated with severe gastrointestinal symptoms, circulatory collapse, and death in a large proportion of patients. The CSF is normal. Examination of the brain in such cases discloses myriads of punctate hemorrhages in the white matter. Microscopically, the lesions consist of capillary necrosis and of pericapillary zones of degeneration, which, in turn, are ringed by red cells (brain purpura or encephalorrhagia, incor-

rectly referred to as hemorrhagic encephalitis). These neuropathologic changes are not specific for arsenical poisoning but have been observed in such diverse conditions as pneumonia, gram-negative bacillary septicemia from urinary tract infections, sulfonamide and phosgene poisoning, dysentery, disseminated intravascular coagulation, and others.

The diagnosis of arsenical poisoning depends on the demonstration of increased levels of arsenic in the hair and urine. Arsenic is deposited in the hair within 2 weeks of exposure and may remain fixed there for long periods. Concentrations of more than 0.1 mg arsenic per 100 mg hair are indicative of poisoning. Arsenic also remains within bones for long periods and is slowly excreted in the urine and feces. Excretion of more than 0.1 mg arsenic per liter of urine is considered abnormal; levels greater than 1 mg/L may occur soon after acute exposure. We would caution, however, that individuals who consume fish on a regular basis, as occurs in our coastal region of the country, may have slightly or moderately elevated levels of arsenic and that various conditions such as neuropathy and amyotrophic lateral sclerosis (ALS) may be mistakenly attributed to this innocuous finding. The levels return to normal within a few months of abstaining from fish.

The CSF protein level may be raised (50 to 100 mg/dL).

Treatment Acute poisoning is treated by gastric lavage, vasoconstrictor agents, dimercaprol (BAL), maintenance of renal perfusion, and exchange transfusions if massive hemoglobinuria occurs. Once polyneuropathy has occurred, it is little affected by treatment with BAL, but other manifestations of chronic arsenical poisoning respond favorably. There has been a gradual recovery from the polyneuropathy under our care.

Manganese

Manganese poisoning results from the chronic inhalation and ingestion of manganese particles and occurs in miners of manganese ore and in workers who separate manganese from other ore. Several clinical syndromes have been observed. The initial stages of intoxication may be marked by a prolonged confusional-hallucinatory state. Later, the symptoms are predominantly extrapyramidal. They are often described as parkinsonian in type, but in the patients seen by the authors, the resemblance was not close: an odd gait ("cock" walk), dystonia and rigidity of the trunk, postural instability, and falling backward were features seen in two South American miners. Others, however, have reported stiffness and awkwardness of the limbs, often with tremor of the hands, "cogwheel" phenomenon, gross rhythmic movements of the trunk and head, and retropulsive and propulsive gait. Corticospinal and corticobulbar signs may be added. Progressive weakness, fatigability, and sleepiness as well as psychiatric symptoms (manganese madness) are other clinical features. Rarely, severe axial rigidity and dystonia, like those of Wilson disease, are said to have been the outstanding manifestations.

Neuronal loss and gliosis, affecting mainly the pallidum and striatum but also the frontoparietal and cerebellar cortex and hypothalamus, have been described, but the pathologic changes have not been carefully studied.

Treatment The neurologic abnormalities have not responded to treatment with chelating agents. In the chronic dystonic form of manganese intoxication, dramatic and sustained improvement has been reported with the administration of L-dopa; patients with the more common parkinsonian type of manganese intoxication have shown only slight if any improvement with L-dopa.

Mercury

Mercury poisoning arises in two forms, one due to inorganic compounds (elemental or mercury salt) and the other, more dangerous, to organic mercury. The sources of potential exposure are reviewed by Clarkson and colleagues. Among the *organic compounds*, methyl mercury gives rise to a wide array of serious neurologic symptoms that may be delayed for days or weeks after exposure, including tremor of the extremities, tongue, and lips; mental confusion; and a progressive cerebellar syndrome, with ataxia of gait and arms, intention tremor, and dysarthria. Choreaathetosis and parkinsonian facies have also been described. Changes in mood and behavior are prominent, consisting at first of subjective weakness and fatigability and later of extreme depression and lethargy alternating with irritability. This *delayed form of subacute mercury poisoning* has been reported in chemical laboratory workers after exposure to methyl mercury compounds. These agents, particularly dimethyl mercury, are extremely hazardous because they are absorbed transdermally and by inhalation, allowing severe toxicity to occur with even brief contact. In a fatal case of a chemist reported by Nierenberg et al, a rapidly progressive ataxia and stupor progressing to coma developed 154 days after exposure. Cerebellar function was most severely impaired, and visual function was affected.

The pathologic changes are characterized by a striking degeneration of the granular layer of the cerebellar cortex, with relative sparing of the Purkinje cells and neuronal loss and gliosis of the calcarine cortex and to a lesser extent of other parts of the cerebral cortex similar to the Minamata cases described later.

The chronic form of *inorganic mercury poisoning* occurs in persons exposed to large amounts of the metal used in the manufacture of thermometers, mirrors, incandescent lights, x-ray machines, and vacuum pumps. Since mercury volatilizes at room temperature, it readily contaminates the air and then condenses on the skin and respiratory mucous membranes. Nitrate of mercury, used formerly in the manufacture of felt hats ("mad hatters"), and phenyl mercury, used in the paper, pulp, and electrochemical industries, are other sources of intoxication. Paresthesias, lassitude, confusion, incoordination, and intention tremor are characteristic, and, with continued exposure, a delirious state occurs. Headache, various bodily pains, visual and hearing disorders, and corticospinal signs may be added, but their pathologic basis is unknown. The term *erethism* was coined to describe the timidity, memory loss, and insomnia that were said to be characteristic of chronic intoxication. If the exposure is more than a minimal degree over a long period, gastrointestinal disturbances are prone to occur (anorexia, weight loss), as well as stomatitis and gingivitis with loosening of the teeth. Acute exposure to inorganic mercury in larger amounts is even more corrosive to the gastrointestinal system and produces nausea, vomiting, hematemesis, abdominal pain, and bloody diarrhea as well as renal tubular necrosis.

Isolated instances of *polyneuropathy* associated with exposure to mercury have also been reported (Albers et al, Agocs et al) and may be responsible for the paresthesias that accompany most cases as well as the acrodyne syndrome described below. The polyneuropathy associated with mercury poisoning is discussed on pages 1130 and 1132. The inhalation of vaporized mercury as a result of extensive dental work, or simply the presence of a large number of fillings ("amalgam illness"), is alleged to affect the peripheral nerves or to cause fatigue, but the connection is highly doubtful.

The presence of mercury in industrial waste has contaminated many sources of water supply and fish, which are ingested by hu-

mans and cause mercurial poisoning. So-called Minamata disease is a case in point. Between 1953 and 1956, a large number of villagers living near Minamata Bay in Kyushu Island, Japan, were afflicted with a syndrome of chronic mercurialism, traced to the ingestion of fish that had been contaminated with industrial wastes containing methyl mercury. Concentric constriction of the visual fields, hearing loss, cerebellar ataxia, postural and action tremors, and sensory impairment of the legs and arms and sometimes of the tongue and lips were the usual clinical manifestations. The syndrome evolved over a few weeks. Pathologically there was diffuse neuronal loss in both cerebral and cerebellar cortices, most marked in the anterior parts of the calcarine cortex and granule cell layer of the cerebellum. CT scans in survivors, years after the mass poisoning, disclosed bilaterally symmetrical areas of decreased attenuation in the visual cortex and diffuse atrophy of the cerebellar hemispheres and vermis, especially the inferior vermis (Tokuomi et al).

A painful neuropathy of children (acrodynia) has been traced to mercury exposure from interior latex paint, to calomel (mercurous chloride), to teething powders, and to a mercuric fungicide used in washing diapers (Agocs et al, Clarkson). Albers and colleagues observed the appearance of symptoms (mild decrease in strength, tremor, and incoordination) 20 to 35 years after exposure to elemental mercury. These authors believed that the natural neuronal attrition with aging had unmasked the neurologic disorder, a theory which we cannot validate.

Treatment In the *treatment* of chronic mercury poisoning, penicillamine has been the drug of choice, since it can be administered orally and appears to chelate mercury selectively, with less effect on copper, which is an essential element in many metabolic processes. Dimercaptosuccinic acid (succimer), which is also given orally and has few side effects, will probably prove to be a superior form of treatment (Clarkson). Because it increases the concentration of mercury in the brain, BAL is an unsuitable chelating agent.

Phosphorus and Organophosphate Poisoning

Nervous system function may be deranged as part of acute and frequently fatal poisoning with inorganic phosphorus compounds (found in rat poisons, roach powders, and match heads). More important clinically is poisoning with organophosphorus compounds, the best known of which is triorthocresyl phosphate (TOCP).

Organophosphates are widely used as *insecticides*. Since 1945, approximately 15,000 individual compounds in this category have come into use. Certain ones, such as tetraethylpyrophosphate, have been the cause of major outbreaks of neurologic disorder, especially in children. These substances have an acute anticholinesterase effect but no delayed neurotoxic action. Chlorophos, which is a 1-hydroxy-2,2,2-trichloroethylphosphonate, is an exception; it has both an acute and delayed action, as does TOCP.

The *immediate* anticholinesterase effect manifests itself by headache, vomiting, sweating, abdominal cramps, salivation, wheezing (secondary to bronchial spasm), miosis, and muscular weakness and twitching. Most of these symptoms can be reversed by administration of atropine and pralidoxine. The *delayed effect* manifests 2 to 5 weeks following acute organophosphorus insecticide poisoning. This takes the form of a distal symmetrical sensorimotor (predominantly motor) polyneuropathy, progressing to muscle atrophy (see Chap. 46). Recovery occurs to a variable degree, and then, in patients poisoned with TOCP, signs of cortico-

spinal damage become detectable. The severity of paralysis and its permanence vary with the dosage of TOCP. Whether a polyneuropathy can arise without the preceding symptoms of cholinergic toxicity is debated; however, based on a review of the subject and a study of 11 patients exposed to these agents, 3 of whom later acquired sensory neuropathy, Moretto and Lotti express the view that such an occurrence must be rare.

In addition to the acute and delayed neurotoxic effects of organophosphorus, an *intermediate syndrome* has been described (Senanayake and Karalliedde). Symptoms come on 24 to 96 h after the acute cholinergic phase and consist of weakness or paralysis of proximal limb muscles, neck flexors, motor cranial nerves, and respiratory muscles. Respiratory paralysis may prove fatal. In patients who survive, the paralytic symptoms last for 2 to 3 weeks and then subside. The intermediate and delayed symptoms do not respond to atropine or other drugs.

Several striking outbreaks of TOCP poisoning have been reported. During the latter part of the prohibition era and to a lesser extent thereafter, outbreaks of so-called jake paralysis were traced to drinking an extract of Jamaica ginger that had been contaminated with TOCP. Adams had examined several "ginger jake" patients many years later and related to us that he found only signs of corticospinal disease. Presumably in the early stage of this disease they were obscured by the neuropathy. Another outbreak occurred in Morocco, in 1959, when lubricating oil containing TOCP was used deliberately to dilute olive oil. Several other outbreaks have been caused by the ingestion of grain and cooking oil that had been stored in inadequately cleaned containers previously used for storing TOCP.

The effect of TOCP on the peripheral nervous system has been studied extensively in experimental animals. In cats, there occurs a dying back from the terminal ends of the largest and longest medullated motor nerve fibers, including those from the annulospiral endings of the muscle spindles (Cavanagh and Patangia). The long fiber tracts of the spinal cord show a similar dying-back phenomenon. Abnormal membrane-bound vesicles and tubules were observed by Prineas to accumulate in axoplasm before degeneration. These effects have been traced to the inhibitory action of TOCP on esterases. There is still uncertainty as to the details of these reactions, and no treatment for the prevention or control of the neurotoxic effects has been devised.

Thallium

In the late nineteenth century, thallium was used medicinally in the treatment of venereal disease, ringworm, and tuberculosis and later in rodenticides and insecticides. Poisoning was fairly common. Sporadic instances of poisoning still occur, usually as a result of accidental or suicidal ingestion of thallium-containing rodenticides and rarely from overuse of thallium-containing depilatory agents. Patients who survive the effects of acute poisoning develop a rapidly progressive and painful sensory polyneuropathy, optic atrophy, and occasionally ophthalmoplegia—followed, 15 to 30 days after ingestion, by diffuse alopecia (see page 1130). The latter feature should always suggest the diagnosis of thallium poisoning, which can be confirmed by finding this metallic element in the urine. Two of our patients had a severe sensory and mild motor polyneuropathy and alopecia, from which they were recovering months later. It is not uncommon for the neuropathy to have a painful component involving acral regions. The condition can end fatally. The use of potassium chloride by mouth may hasten thallium excretion.

Other Metals

Iron, antimony, tin, aluminum, zinc, barium, bismuth, copper, silver, gold, platinum, and lithium may all produce serious degrees of intoxication. The major manifestations in each case are gastrointestinal or renal, but certain neurologic symptoms—notably headache, irritability, confusional psychosis, stupor, coma, and convulsions—may be observed in any of these if the poisoning is severe, often as a terminal event.

Gold preparations, which are still used occasionally in the treatment of arthritis, may, after several months of treatment, give rise to focal or generalized myokymia and a rapidly progressive, symmetrical polyneuropathy (Katrak et al). The adverse effects of *platinum* are discussed later, with the antineoplastic agents. *Lithium* has been discussed earlier.

Attention has already been drawn to the possible causative role of *aluminum intoxication* in so-called dialysis dementia or encephalopathy (page 971). Removal of aluminum from the water used in renal dialysis has practically eliminated this disorder. It should be noted that the neuropathologic changes in experimental aluminum intoxication (see later) are not those observed in dialysis dementia. Perl and colleagues have reported the accumulation of aluminum in tangle-bearing neurons of patients with Alzheimer disease and in the Guamanian Parkinson–dementia–ALS complex. However, analysis of neuritic plaques by nuclear microscopy, without using chemical stains, failed to demonstrate the presence of aluminum (Landsberg et al). The significance of these findings remains to be determined. Longstreth and colleagues have described a progressive neurologic disorder consisting of intention tremor, incoordination, and spastic paraparesis in three patients who had worked for more than 12 years in the same pot room of an aluminum smelting plant. Similar cases clearly attributable to aluminum intoxication have not been reported, however.

Organic compounds of *tin* may seriously damage the nervous system. Diffuse edema of the white matter of the brain and spinal cord has been produced experimentally with *triethyltin*. Presumably this was the basis of the mass poisoning produced by a triethyltin-contaminated drug called Stalinon. The illness was characterized by greatly elevated intracranial pressure and by a spinal cord lesion in some cases (Alajouanine et al). *Trimethyltin* intoxication is much rarer; seizures are the main manifestation. Experimental studies in rats have shown neuronal loss in the hippocampus, largely sparing the Sommer sector, with later involvement of neurons in the pyriform cortex and amygdala (see review by LeQuesne).

A stereotyped episodic encephalopathy has been associated with *bismuth intoxication*, usually arising from the ingestion of bismuth subgallate. Large outbreaks have been reported in Australia and France (Burns et al, Buge et al). The onset of the neurologic disturbance is usually subacute, with a mild and fluctuating confusion, somnolence, difficulty in concentration, tremulousness, and sometimes hallucinations and delusions. With continued ingestion of bismuth, there occurs a rapid (24- to 48-h) worsening of the confusion and tremulousness, along with diffuse myoclonic jerks, seizures, ataxia, and inability to stand or walk. These symptoms regress over a few days to weeks when the bismuth is withdrawn, but some patients have died of acute intoxication. High concentrations of bismuth were found in the cerebral and cerebellar cortices and in the nuclear masses throughout the brain. These concentrations can be recognized as hyperdensities in the CT scan (Buge et al).

Industrial Toxins

Some of these, the heavy metals, have already been considered. In addition, a large number of synthetic organic compounds are widely used in industry and are frequent sources of toxicity, and the list is constantly being expanded. The reader is referred to the references at the end of the chapter, particularly to the most current text, edited by Spencer and Schaumburg, for details concerning these compounds. Here we can do little more than enumerate the most important ones: chlorinated diphenyls (e.g., DDT) or chlorinated polycyclic compounds (Kepone), used as insecticides; diethylene dioxide (Dioxane); carbon disulfide; the halogenated hydrocarbons (methyl chloride, tetrachloroethane, carbon tetrachloride, trichloroethylene, and methyl bromide); naphthalene (used in moth repellants); benzine (gasoline); benzene and its derivatives [toluene, xylene, nitrobenzene, phenol, and amyl acetate (banana oil)] and the hexacarbon solvents (*n*-hexane and methyl *n*-butyl ketone).

With a few exceptions, the acute toxic effects of these substances are much the same from one compound to another. In general, the primary effect is on nonneurologic structures. Neural symptoms consist of varying combinations of headache, restlessness, drowsiness, confusion, delirium, coma, and convulsions, which, as a rule, occur late in the illness or preterminally. Some of these industrial toxins [carbon disulfide, carbon tetrachloride and tetrachloroethane, acrylamide, *n*-hexane, and diethylene glycol (Sterno; see Rollins)] may cause polyneuropathy, which becomes evident with recovery from acute toxicity. Extrapyramidal symptoms may result from chronic exposure to carbon disulfide. A syndrome of persistent fatigue, lack of stamina, inability to concentrate, poor memory, and irritability has also been attributed to chronic exposure to solvents, but these symptoms are quite non-specific, and evidence for such a syndrome is unsupported by convincing experimental or epidemiologic studies.

Of the aforementioned industrial toxins, the ones most likely to cause neurologic disease are *toluene* (methyl benzene) and the *hexacarbons*. The chronic inhalation of fumes containing toluene (usually in glue, contact cement, or certain brands of spray paint) may lead to severe and irreversible tremor and cerebellar ataxia, affecting movements of the eyes (opsoclonus, ocular dysmetria) and limbs, as well as stance and gait. Cognitive impairment is usually associated; corticospinal tract signs, progressive optic neuropathy, sensorineural hearing loss, and hyposmia occur in some patients. Generalized cerebral atrophy and particularly cerebellar atrophy are evident in CT scans (Fornazzari et al, Hormes et al). Also, it has become apparent that acute toluene intoxication is an important cause of seizures, hallucinations, and coma in children (King et al).

The prolonged exposure to high concentrations of *n*-hexane or methyl-*n*-butyl ketone may cause a sensorimotor neuropathy, so-called glue-sniffer's neuropathy (page 1132). These solvents are metabolized to 2,5-hexanedione, which is the agent that damages the peripheral nerves. The neuropathy may result from exposure in certain industrial settings (mainly the manufacture of vinyl products) or, more often, from the deliberate inhalation of vapors from solvents, lacquers, glue, or glue thinners containing *n*-hexane (see also Chap. 46). Impure trichloroethylene, through its breakdown product dichloroacetylene, has a predilection for the trigeminal nerve, which can be damaged selectively.

Hydrogen peroxide poisoning, usually by accidental ingestion, causes multiple small cerebral infarcts through a mechanism

of gas embolus (Ijichi et al). Most cases have been reversible. According to Humberson et al (cited by Ijichi and colleagues) 120 mL of 35% hydrogen peroxide releases 14 L of oxygen on contact with organic tissue. The lung is involved, and the unmistakable brain lesions consist of tiny gas bubbles concentrated in parasagittal watershed areas.

ANTINEOPLASTIC AND IMMUNOSUPPRESSIVE AGENTS

The increasing use of potent antineoplastic agents has given rise to a diverse group of neurologic complications, the most important of which are subsequently summarized. A more detailed account of these agents—as well as the neurologic complications of corticosteroid therapy, immunosuppression, and radiation—can be found in the monograph edited by Rottenberg and in the review of Tuxen and Hansen. The neurotoxic effects of certain agents used in the treatment of brain tumors are also considered in Chap. 31.

Vincristine

This drug is used in the treatment of acute lymphoblastic leukemia, lymphomas, and some solid tumors. Its most important toxic side effect, and the one that limits its use as a chemotherapeutic agent, is a peripheral neuropathy. Paresthesias of the feet, hands, or both may occur within a few weeks of the beginning of treatment; with continued use of the drug, a progressive symmetrical neuropathy evolves (mainly sensory with reflex loss). Cranial nerves are affected less frequently but ptosis and lateral rectus, facial, and vocal cord palsies have been observed. Autonomic nervous system function may also be affected: constipation and impotence are frequent complications; orthostatic hypotension, atonicity of the bladder, and adynamic ileus are less frequent. The polyneuropathy due to vincristine is described more fully on page 1133. Inappropriate antidiuretic hormone secretion and seizures have been reported but are uncommon.

Although rarely noted in the literature, the authors have seen an instance of reversible posterior leukoencephalopathy with cortical blindness and headache after a single dose of vincristine, identical to the syndrome reported with the use of cyclosporine and FK-506 (Fig. 43-1). This radiologic appearance is also well known in hypertensive encephalopathy as discussed in Chap. 34. The main drugs implicated in this disorder are listed in Table 43-1. It has not been satisfactorily established if all such cases are the result of acute hypertension caused by the implicated drug or if there might be an additional direct toxic effect on the white matter.

The neural complications of *vinblastine* are similar to those of vincristine but are usually avoided because bone marrow suppression limits the dose of the drug that can safely be employed. *Vinorelbine* is a more recently introduced semisynthetic vinca alkaloid. It has much the same antitumor activity as vincristine but is supposedly less toxic.

Cisplatin

Cisplatin, a heavy metal that inhibits DNA synthesis, is effective in the treatment of gonadal and head and neck tumors, as well as carcinoma of the bladder, prostate, and breast. The dose-limiting factors in its use are nephrotoxicity and vomiting and a peripheral neuropathy (see page 1133). The latter manifests itself by numbness and tingling in fingers and toes, sometimes painful—symp-

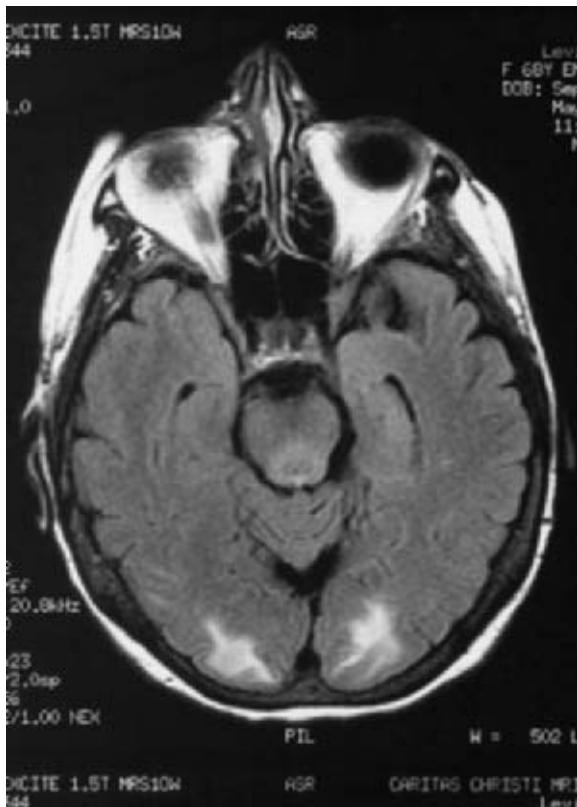

Figure 43-1. Toxic reversible posterior leukoencephalopathy. Axial FLAIR magnetic resonance imaging in a patient with cortical blindness and severe headache days after receiving vincristine. This syndrome and radiographic findings are more typical following the use of cyclosporine, FK-506, and other chemotherapies. Compare to the similar conditions of hypertensive encephalopathy and toxemia shown in Fig. 34-29, page 729.

toms that are being observed with increasing frequency. This toxic manifestation appears to be related to the total amount of drug administered, and it usually improves slowly after it has been discontinued. Biopsies of peripheral nerve have shown a primary axonal degeneration. Approximately one-third of patients receiving this drug also experience tinnitus or high-frequency hearing loss or both. Ootoxicity is also dose-related, cumulative, and only occasionally reversible. Some protective effect has been claimed with the use of the melanocortin compound ACTH (4-9), but the benefits in a trial by Gerristen and colleagues were quite small and probably do not justify its administration on a routine basis. Retrobulbar neuritis occurs rarely. Seizures associated with drug-induced hyponatremia and hypomagnesemia have been reported.

Paclitaxel and Docetaxel

Taxol (paclitaxel) and Taxotere (docetaxel) are newer anticancer drugs derived from the bark of the western yew. Both are particularly useful in the treatment of ovarian and breast cancer, but they have a wide range of antineoplastic activities. A purely or predominantly sensory neuropathy is a common complication. These drugs are thought to cause neuropathy by their action as inhibitors of the depolymerization of tubulin, thereby promoting excessive microtubule assembly within the axon. The neuropathy is dose-dependent, occurring with doses greater than 200 mg/m^2 of paclitaxel and at a wide range of dose levels for docetaxel (generally over

Table 43-1

Diseases and drugs associated with reversible posterior leukoencephalopathy

- Severe hypertension, spontaneous or induced (Chap. 34)
- Toxemia-eclampsia (Chap. 34)
- Cyclosporin
- Methotrexate (intravenous and rarely oral)
- Cyclophosphamide
- FK-506
- Interferon (intravenous)
- Tacrolimus
- L-Asparaginase
- Cisplatin
- Cytarabine
- Intravenous immunoglobulin
- Granulocyte colony stimulating factor
- Erythropoietin
- Combination chemotherapies, particularly those including cyclophosphamide or cytarabine

600 mg/m^2). Symptoms may begin 1 to 3 days following the first dose and affect the feet and hands simultaneously. Autonomic neuropathy (orthostatic hypotension) may occur as well. The neuropathy is axonal in type, with secondary demyelination, and is at least partially reversible after discontinuation of the drug.

Procarbazine

This drug, originally synthesized as an MAO inhibitor, is now an important oral agent in the treatment of Hodgkin disease and other lymphomas and has found some use in bronchogenic carcinoma and malignant gliomas. It has also proved to be especially effective in the treatment of oligodendrogiomas. Neural complications are infrequent and usually take the form of somnolence, confusion, agitation, and depression. Diffuse aching pain in proximal muscles of the limbs and mild symptoms and signs of polyneuropathy occur in 10 to 15 percent of patients treated with relatively high doses. A reversible ataxia has also been described. Procarbazine, taken in conjunction with phenothiazines, barbiturates, narcotics, or alcohol, may produce serious degrees of oversedation. Other toxic reactions, such as orthostatic hypotension, are related to the MAO inhibitory action of procarbazine.

L-Asparaginase

This enzymatic inhibitor of protein synthesis is used in the treatment of acute lymphoblastic leukemia. Drowsiness, confusion, delirium, stupor, coma, and diffuse EEG slowing are the common neurologic effects and are dose-related and cumulative. They may occur within a day of onset of treatment and clear quickly when the drug is withdrawn, or they may be delayed in onset, in which case they persist for several weeks. These abnormalities are at least in part attributable to the systemic metabolic derangements induced by L-asparaginase, including liver dysfunction.

In recent years, increasing attention has been drawn to cerebrovascular complications of L-asparaginase therapy, including ischemic and hemorrhagic infarction and cerebral venous and dural sinus thrombosis. Fineberg and Swenson have analyzed the clinical

features of 38 such cases. These cerebrovascular complications are attributable to transient deficiencies in plasma proteins that are important in coagulation and fibrinolysis.

5-Fluorouracil

This is a pyrimidine analogue, used mainly as a secondary treatment of cancer of the breast, ovary, and gastrointestinal tract. A small proportion of patients receiving this drug develop dizziness, cerebellar ataxia of the trunk and the extremities, dysarthria, and nystagmus—symptoms that are much the same as those produced by cytarabine (Ara-C; see below). These abnormalities must be distinguished from metastatic involvement of the cerebellum and paraneoplastic cerebellar degeneration. The drug effects are usually mild and subside within 1 to 6 weeks after discontinuation of therapy. The basis of this cerebellar syndrome is not known.

Methotrexate

Administered in conventional oral or intravenous doses, methotrexate (MTX) is not usually neurotoxic. However, given intrathecally to treat meningeal leukemia or carcinomatosis, MTX commonly causes aseptic meningitis, with headache, nausea and vomiting, stiff neck, fever, and cells in the spinal fluid. Very rarely, probably as an idiosyncratic response to the drug, intrathecal administration results in an acute paraplegia that may be permanent. The pathology of this condition has not been studied.

The most serious and more common of the neurologic problems associated with systemic MTX chemotherapy is a leukoencephalopathy or leukomyelopathy, especially when given in combination with cranial or neuraxis radiation therapy (page 564). This develops several months after repeated intrathecal or high systemic doses of MTX, and a few milder cases are known to have occurred without radiation treatments, i.e., with oral or intravenous MTX alone such as the case reported by Worthley and McNeil. We have seen one such instance in a woman receiving oral MTX for a systemic vasculitis; no alternative explanation for widespread white matter changes and mild dementia could be discerned. Nonetheless, this must be quite uncommon. The full-blown syndrome consists of the insidious evolution of dementia, pseudobulbar palsy, ataxia, focal cerebral cortical deficits, or paraplegia. Milder cases show only radiographic evidence of a change in signal intensity in the posterior cerebral white matter (“posterior leukoencephalopathy”) that is similar to the imaging findings that follow cyclosporine use (see further on) and hypertensive encephalopathy (see Fig. 43-1). In severe cases, the brain shows disseminated foci of coagulation necrosis of white matter, usually periventricular, which can be detected with CT and MRI.

Mineralizing microangiopathy (fibrosis and calcification of small vessels, mainly in the basal ganglia) is yet another complication of MTX therapy. It may occur with MTX treatment or with cranial irradiation but is particularly common when both forms of treatment are combined. The present authors have the impression that the severe necrotic lesions possess features comparable to (and therefore maybe the result of) the coagulative necrosis of radiation encephalopathy.

The Nitrosoureas

Carmustine (BCNU) and lomustine (CCNU) are nitrosoureas used to treat malignant cerebral gliomas. They are not neurotoxic when

given in conventional intravenous doses, but intracarotid injection of the drugs may cause orbital, eye, and neck pain, focal seizures, confusion, and possibly focal neurologic deficits. Postmortem examinations of patients who had been treated with intravascular BCNU have disclosed a diffuse vasculopathy characterized by fibrinoid necrosis and microthrombi and diffuse foci of swollen axis cylinders and myelin vacuolization (Burger et al, Kleinschmidt-de Masters).

Cytarabine (Ara-C)

This drug, long used in the treatment of acute nonlymphocytic leukemia, is not neurotoxic when given in the usual systemic daily doses of 100 to 200 mg/m². The administration of very high doses (up to 30 times the usual dose) has been shown to induce remissions in patients refractory to conventional treatments. It also may produce, however, a severe degree of cerebellar degeneration in a considerable proportion of cases (4 of 24 reported by Winkelman and Hines). Ataxia of gait and limbs, dysarthria, and nystagmus develop as early as 5 to 7 days after the beginning of high-dose treatment and worsen rapidly. Postmortem examination has disclosed a diffuse degeneration of Purkinje cells, most marked in the depths of the folia, as well as a patchy degeneration of other elements of the cerebellar cortex. Other patients receiving high-dose Ara-C have developed a mild, reversible cerebellar syndrome with the same clinical features. Patients more than 50 years of age are said to be far more likely to develop cerebellar degeneration than those younger than 50; therefore the former should be treated with a lower dosage (Herzig et al).

Cyclosporine and Tacrolimus (FK-506)

These immunosuppressive drugs are used to prevent transplant rejection and to treat aplastic anemia and certain intrinsic immune diseases. Tremor is perhaps the most frequent side effect, particularly of tacrolimus, and myoclonus may be added. Sometimes these impart a stuttering character to speech. Headache and insomnia are common. Seizures may be a manifestation of toxicity, but the cause may lie with the other complications of organ transplantation and immunosuppression. The neurologic effects of these drugs have been reviewed by Wijdicks. As already noted, a posterior leukoencephalopathy syndrome resembling hypertensive encephalopathy—headache, vomiting, confusion, seizures, and visual loss (cortical blindness)—may follow the use of either drug (see Table 43-1). The appearance on CT scans and MRI of symmetrical signal and density changes mainly in the posterior white matter likewise conform to the pattern that is seen in hypertensive encephalopathy. Lesions may also appear subcortically in the frontal and parietal lobes. Interferon treatment for malignant melanoma and a number of other chemotherapeutic agents have been associated with the same condition. Hinckley and colleagues have described several such cases and suggested that cyclosporin alters the blood-brain barrier and that the fluid overload and hypertension which accompanies the use of cyclosporin underlies the radiologic changes. A variety of psychotic syndromes with delusions, paranoia, and visual hallucinations have also been ascribed to the use of these drugs (see Wijdicks).

Thalidomide

Despite the catastrophic effects of thalidomide on the developing fetus (following its introduction as a soporific in 1957), this drug

has now found several specific uses in the treatment of immunologic, neoplastic, and infectious diseases. It is effective in the treatment of leprosy, erythema nodosum, and the oral ulcerations of AIDS and Behçet disease. Experimental uses include suppression of graft-versus-host reactions and inhibition of blood vessel proliferation in vascular tumors such as renal cell cancer. A dose-dependent sensory neuropathy is the limiting factor in its use, and serial electrophysiologic testing is recommended if the medication is to be prescribed for protracted periods. Of course, it must not be given to a woman who is or might be pregnant.

Antibiotics and Other Medications

Numerous antibiotics, cardioactive medications, and other drugs may have adverse effects on the central or peripheral nervous system. Some of the latter are addressed on page 1134. Here we mention mainly that penicillin and its derivatives such as imipenem, and to a lesser degree, cephalosporins are capable of causing seizures when high serum concentrations are attained. This is favored in most instances by concomitant renal failure.

Other important examples of antibiotic toxicity are optic neuropathy due to ethambutol toxicity; ototoxicity and neuromuscular blockade from aminoglycoside and fluoroquinolone antibiotics (page 216); peripheral neuropathy, encephalopathy, and an Antabuse-like reaction to alcohol in patients taking metronidazole; a metronidazole induced polyneuropathy, INH neuropathy and optic neuropathy, and possibly a peripheral neuropathy due to chloramphenicol. A curious and reversible cerebellar syndrome due to metronidazole with MRI signal changes in the dentate nuclei has been reported by Woodruff and colleagues and by others.

The most notorious toxic consequences with this group of drugs were seen with *clioquinol*, which was sold as Entero-vioform and was used in many parts of the world to prevent traveler's diarrhea and as a treatment for chronic gastroenteritis. In 1971, clinical observations began to appear in medical journals of a subacute myelo-optic neuropathy (SMON). During the 1960s, more than 10,000 cases of this disease were collected in Japan by Tsubaki et al. Usually the illness began with ascending numbness and weakness of the legs, paralysis of sphincters, and autonomic disorder. Later, vision was affected. The onset was acute in about two-thirds of the cases and subacute in the remainder. The occurrence of these neurologic complications was found to be related to the prolonged use of *clioquinol*. In Japan the drug was withdrawn from the market, and the incidence of SMON immediately fell, supporting the theory that it was caused by the drug. Recovery was usually incomplete. Two patients seen by the authors several years after onset of the disease had been left with optic atrophy and a spastic-ataxic paraparesis.

Also mentioned here, because neurologists are often asked to consult on these cases, is a curious effect of the anesthetic propofol. Seizures and myoclonic-like movements have been seen in a small number of individuals, presumably as an idiosyncratic effect. Sometimes these take the form of less organized twitching, opisthotonus, or involuntary movements. While some inhaled anesthetics such as enflurane can cause seizures in susceptible patients, propofol does not share the activating effects of the volatile anesthetics. In our own experience, the seizures have occurred in the first hour after emergence from anesthesia but as many cases are reported during induction, emergence, or after the use of the drug (see Walder).

PART 5

DISEASES OF SPINAL CORD, PERIPHERAL NERVE, AND MUSCLE

This page intentionally left blank.

CHAPTER 44

DISEASES OF THE SPINAL CORD

Diseases of the nervous system may be confined to the spinal cord, where they produce a number of distinctive syndromes. These syndromes relate to the special physiologic and anatomic features of the cord, such as its prominent function in sensorimotor conduction and relatively primitive reflex activity; its long, cylindrical shape; its small cross-sectional size; its tight envelopment by meninges; the peripheral location of myelinated fibers next to the pia; the special arrangement of its blood vessels; and its relationship to the vertebral column. Woolsey and Young estimate that there are about 30 diseases known to affect the spinal cord, of which half are seen with regularity. These processes express themselves by a number of readily recognized syndromes and, as will be evident, certain diseases preferentially evoke one syndrome and not others. The syndromic grouping of the spinal cord disorders, which is in keeping with the general plan of this book, facilitates clinical diagnosis and reduces the number of ancillary examinations needed for confirmation.

The main syndromes to be considered in this chapter are: (1) a complete or almost complete sensorimotor myelopathy that involves most or all of the ascending and descending tracts (transverse myelopathy); (2) a combined painful radicular and transverse cord syndrome; (3) the hemicord (Brown-Séquard) syndrome; (4) a ventral cord syndrome, sparing posterior column function; (5) a high cervical-foramen magnum syndrome; (6) a central cord or syringomyelic syndrome; (7) a syndrome of the conus medullaris; and (8) a syndrome of the cauda equina (see also pages 1081 and 1082). In addition, an important distinction is made between lesions within the cord (*intramedullary*) and those that compress the cord from without (*extramedullary*). Most of the processes to be considered here cause one or the other of these syndromes, and each of them will be considered in the course of exposition of the major categories of spinal cord disease.

The anatomic and physiologic considerations pertinent to an understanding of disorders of the cord and of the spine can be found in Chaps. 3, 9 (particularly Fig. 9-5), and 11, on motor paralysis, somatic sensation, and back pain, respectively.

THE SYNDROME OF ACUTE PARAPLEGIA OR QUADRIPLEGIA DUE TO COMPLETE TRANSVERSE LESIONS OF THE SPINAL CORD (TRANSVERSE MYELOPATHY)

This syndrome is best considered in relation to trauma, its most frequent cause, but it occurs also as a result of infarction or hemorrhage and with rapidly advancing compressive, necrotizing, demyelinative, or inflammatory lesions (transverse myelitis). Each of these categories of acute spinal cord disease is discussed in the following pages. For convenience we have included in this group radiation myelopathy, which is transverse but evolves subacutely.

Trauma to the Spine and Spinal Cord

Throughout recorded medical history, advances in the understanding of spinal cord disease have coincided largely with periods of warfare. The first thoroughly documented study of the effects of sudden total cord transection was by Theodor Kocher in 1896, based on his observations of 15 patients. During World War I, Riddoch—and later Head and Riddoch—gave the classic descriptions of spinal transection in humans; Lhermitte and Guillain and Barré are credited with refining these observations. Little could be done for those patients, however; fully 80 percent died in the first few weeks (from infections), and survival was possible only if the spinal cord lesion was partial. World War II marked a turning point in the understanding and management of spinal injuries. The advent of antibiotics and the ability to control skin, bladder, and pulmonary infections permitted the survival of unprecedented numbers of soldiers with spinal cord injuries and provided the opportunity for long-term observation. In special centers, such as the Long Beach, Hines, and West Roxbury Veterans Administration Hospitals in the United States and the Stoke Mandeville National Spinal Injuries Centre in England, the care and rehabilitation of the paraplegic were brought to a very high level. Studies conducted in these centers have greatly enhanced our knowledge of the functional capacity of the chronically isolated spinal cord. Kuhn, Munro, Martin and Davis, Guttmann, Pollock, and their associates, listed in the references, have made particularly important contributions to this subject.

Mechanisms of Spine and Spinal Cord Injury Although trauma may involve the spinal cord alone, the vertebral column is almost invariably injured at the same time. Often there is an associated head injury as pointed out in Chap. 35.

A useful classification of *spinal injuries* is one that divides them into fracture-dislocations, pure fractures, and pure dislocations. The relative frequency of these types is about 3:1:1. Except for bullet, shrapnel, and stab wounds, a direct blow to the spine is a relatively uncommon cause of serious spinal cord injury. In civilian life, most spinal injuries are the result of *force applied at a distance* from the site of spinal fracture and dislocation. All three types of spinal injury previously mentioned are produced by a similar mechanism, usually a vertical compression of the spinal column to which anteroflexion is added; or, the mechanism may be one of vertical compression and retroflexion (commonly referred to as hyperextension). The most important variables in the mechanics of vertebral injury are the structure of the bones at the level of the injury and the intensity, direction, and point of impact of the force.

In keeping with the mechanism of force applied at a distance, many spinal injuries are due to blows to the head. If the cranium is struck by a hard object at high velocity, a skull fracture occurs, the force of the injury being absorbed mainly by the elastic quality of the skull. If the traumatizing force is relatively soft yet unyield-

ing or is applied more slowly, the spine, and particularly its most mobile (cervical) portion, will be the part injured. If the neck happens to be rigid and straight and the force is applied quickly to the head, the atlas and the odontoid process of the axis may break. If the force is applied less quickly, an element of flexion or extension is added.

In the case of severe forward *flexion injury*, the head is bent sharply forward when the force is applied. The adjacent cervical vertebrae are forced together at the level of maximum stress. The anteroinferior edge of the upper vertebral body is driven into the one below, sometimes splitting it in two. The posterior part of the fractured body is displaced backward and compresses the cord. Concomitantly, there is tearing of the interspinous and posterior longitudinal ligaments. Less severe degrees of anteroflexion injury produce only dislocation. Vulnerability to the effects of anteroflexion (and to some extent to retroflexion injuries) is increased by the presence of cervical spondylosis or ankylosing spondylitis or by a congenital stenosis of the spinal canal.

In *hyperextension injuries*, the mechanism is one of vertical compression with the head in an extended position. Stress is mainly on the posterior elements (the laminae and pedicles) of the mid-cervical vertebrae (C4 to C6), which may be fractured unilaterally or bilaterally—and on the anterior ligaments. This dual disruption in the spinal architecture allows for displacement of one vertebral body on the adjacent one. The dislocation results in the cord being caught between the laminae of the lower vertebra and the body of the one above.

It should be pointed out that a hyperextension injury to the spinal cord commonly occurs without apparent damage or misalignment of the vertebrae when viewed radiologically. In these instances the spinal cord damage, which can be nonetheless profound and permanent, is caused by a sudden inward bulge of the ligamentum flavum or a transient vertebral dislocation followed by spontaneous realignment. This type of spinal cord damage, without radiologic evidence of fracture or dislocation, is particularly common in children. That rupture of the supporting ligamentous elements has nonetheless occurred can be revealed by gentle flexion and extension of the neck under radiologic observation which demonstrates slight dislocation of the vertebra (spinal instability).

Computed tomography (CT), magnetic resonance imaging (MRI), and plain lateral spine films are all satisfactory means of demonstrating the vertebral injury, but the tearing and bulging of ligaments from vertebral dislocation is dependably demonstrated only by MRI (or by contrast myelography) and can otherwise only be inferred from the spinal displacement. As mentioned, radiologic studies during cautious flexion or extension of the neck are the only way one can demonstrate instability from ligamentous rupture alone, although MRI may reveal signal changes in the traumatized ligaments.

Another mechanism of cord and spinal root injury, involving extremes of extension and flexion of the neck, is so-called whiplash or recoil injury, most often the result of an automobile accident. When a vehicle is struck sharply from behind, the head of the occupant is flung back uncontrollably; or, if a fast-moving vehicle stops abruptly, there is sudden forward flexion of the neck, followed by retroflexion. Under these conditions the occipitotonuchal and sternocleidomastoid muscles and other supporting structures of the neck and head are affected much more often than the spinal cord or roots. Nevertheless, in rare instances, quadripareisis, temporary or permanent, results from a violent whiplash injury. The exact mechanism of neural injury in these circum-

stances is not clear; perhaps there is a transient posterior dislocation of a vertebral body, a momentary buckling of the ligamentum flavum, or retropulsion of the intervertebral disc into the spinal canal. The presence of a congenitally narrow cervical spinal canal or of spinal diseases such as cervical spondylosis, rheumatoid arthritis, or ankylosing spondylitis adds greatly to the hazard of damage to the cord or roots. Also, preexisting spondylotic symptoms may be aggravated and become the source of chronic pain. There are in addition examples of spinal cord compression that result from the prolonged hyperextension of the cervical spine during a protracted period of stupor. This accounts for some cases of quadriplegia in opiate or other drug addicts following a period of sustained unresponsiveness (Ell et al). Arterial hypotension may be an added factor in some instances.

A special type of spinal cord injury, occurring most often in wartime, is one in which a high-velocity missile penetrates the vertebral canal and damages the spinal cord directly. In some cases the missile strikes the vertebral column without entering the spinal canal but virtually shatters the contents of the dural tube or produces lesser degrees of impairment of spinal cord function. Rarely, the transmitted shock wave will cause a paralysis of spinal cord function that is completely reversible in a day or two (*spinal cord concussion*, described further on).

Acute traumatic paralysis may also be the indirect consequence of a vascular mechanism. Fibrocartilaginous emboli from an intervertebral disc that has ruptured into radicular arteries or veins of the spinal cord may cause infarction. Or, a traumatic dissecting aneurysm of the aorta may occlude the segmental arteries of the spinal cord, as in the cases reported by Weisman and Adams and by Kneisley.

An analysis of 2000 cases of spinal injury collected from the medical literature by Jefferson up to 1927 showed that most vertebral injuries occurred at the levels of the first and second cervical, fourth to sixth cervical, and eleventh thoracic to second lumbar vertebrae. These preferred sites of injury are the same today. Industrial accidents most often involved the thoracolumbar vertebrae. Impact to the head with the neck flexed or sharply retroflexed, as mentioned earlier, was the main cause of injuries to the cervical region. These are not only the most mobile portions of the vertebral column but also the regions in which the cervical and lumbar enlargements of the cord greatly reduce the space between neural and bony structures. The thoracic cord is relatively small and its spinal canal is capacious; additional protection is provided by the high articular facets (making dislocation difficult) and limitations in anterior movement imposed by the thoracic cage.

In the authors' general experience, the usual circumstances of spinal cord injury have been motor vehicle accidents, falls (mainly during a state of alcoholic intoxication), gunshot or stab wounds, diving accidents, motorcycle accidents, crushing industrial injuries, and birth injury in that order of frequency. The majority of the fatal cases have been associated with fracture-dislocations or dislocations of the upper cervical spine (C1 to C4 vertebrae) with resultant sudden respiratory paralysis. Among non-fatal cases, fracture-dislocation of the mid and lower cervical spine is the most frequent established mechanism of spinal cord injury in civilian life.

In the United States, the annual incidence of spinal cord injury is 5 cases per 100,000 population; males predominate (4:1). Each year about 3500 persons die in close relation to their injury, and another 5000 are left with complete or nearly complete loss of spinal cord function.

Pathology of Spinal Cord Injury As a result of squeezing or shearing of the spinal cord, there is destruction of gray and white matter and a variable amount of hemorrhage, chiefly in the more vascular central parts. These changes, designated as *traumatic necrosis* of the spinal cord, are maximal at the level of injury and one or two segments above and below it. Rarely is the cord cut in two, and seldom is the pia-arachnoid lacerated. Separation of the constituent pathologic entities—such as hematomyelia, concussion, contusion, and hematorrhachis (bleeding into the spinal canal)—is of little value either clinically or pathologically. As a lesion heals, it leaves a gliotic focus or cavitation with variable amounts of hemosiderin and iron pigment. Progressive cavitation (traumatic syringomyelia) may develop after an interval of months or years and as it extends above the main lesion, lead to a delayed central or incomplete transverse cord syndrome. In most traumatic lesions, the central part of the spinal cord, with its vascular gray matter, tends to suffer greater injury than the peripheral parts. In some instances, the lesion is virtually restricted to the anterior and posterior gray matter, giving rise to segmental weakness and sensory loss in the arms with few long tract signs. This is the *central cervical cord syndrome*, also called the *Schneider syndrome* (see further on). Fragments of this syndrome commonly occur as transient phenomena that reverse over several days.

As with most lesions, the total clinical effect is composed of an irreversible structural component and a reversible disorder of function, each of which varies in degree. The extent and permanence of the clinical manifestations are, therefore, determined by the relative proportions of these two elements.

Experimental Spinal Cord Injury Investigation of the pathophysiology of acute spinal cord injury dates from the experimental studies of Allen in the early 1900s. His method consisted of dropping graded weights onto the dura-covered thoracic cord of surgically prepared animals. The technique was refined over the years by precise measurements of the velocity, force, and direction of the dropped weights. This type of impact on the cord, of sufficient severity to render the animal immediately paraplegic and abolish sensory evoked responses from structures below the lesion, indicates that action potentials can no longer be conducted across the injured spinal cord segment. No histologic changes, by either light or electron microscopy, can be detected for several minutes after impact. The earliest tissue alterations consist of hyperemia and small hemorrhages in the central gray matter. By 1 h, the microscopic hemorrhages coalesce and become macroscopically visible. Tissue oxygen saturation is diminished in the region. Within 4 h, the central part of the cord swells and a spreading edema pervades the surrounding white matter; however, necrosis may not be evident for up to 8 h, an observation that has led to numerous strategies designed to spare the long tracts. Surgical intervention to minimize white matter edema—such as laminectomy and myelotomy—spinal cord cooling, hyperbaric exposure, and the administration of pharmacologic measures have been tried but have had no meaningful effects on the evolving lesion. The early administration of high-dose corticosteroids produces some benefit in experimental models, but the clinical benefits are questionable (see further on).

Certain mechanisms that are thought to be operative in the death of cerebral neurons exposed to ischemia or to traumatic forces have also been invoked in spinal cord injury. These include release of so-called excitotoxins such as glutamate and exposure of neurons to calcium and to agents that produce free radicals. The latter mechanism may explain the salutary effect of high doses of

corticosteroids in experimental models rather than the ostensible effect of these drugs on edema. Osterholm postulated that the initial event in acute impact injury was the release of norepinephrine from injured neurons in the central gray matter and that the subsequent vasoconstriction was responsible for both the central hemorrhagic and lateral white matter lesions. Later experimental work failed to substantiate this. Also, the contention that opioid release at the moment of trauma plays an important role in tissue damage has not been confirmed. The main problem with all the experimental work is that it only imperfectly reproduces the various types of spinal injury in humans.

Clinical Effects of Spinal Cord Injury When the spinal cord is suddenly and virtually or completely severed, three disorders of function are at once evident: (1) all voluntary movement in parts of the body below the lesion is immediately and permanently lost; (2) all sensation from the lower (aboral) parts is abolished; and (3) reflex functions in all segments of the isolated spinal cord are suspended. The last effect, called *spinal shock*, involves tendon as well as autonomic reflexes. It is of variable duration (1 to 6 weeks as a rule but sometimes far longer) and is so dramatic that Riddoch used it as a basis for dividing the clinical effects of spinal cord transection into two stages, that of spinal shock and areflexia followed by the stage of heightened reflex activity. The separation of these two stages is not as sharp as this statement might imply but is nevertheless fundamental and useful for exposition. Less complete lesions of the spinal cord result in little or no spinal shock, and the same is true of any type of lesion that develops slowly. The features of complete spinal cord transection are presented later in detail for several reasons in addition to the practical value of understanding the evolution of cord lesions. They occupy a special place in classic neurology and are a guide to the processes that occur in nontraumatic and lesser types of cord damage.

Stage of Spinal Shock or Areflexia The loss of motor function at the time of injury—tetraplegia with lesions of the fourth to fifth cervical segments or above, paraplegia with lesions of the thoracic cord—is accompanied by immediate areflexia of bladder and bowel, gastric atony, loss of sensation below a level corresponding to the spinal cord lesion, muscular flaccidity, and almost complete suppression of all spinal segmental reflex activity below the lesion. As a result of their sudden separation from higher levels, the neural elements below the lesion fail to perform their normal function. However, the physiologic basis of this reflex segmental paralysis is incompletely understood as noted later. Also impaired in the segments below the lesion is the control of autonomic function. Vasomotor tone, sweating, and piloerection in the lower parts of the body are temporarily abolished. Systemic hypotension may be severe and contribute to the spinal cord damage. The lower extremities lose heat if left uncovered, and they swell if dependent. The skin becomes dry and pale, and ulcerations may develop over bony prominences. The sphincters of the bladder and the rectum remain contracted to some degree due to the loss of inhibitory influence of higher central nervous system (CNS) centers, but the detrusor of the bladder and smooth muscle of the rectum are areflexic. Urine accumulates until the intravesicular pressure is sufficient to overcome the sphincters; then dribbles escape (overflow incontinence). There is also passive distention of the bowel, retention of feces, and absence of peristalsis (paralytic ileus). Genital reflexes (penile erection, bulbocavernosus reflex, contraction of dartos muscle) are abolished or profoundly depressed.

The duration of the stage of spinal shock with complete are-

flexia varies considerably as mentioned. In a small number (5 of Kuhn's 29 patients, for example) it is permanent, or only fragmentary reflex activity is regained many years after the injury. In such patients the spinal segments below the level of transection may have themselves been injured—perhaps by a vascular mechanism, although this explanation is unproven. More likely there is a loss of the brainstem-spinal facilitatory mechanisms and an increase in inhibitory activity in the isolated segments. In other patients, minimal genital and flexor reflex activity can be detected within a few days of the injury. In the majority, this minimal reflex activity appears within a period of 1 to 6 weeks. Usually the bulbocavernosus reflex is the first to return. Noxious stimulation of the plantar surfaces evokes a tremulous twitching and brief flexion or extension movements of the great toes. Contraction of the anal sphincter can be elicited by plantar or perianal stimulation, and other genital reflexes reappear at about the same time.

The explanation of spinal shock, which is brief in submammalian forms and more lasting in higher mammals, especially in primates, is believed to be the sudden interruption of suprasegmental descending fiber systems that normally keep the spinal motor neurons in a continuous state of subliminal depolarization (ready to respond). In the cat and monkey, Fulton found the facilitatory tracts in question to be the reticulospinal and vestibulospinal. Subsequent studies showed that in monkeys, some degree of spinal shock could result from interruption of the corticospinal tracts alone. This cannot be the significant factor, however, at least in humans, because spinal shock does not result from acute cerebral and brainstem lesions that interrupt the corticospinal tracts. The F-waves, electrophysiologic responses that reflect the functioning of the motor neurons of the isolated segment of the cord, are suppressed until spasticity supervenes, at which time they become overly easy to elicit.

Stage of Heightened Reflex Activity This is the more familiar neurologic state that emerges within several weeks or months after spinal injury. Usually, after a few weeks, the reflex responses to stimulation, which are initially minimal and unsustained, become stronger and more easily elicitable and as time passes come to include additional and more proximal muscles. Gradually the typical pattern of heightened flexion reflexes emerges: dorsiflexion of the big toe (Babinski sign); fanning of the other toes; and later, flexion or slow withdrawal movements of the foot, leg, and thigh with contraction of the tensor fascia lata muscle (the last several features often referred to as "triple flexion"). Tactile stimulation of the foot may suffice as a stimulus, but a painful stimulus is more effective. The Achilles reflexes and then the patellar reflexes return. Retention of urine becomes less complete, and at irregular intervals urine is expelled by spontaneous contractions of the detrusor muscle. Reflex defecation also begins. After several months the withdrawal reflexes become greatly exaggerated, to the point of flexor spasms, and may be accompanied by profuse sweating, piloerection, and automatic emptying of the bladder (occasionally of the rectum). This is the "mass reflex," which can be evoked by stimulation of the skin of the legs or by some interoceptive stimulus, such as a full bladder. Varying degrees of heightened flexor reflex activity may last for years. Heat-induced sweating is defective, but reflex-evoked ("spinal") sweating may be profuse (see Kneisley). Presumably, in such cases the lateral horn cells in much of the thoracic cord are still viable and are disinhibited. Above the level of the lesion, thermoregulatory sweating may be exaggerated and is accompanied by cutaneous flushing, pounding headache, hypertension, and reflex bradycardia. This syndrome ("autonomic dys-

reflexia") is episodic and occurs in response to a certain stimuli, such as a distended bladder or rectum. It has been ascribed to the reflex release of adrenalin from the adrenal medulla and of norepinephrine from the disinhibited sympathetic terminals caudal to the lesion.

Extensor reflexes eventually develop in most cases (18 of 22 of Kuhn's patients who survived more than 2 years), but their appearance does not lead to the abolition of the flexor reflexes. The overactivity of extensor muscles may appear as early as 6 months after the injury, but this only happens, as a rule, after the flexor responses are fully developed. Extensor responses are at first manifest in certain muscles of the hip and thigh and later of the leg. In a few patients extensor reflexes are organized into support reactions sufficient to permit *spinal standing*. Kuhn observed that extensor movements were at first provoked most readily by a sudden shift from a sitting to a supine position and later by proprioceptive stimuli (squeezing of the thigh muscles) and tactile stimuli from wide areas. Marshall, in a study of 44 patients with chronic spastic paraplegia of spinal origin, found all possible combinations of flexor and extensor reflexes; the type of reflex obtained was determined by the intensity and duration of the stimulus (a mild prolonged noxious stimulus evoked an ipsilateral extensor reflex; an intense brief stimulus, a flexor response).

From these observations one would suspect that the ultimate posture of the legs—flexion or extension—does not depend solely on the completeness or incompleteness of the spinal cord lesion, as originally postulated by Riddoch. The development of *paraplegia in flexion* (extreme flexion of the hips and knees, as in a fetal position) relates also to the level of the lesion, being seen most often with cervical lesions and progressively less often with more caudal ones. Important also are repeated flexor spasms, which are more frequent with higher lesions, and the ensuing contractures ultimately produce a fixed flexor posture. Conversely, reduction of flexor spasms by elimination of nociceptive stimuli (infected bladder, decubiti, etc.) favors an extensor posture of the legs (*paraplegia in extension*). According to Guttmann, the positioning of the limbs during the early stages of paraplegia greatly influences their ultimate posture. Thus, prolonged fixation of the paralyzed limbs in adduction and semiflexion favors subsequent paraplegia in flexion. Placing the patient prone or placing the limbs in abduction and extension facilitates the development of predominantly extensor postures. Nevertheless, strong and persistent extensor postures are usually observed only with partial lesions of the spinal cord.

Of some interest is the fact that many patients report sensory symptoms in segments of the body below the level of their transection. Thus, a tactile stimulus above the level of the lesion may be felt below the transection (synesthesia). Patients describe a variety of paresthesias, the most common being a dull, burning pain in the lower back and abdomen, buttocks, and perineum. We have encountered several patients in whom aching testicular or rectal pain was a distressing problem. The pain may be intense and last for a year or longer, after which it gradually subsides. It persists after rhizotomy but can be abolished by anesthetizing the stump of the proximal (upper) segment of the spinal cord, according to Pollock and his collaborators. Transmission of sensation over splanchnic afferents to levels of the spinal cord above the lesion, the conventional explanation, is therefore not the most plausible one.

The overactivity of neurons in the isolated segments of the spinal cord has several explanations. One assumes that suprasegmental inhibitory influences have been removed by the transection, so that afferent sensory impulses evoke exaggerated nocifensive

and phasic and tonic myotatic reflexes. But isolated neurons also become hypersensitive to neurotransmitters. Since the early experiments of Cannon and Rosenblueth it has been known that section of sympathetic motor fibers leaves the denervated structures hypersensitive to epinephrine; these authors also found the motor neurons in the isolated spinal segments to be abnormally sensitive to acetylcholine.

Various combinations of residual deficits (of lower and upper motor neurons and sensory neurons) are to be expected. Some of the resulting clinical pictures are complete or incomplete voluntary motor paralysis; a flaccid atrophic paralysis of upper limb muscles (if appropriate segments of gray matter are destroyed) with spastic weakness of the legs; a partial or rarely a complete Brown-Séquard syndrome (pages 51 and 140); and each of these occurs with variable sensory impairment in the legs and arms. High cervical lesions may result in extreme and prolonged tonic spasms of the legs due to release of tonic myotatic reflexes. Under these circumstances, attempted voluntary movement may excite intense contraction of all flexor and extensor muscles lasting for several minutes. Segmental damage in the low cervical or lumbar gray matter, destroying inhibitory Renshaw neurons, may release activity of remaining anterior horn cells, leading to spinal segmental spasticity. Any residual symptoms persisting after 6 months are likely to be permanent, although in a small proportion of patients some return of function (particularly sensation) is possible after this time. Loss of motor and sensory function above the lesion, coming on years after the trauma, occurs occasionally and is due to an enlarging cavity in the proximal segment of the cord (see further on, under "Syringomyelia").

Transient Cord Injury (Spinal Cord Concussion) These terms refer to a transient loss of motor and/or sensory function of the spinal cord that recovers within minutes or hours but sometimes persists for a day or several days. In most instances the symptoms are already diminishing and few neurologic abnormalities are found at the time of the first examination. There are a number of such transient syndromes; bibrachial weakness; quadriparesis (occasionally hemiparesis); paresthesias and dysesthesias in a similar distribution to the weakness; or sensory symptoms alone ("burning hands syndrome"). In the first and last of these the central gray matter of the cervical cord is implicated. It is assumed that the cord undergoes some form of elastic deformation when the head is struck at the vertex or frontally and the cervical spine is compressed or hyperextended; however, the same effects can be produced by direct blows to the spine or forceful falls flat on the back and occasionally by a sharp fall on the tip of the coccyx. Little is known of the pathologic changes or the mechanisms that underlie these reversible syndromes.

Spinal cord concussion from direct impact is observed most frequently in athletes engaged in contact sports (football, rugby, and hockey). An incomplete and reversible myelopathy occurs referable to the level of the injury. A congenitally narrow cervical canal is thought to predispose to spinal cord concussion and to increase the risk of recurrence. As with cerebral concussion, particularly if there have been previous concussions, a difficult decision arises—whether to allow resumption of competitive sports. There are no reliable data on which to base this decision—only guidelines that favor continued participation if the deficit has been brief. Certainly, it is advisable in most cases to be certain that spinal instability has not been induced by the injury. This can be ascertained by obtaining flexion and extension radiographs of the af-

fected spinal region. The subject is reviewed by Zwimpfer and Bernstein.

Central Cord Syndrome (Schneider Syndrome) and "Cruciate Paralysis" In the case of acute central cord damage (Schneider syndrome), the loss of motor function is characteristically more severe in the upper limbs than in the lower ones and particularly severe in the hands. Bladder dysfunction with urinary retention occurs in some of cases, and sensory loss is often slight (hyperpathia over the shoulders and arms may be the only sensory abnormality). Damage of the centrally situated gray matter may leave an atrophic, areflexic paralysis and a segmental loss of pain and thermal sensation from interruption of crossing pain and thermal fibers. Other cases are transient as noted earlier. Retroflexion injuries of the head and neck are the ones most often associated with the central cord syndrome, but hematomyelia, necrotizing myelitis, fibrocartilagenous embolism, and infarction due to dissection or compression of the vertebral artery in the medullary-cervical region are other causes (Morse).

According to Dickman and colleagues, approximately 4 percent of patients who survive injuries of the very rostral cervical cord demonstrate a related syndrome referred to by these authors as "cruciate paralysis." The state is similar to the central cord syndrome except that the weakness is even more selective, being practically limited to the arms, a feature that is attributable to the segregation of corticospinal fibers to the arms (rostral) and to the legs (caudal) within the pyramidal decussation. The arm weakness may be asymmetrical or even unilateral; sensory loss is inconsistent. The patients described have had injuries, basically contusions, of the C1–C2 region. Whether the lesion lies strictly within the decussating corticospinal tract or involves central gray matter is not always clear; MRI imaging has implicated the latter anatomic region (Inamasu et al). Sensory evoked potentials are normal, while magnetic stimulation of the corticospinal tract may be abnormal.

Examination and Management of the Spine-Injured Patient The level of the spinal cord and vertebral lesions can be determined from the clinical findings. Diaphragmatic paralysis occurs with lesions of the upper three cervical segments (an unrelated transient arrest of breathing is common in severe head injury). Complete paralysis of the arms and legs usually indicates a fracture or dislocation at the fourth to fifth cervical vertebrae. If the legs are paralyzed and the arms can still be abducted and flexed, the lesion is likely to be at the fifth to sixth cervical vertebrae. Paralysis of the legs and only the hands indicates a lesion at the sixth to seventh cervical level. Below the cervical region, the spinal cord segments and roots are not directly opposite their similarly numbered vertebrae (Fig. 44-1). The spinal cord ends at the first lumbar vertebra, usually at its rostral border. Vertebral lesions below this point give rise predominantly to cauda equina syndromes; these carry a better prognosis than injuries to the lower thoracic vertebrae, which involve both cord and multiple roots.

The level of sensory loss on the trunk, determined by perception of pinprick, is an accurate guide to the level of the lesion, with a few qualifications. (See Figs. 9-2 and 9-3 for maps of the sensory dermatomes.) Lesions of the lower cervical cord, even if complete, may show a sparing of sensation down to the nipple line because of the contribution of the C3 and C4 cutaneous branches of the cervical plexus, which variably innervate skin below the clavicle. Or, a lesion that involves only the outermost fibers of the spinothalamic pathways, sparing the innermost ones, results in a sensory

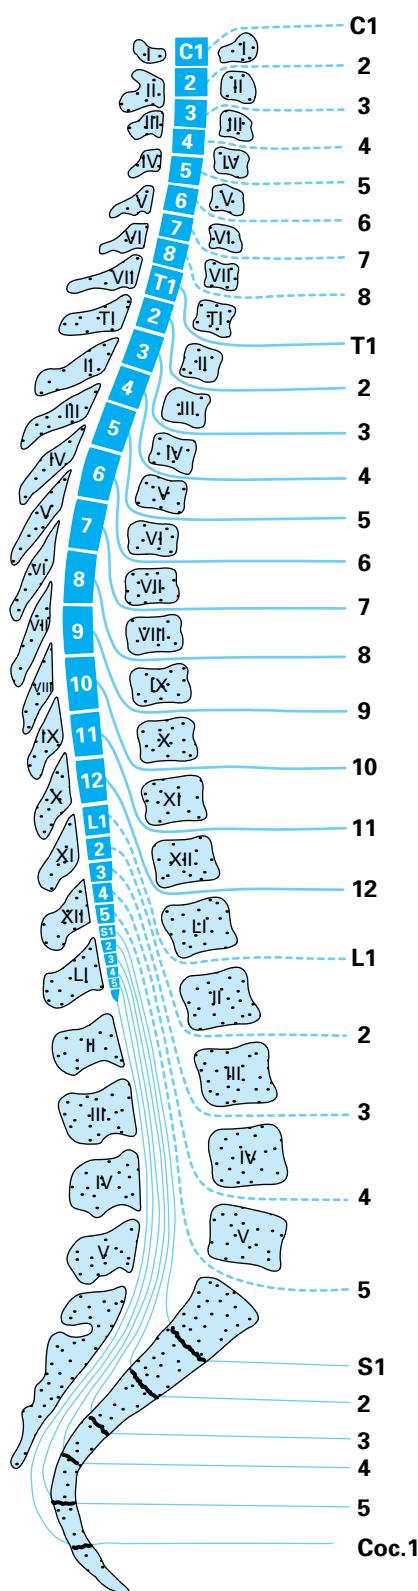

Figure 44-1. The relationship of spinal segments and roots to the vertebral bodies and spinous processes. The cervical roots (except C8) exit through foramina above their respective vertebral bodies, and the other roots issue below these bodies. (From Haymaker and Woodhall: *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

level (to pain and temperature) well below the level of the lesion. In all cases of spinal cord and cauda equina injury, the prognosis for recovery is more favorable if any movement or sensation is elicitable during the first 48 to 72 h.

If the spine can be examined safely, it should be inspected for angulations or irregularities and gently percussed to elicit signs of bony injury. Collateral injury of the thorax, abdomen, and long bones must always be sought.

In all cases of suspected spinal injury, the immediate concern is that movement (especially flexion) of the cervical spine be avoided. The patient should be placed supine on a firm, flat surface (with one person assigned, if possible, to keeping the head and neck immobile) and should be transported by a vehicle that can accept the litter. The board may be placed under the patient gently rolling him to one side with the head, neck, and body held in alignment. Preferably, the patient should be transported by an ambulance equipped with spine boards, to which the head is firmly fixed by straps. This provides a more effective means of immobilization than sandbags or similar objects placed on each side of the head and neck. On arrival at the hospital, it is useful to have the patient remain on the board until a lateral film or a CT or MRI of the cervical spine has been obtained.

A neurologic examination with detailed recording of motor, sensory, and sphincter function is necessary to follow the clinical progress of spinal cord injury. Common practice is to define the injury according to the standards of the American Spinal Injury Association and to assign the injury to a point on the Frankel Scale.

1. Complete: motor and sensory loss below the lesion
2. Incomplete: some sensory preservation below the zone of injury
3. Incomplete: motor and sensory sparing, but the patient is nonfunctional
4. Incomplete: motor and sensory sparing and the patient is functional (stands and walks)
5. Complete functional recovery: reflexes may be abnormal

Obviously, groups 2, 3, and 4 have a more favorable prognosis for recovery of ambulation than does group 1.

Once the degrees of injury to spine and cord have been assessed, some centers continue to administer methylprednisolone in high dosage (bolus of 30 mg/kg followed by 5.4 mg/kg every hour), beginning within 8 h of the injury and continued for 23 h. This measure, according to the multicenter National Acute Spinal Cord Study (Bracken et al) resulted in a slight but significant improvement in both motor and sensory function. Despite its widespread use, the therapeutic value of this measure has been questioned after careful reanalysis of the data (Nesathurai; Hurlbert) and it is no longer considered essential. Also, in a small series of patients, the administration of G_{M1} ganglioside (100 mg intravenously each day from the time of the accident) was found to enhance ultimate recovery to a modest degree (Geisler et al) but this finding has not been corroborated.

Next, radiologic examinations are undertaken to determine the alignment of vertebrae and pedicles, fracture of the pedicle or vertebral body, compression of the spinal cord or cauda equina due to malalignment, or bone debris in the spinal canal, and the presence of tissue damage within the cord. The MRI is ideally suited to display these processes but if it is not available myelography with CT scanning is an alternative. Instability of the spinal elements can often be inferred from dislocations or from certain fractures of the

pedicles, pars articularis, or transverse processes, but gentle flexion and extension of the injured areas must sometimes be undertaken and plain films obtained in each position.

If a cervical spinal cord injury is associated with vertebral dislocation, traction on the neck is necessary to secure proper alignment and maintain immobilization. This is best accomplished by use of a halo brace, which, of all the appliances used for this purpose provides the most rigid external fixation of the cervical spine. This type of fixation is usually continued for 4 to 6 weeks, after which a rigid collar may be substituted.

Concerning the early surgical management of spinal cord injury, there have been two schools of thought. One, represented by Guttmann and others, advocates reduction and alignment of the dislocated vertebrae by traction and immobilization until skeletal fixation is obtained, and then rehabilitation. The other school, represented by Munro and later by Collins and Chehrazi, proposes early surgical decompression, correction of bony displacements, and removal of herniated disc tissue and intra- and extramedullary hemorrhage; often the spine is fixed at the same time by a bone graft or other form of stabilization. The issue of acute decompressive surgery remains contentious to the present day. The MRI scan has altered these empirical approaches by clearly demonstrating hematomas and other sources of compression that may be amenable to surgery. With complete spinal cord lesions, most surgeons do not favor surgery.

The results of the conservative and aggressive surgical plans of management have been difficult to compare and have not been evaluated with modern neurologic techniques. Collins, a participant in the National Institutes of Health (NIH) study of acute management of spinal cord injury 20 years ago, concluded that the survival rate was increased as a result of early surgical stabilization of fractures and fixation of the spine. Other neurosurgeons, however, have not been able to document a reduction in neurologic disability as a result of early operation, and they have increasingly inclined toward nonoperative management of both complete and partial spinal cord lesions (see, for example, Clark; Murphy et al). Most American neurosurgeons take the less aggressive stance, delaying operation or operating only on patients with compound wounds or those with progression or worsening of the neurologic deficit despite adequate reduction and stabilization. In any given case, the approach must be guided by the particular features of the patient's injuries. A detailed description of the orthopedic and neurosurgical treatment of spinal fracture-dislocations is beyond the scope of a textbook of neurology but can be found in major textbooks of neurosurgery, and in the book on neurological intensive care by Ropper and colleagues listed in the References.

The greatest risk to the patient with spinal cord injury is in the first 10 days when gastric dilatation, ileus, shock, and infection are threats to life. According to Messard and colleagues, the mortality rate falls rapidly after 3 months; beyond this time, 86 percent of paraplegics and 80 percent of quadriplegics will survive for 10 years or longer. In children, the survival rate is even higher according to DeVivo and colleagues, who found that the cumulative 7-year survival rate in spinal cord-injured children (who had survived at least 24 h after injury) was 87 percent. Advanced age at the time of injury and being rendered completely quadriplegic were the worst prognostic factors.

The aftercare of patients with paraplegia, in addition to psychologic support, is concerned with management of bladder and bowel disturbances, care of the skin, prevention of pulmonary embolism, and maintenance of nutrition. Decubitus ulcers can be pre-

vented by frequent turning to avoid pressure necrosis, use of special mattresses, and meticulous skin care. Deep lesions require debridement and full-thickness grafting. At first, continual catheterization is necessary; then, after several weeks, the bladder can be managed by intermittent catheterization once or twice daily, using a scrupulous aseptic technique. Close watch is kept for bladder infection, which is treated promptly should it occur. Bacteruria is common and does not require treatment with antibiotics unless there is associated pyuria. Morning suppositories and periodically spaced enemas are the most effective means of controlling fecal incontinence. Chronic pain (present in 30 to 50 percent of cases) requires the use of nonsteroidal anti-inflammatory medication, injections of local anesthetics, and transcutaneous nerve stimulation. A combination of carbamazepine or gabapentin and either clonazepam or tricyclic antidepressants may be helpful in cases of burning leg and trunk pain. Recalcitrant pain may require more aggressive therapy, such as epidural injections of analgesics or corticosteroids or an implanted spinal cord stimulator that is applied to the dorsal columns, but often even these measures are ineffective. Spasticity and flexor spasms may be troublesome; oral baclofen, diazepam, or tizanidine may provide some relief. In permanent spastic paraparesis with severe stiffness and adductor and flexor spasms of the legs, intrathecal baclofen, delivered by an automated pump in doses of 12 to 400 mg/day, has also been helpful. The drug is believed to act at the synapses of spinal reflexes (Penn and Kroin). One must always be alert to the threat of pulmonary embolism from deep-vein thrombi, although the incidence is surprisingly low after the first several months. Physical therapy, muscle re-education, and the proper use of braces are all important in the rehabilitation of the patient. All this is best carried out in special centers for rehabilitation of spinal cord injuries.

Radiation Injury of the Spinal Cord

Delayed necrosis of the spinal cord and brain is a well-recognized sequela of radiation therapy for tumors in the thorax and neck. A lower motor neuron syndrome, presumably due to injury to the gray matter of the spinal cord, may also follow radiation therapy that includes the cord in its ports, as described below. Mediastinal irradiation for Hodgkin disease or for other lymphomas is a typical setting for the development of these complications.

Transient Radiation Myopathy An "early" type of radiation myopathy (appearing 3 to 6 months after radiotherapy) is characterized mainly by sensations in the extremities. The paresthesias may be evoked or exacerbated by neck flexion (Lhermitte symptom). In one of our patients there was impairment of vibratory and position sense in the legs, but no weakness. The sensory abnormalities disappear after a few months and, according to Jones, are not followed by the delayed progressive radiation myelopathy described later. The pathology has not been fully elucidated, but there is said to be a spongy appearance of the white matter with demyelination and depletion of oligodendrocytes.

Delayed Progressive Radiation Myopathy This is one of the most dreaded complications of radiation therapy. It is a progressive myelopathy that follows, after a characteristic latent period, the irradiation of malignant tissues in the vicinity of the spinal cord. The incidence of this complication is difficult to determine because many patients die of their malignant disease before the cord lesion fully evolves, but it is estimated to be between 2 and 3 percent

(Palmer). According to Douglas and colleagues, patients who have undergone hyperthermia as a treatment for cancer are particularly vulnerable to radiation myelopathy.

Clinical Features The neurologic disorder first appears 6 months or more after the course of radiation therapy, usually between 12 and 15 months (latent periods as long as 60 months or even longer have been reported). The onset is insidious, usually with sensory symptoms—paresthesias and dysesthesias of the feet or a Lhermitte phenomenon, and similar symptoms in the hands in cases of cervical cord damage. Weakness of one or both legs usually follows the sensory loss. Initially, local pain is notably absent, in distinction to the effects of spinal metastases. In some cases, the sensory abnormalities are transitory; more often, additional signs make their appearance and progress, at first rapidly and then more slowly and irregularly, over a period of several weeks or months, with involvement of the corticospinal and spinothalamic pathways. The neurologic disturbance may take the form of a Brown-Séquard syndrome, but with progression it is usually overtaken by a transverse myelopathy.

Reagan and coworkers, who have had much experience with this condition at the Mayo Clinic, describe yet another myelopathic radiation syndrome—namely, a slowly evolving amyotrophy, with weakness and atrophy of muscles and areflexia in parts of the body supplied by anterior horn cells of the irradiated spinal segments. Most patients with this form of the disease die within a year of onset. Knowledge of the pathology is incomplete. This syndrome is reminiscent of the delayed motor neuron myelopathy following electrical or lightning injury described in the next section.

The CSF in delayed progressive radiation myelopathy is normal except for a slight elevation of protein content in some cases. MRI demonstrates an abnormal signal intensity, decreased in T1-weighted and increased in T2-weighted images. Early in the course of the myelopathy the cord may be swollen, and there is often enhancement with gadolinium infusion. The cord lesion corresponds to the irradiated portal, which can be identified by the radiation effect on the marrow of the overlying vertebral bodies. The spinal cord lesion tends to be more extensive in rostral-caudal dimension than the usual vascular or demyelinative lesion. These are important points to establish, because a mistaken diagnosis of intraspinal tumor may lead to an unnecessary operation or further irradiation.

Pathologic Findings Corresponding with the level of the irradiated area and extending over several segments, there is an irregular zone of coagulation necrosis involving both white and gray matter, the former to a greater extent than the latter. Varying degrees of secondary degeneration are seen in the ascending and descending tracts. Vascular changes—necrosis of arterioles or hyaline thickening of their walls, with thrombotic occlusion of their lumens—are prominent in the most severely damaged portions of the cord. Most neuropathologists have attributed the parenchymal lesion to the blood vessel changes; others believe that the degree of vascular change is insufficient to explain the necrosis (Malamud et al; Burns et al). Certainly the most severe parenchymal changes in the cord are typical of infarction; but the insidious onset and slow, steady progression of the clinical disorder and the coagulative nature of the necrosis would then have to be explained by a steady succession of vascular occlusions. Exceptional instances, in which a transverse myelopathy has developed within a few hours (as described by Reagan et al), are more readily explained by thrombotic occlusion of a larger spinal artery.

Neurologists attached to tumor treatment centers are some-

times confronted with a patient who exhibits the late development (up to 10 to 15 years after radiation) of a slowly progressive sensorimotor paralysis of a limb (motor weakness predominates). The condition raises questions of recurrent tumor or the development of a local sarcoma, but the absence of a mass lesion and of pain, and the signs on neurologic examination are most consistent with a regional fibrosing plexopathy or neuropathy. Examples that we have seen are multiple cranial neuropathies after radiation of nasopharyngeal tumors, cervical and especially brachial neuropathies after laryngeal and breast cancers, and lumbosacral plexopathies and cauda equina damage with pelvic radiation. These are discussed further in Chap. 46 on diseases of the peripheral nerves.

Treatment and Prevention It must be kept in mind that radiation myelopathy is an iatrogenic disease and is therefore largely preventable. The tolerance of the adult human spinal cord to radiation—taking into account the volume of tissue irradiated, the duration of the irradiation, and the total dose—has been determined by Kagan and colleagues. These authors reviewed all of the cases in the literature up to 1980 and concluded that radiation injury could be avoided if the total dose was kept below 6000 cGy and was given over a period of 30 to 70 days, provided that each daily fraction did not exceed 200 cGy and the weekly dose was not in excess of 900 cGy. It is noteworthy that in the cases reported by Sanyal and associates, the amount of radiation surpassed these limits. Forewarned with this knowledge, radiation specialists have the impression that the incidence of this complication is decreasing.

A number of case reports remark on temporary improvement in neurologic function after the administration of corticosteroids. This therapy should be tried, because in some patients it appears to arrest the process short of complete destruction of all sensory and motor tracts. Claims have also been made of regression of early symptoms in response to the administration of heparin split products or hyperbaric oxygen, neither confirmed.

Spinal Cord Injury due to Electric Currents and Lightning

Among acute physical injuries to the spinal cord, those due to electric currents and lightning, despite their rarity, are of interest because of their unique clinical characteristics. Electrical forces can also injure the brain and peripheral nerves. These effects are noted briefly, since they are infrequent. It is the spinal cord that is most severely damaged.

Electrical Injuries In the United States, inadvertent contact with an electric current causes about 1000 deaths annually and many more nonfatal but serious injuries. About one-third of the fatal accidents result from contact with household currents.

The factor that governs the damage to the nervous system is the amount of current, or amperage, with which the victim has contact, not simply the voltage, as is generally believed. In any particular case, the duration of contact with the current and the resistance offered by the skin (this is greatly reduced if the skin is moist or a body part is immersed in water) are of critical importance. The physics of electrical injuries is much more complex than these brief remarks indicate (for a full discussion, see the reviews by Panse and by Winkelmann).

Any part of the peripheral or central nervous system may be injured by electric currents and lightning. The effects may be immediate, which is understandable, but of greater interest are the instances of neurologic damage that occur after a delay of 1 day to

6 weeks (1 week on the average) and a rarer syndrome of anterior horn cell damage that arises many years later. The immediate effects are apparently the result of direct heating of the nervous tissue, but the pathogenesis of the delayed effects is not well understood. They have been attributed to vascular occlusive changes induced by the electric current, a mechanism proposed to underlie the delayed effects of radiation therapy (see earlier). However, the latent period is measured in many months or a few years rather than in days and the course is more often progressive than self-limited. Moreover, the few postmortem studies of myelopathy due to electrical injury have disclosed a widespread demyelination of long tracts, to the point of tissue necrosis in some segments, and relative sparing of the gray matter, but no abnormalities of the blood vessels. There may also be spinal fracture from the vigorous muscle contraction.

The syndrome of focal muscular atrophy occurring with a delay of weeks to years after an electric shock has been described by Panse under the title of *spinal atrophic paralysis*. It occurs when the path of the current, usually of low voltage, is from arm to arm (across the cervical cord) or arm to leg. Pain and paresthesias occur immediately in the involved limb but these symptoms are transient. Mild weakness, also unilateral, is immediate, followed in several weeks or months by muscle wasting, most often taking the form of segmental muscular atrophy. Occasionally the syndrome simulates that of amyotrophic lateral sclerosis or transverse myelopathy (most patients have some degree of weakness and spasticity of the legs). However, we have encountered two cases of asymmetric and profound atrophic weakness of the arms that began almost two decades after the shock and progressed over many years without long tract signs, both with a previously presumed diagnosis of amyotrophic lateral sclerosis. In contrast to injuries due to high-tension current, which affects mainly the spinal white matter (see earlier), it is the gray matter that is injured in cases of spinal atrophic paralysis, at least as judged from the clinical effects.

When the head is one of the contact points, the patient may become unconscious or suffer tinnitus, deafness, or headache for a short period following the injury. In a small number of surviving patients, after an asymptomatic interval of days to months, there has been an apoplectic onset of hemiplegia with or without aphasia or a striatal or brainstem syndrome, presumably due to thrombotic occlusion of cerebral vessels with infarction of tissue but this is not well studied.

Lightning Injuries The factors involved in injuries from lightning are less well defined than those from electric currents, but the effects are much the same. The risk of being struck by lightning is about 30 times greater in rural areas than in cities. Direct strikes are often fatal; nearby strikes produce the neurologic damage described below. Topographic prominences such as trees, hills, and towers are struck preferentially, so these should be avoided; a person caught in the open should curl up on the ground, lying on one side with legs close together.

Arborescent red lines or burns on the skin indicate the point of contact of lightning. The path through the body can be approximately deduced from the clinical sequelae. Death is due to ventricular fibrillation or to the effects of intense desiccating heat on vital regions of the brain. Lightning that strikes the head is particularly dangerous, proving fatal in 30 percent of cases. Most persons struck by lightning are initially unconscious, irrespective of where they are struck. In those who survive, consciousness is usually regained rapidly and completely. Rarely, unconsciousness or an

agitated-confusional state may persist for a week or two. There is usually a disturbance of sensorimotor function of a limb or all the limbs, which may be pale and cold or cyanotic. As a rule, these signs are also evanescent, but in some instances they persist, or an atrophic paralysis of a limb or part of a limb makes its appearance after a symptom-free interval of several months as in the case of electrical injury. Persistent seizures are surprisingly rare.

There are a few cases on record of recovery from a severe generalized polyneuropathy after lightning injury, but our only experience with one case suggested a severe and permanent generalized axonal damage (see Chap. 46).

Myelopathy Following Spinal Anesthesia

This subject is introduced here with the other forms of cord injury for want of a better way to classify it. A transient and often asymmetric paraparesis is known to occur following prolonged spinal anesthesia but this is probably the temporary effect of the injected agents on cauda equina roots (Chap. 46). A more serious and permanent injury is caused by inadvertent injection of anesthetic directly into the conus medullaris (see Hamandi and colleagues and Wilkinson et al). Leg weakness and numbness on one side are reported by the patient immediately with the injection (or upon awakening if sedation is used in addition). The MRI reveals an eccentrically placed traumatic lesion within the caudal spinal cord. This complication is rare but has occurred even when experienced anesthesiologists perform the procedure; misidentification of the L3-4 spinal interspace has been the usual problem. Flat tipped needles are as likely to cause injury as are ones with sharp beveled tips. Arachnoiditis from irritative agents may also cause a myelopathy (page 1078).

MYELITIS

In the nineteenth century, almost every disease of the spinal cord was labeled *myelitis*. Morton Prince, writing in *Dercum's Textbook of Nervous Diseases* in 1895, referred to traumatic myelitis, compressive myelitis, and so on, obviously giving a rather imprecise meaning to the term. Gradually, however, as knowledge of neuropathology advanced, one disease after another was removed from this category until only the truly inflammatory ones remained.

Today the spinal cord is known to be the locus of a limited number of infective and noninfective inflammatory processes, some causing selective destruction of neurons, others affecting primarily white matter (tracts), and yet another group involving the meninges and white matter or leading to a necrosis of both gray and white matter. The currently accepted term for all these inflammatory conditions is *myelitis*. Other special terms are used to indicate more precisely the distribution of the process: if it is confined to gray matter, the proper expression is *poliomyelitis*; if to white matter, *leukomyelitis*. If approximately the whole cross-sectional area of the cord is involved, the process is said to be a *transverse myelitis* (although the term is still used more broadly for many myelitides); if the lesions are multiple and widespread over a long vertical extent, the modifying adjectives *diffuse* or *disseminated* are used. The term *meningomyelitis* refers to combined inflammation of meninges and spinal cord, and *meningoradiculitis*, to combined meningeal and root involvement. An inflammatory process limited to the spinal dura is called *pachymeningitis*; and if infected material collects in the epidural or subdural space, it is called *epidural* or *subdural spinal abscess* or *granuloma*, as the case may be. The

adjectives *acute*, *subacute*, and *chronic* denote the tempo of evolution of myelitic symptoms—viz., more or less within days, 2 to 6 weeks, or more than 6 weeks, respectively. The main causes of myelitis are listed below.

Classification of Inflammatory Diseases of the Spinal Cord

- I. Viral myelitis (Chap. 33)
 - A. Enteroviruses (groups A and B Coxsackie virus, poliomyelitis, others)
 - B. Herpes zoster
 - C. Myelitis of AIDS
 - D. Epstein-Barr virus (EBV), cytomegalovirus (CMV), herpes simplex
 - E. Rabies
 - F. Arboviruses—flaviviruses (Japanese, West Nile, etc.)
 - G. HTLV-1 (tropical spastic paraparesis)
- II. Myelitis secondary to bacterial, fungal, parasitic, and primary granulomatous diseases of the meninges and spinal cord (Chap. 32)
 - A. *Mycoplasma pneumoniae*
 - B. Lyme disease
 - C. Pyogenic myelitis
 - 1. Acute epidural abscess and granuloma
 - 2. Abscess of spinal cord
 - D. Tuberculous myelitis (Chap. 32)
 - 1. Pott disease with spinal cord compression
 - 2. Tuberculous meningomyelitis
 - 3. Tubercoloma of spinal cord
 - E. Parasitic and fungal infections producing epidural granuloma, localized meningitis, or meningomyelitis and abscess, especially certain forms of schistosomiasis (Chap. 32).
 - F. Syphilitic myelitis (Chap. 32)
 - 1. Chronic meningoradiculitis (tabes dorsalis)
 - 2. Chronic meningomyelitis
 - 3. Meningovascular syphilis
 - 4. Gummatus meningitis including chronic spinal parochymeningitis
 - G. Sarcoid myelitis (Chap. 32)
- III. Myelitis (myelopathy) of noninfectious inflammatory type (Chap. 36)
 - A. Postinfectious and postvaccinal myelitis
 - B. Acute and chronic relapsing or progressive multiple sclerosis (MS)
 - C. Subacute necrotizing myelitis and Devic disease
 - D. Myelopathy with lupus or other forms of connective tissue disease and antiphospholipid antibody
 - E. Paraneoplastic myelopathy and poliomyelitis (Chap. 31)

From this outline it is evident that many different and totally unrelated diseases are under consideration and that a general description cannot possibly encompass such a diversity of pathologic processes. Overall, myelitis due to MS and postinfectious processes will be found to be the most common causes in practice. This was the case in the series collected by de Seze and colleagues. Excluding compressive myelopathy or trauma, 34 were found to have MS, 5 were postinfectious, and 5 had spinal infarctions; Nowak and coworkers reported a similar distribution. As noted in the previous outline, many of the myelitides are considered elsewhere in this

volume in relation to the diseases of which they are a part. Here it is only necessary to comment on the principal categories and to describe a few of the common subtypes.

Myelitis due to Viruses (See also Chap. 33)

The enteroviruses, of which Coxsackie and poliomyelitis are examples, herpes zoster, arboviruses such as West Nile and the equine encephalitic viruses, and AIDS are the important members of this category. The enteroviruses in particular have an affinity for neurons of the anterior horns of the spinal cord and a motor nuclei of the brainstem (i.e., they are neuronotropic and cause a disease that can be generically termed *poliomyelitis*), and herpes zoster virus for the dorsal root ganglia; hence the disturbances of function are in terms of motor and sensory neurons, respectively, not of spinal tracts. West Nile virus is now showing the same proclivity for anterior horn cell damage. The onset of these conditions is acute and takes the form of a febrile meningomyelitis (see Chap. 33). Although there are systemic symptoms and sometimes cutaneous ones (in the case of zoster), it is the nervous system disorder that is most significant. The patient suffers the immediate effects of nerve cell destruction, and some degree of improvement nearly always follows as some neurons cells recover. Later in life, possibly as the neuronal loss of aging occurs in the anterior horns and dorsal root ganglia, there may be an apparent increased loss of strength in muscles originally weakened by poliomyelitis (“postpolio” syndrome, page 1104).

Relatively infrequent examples of transverse myelitis due to herpes simplex virus (HSV types 1 and 2), varicella-zoster virus (VZV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), and SV70 virus (epidemic conjunctivitis) have been reported, some in patients with immunodeficiency states, mainly AIDS. The situation is more complex clinically, since most of these agents may also produce a postinfectious variety of myelitis, described further on in this chapter and in Chaps. 33 and 36. In HSV type 2 and CMV infections, there may also be an acute lumbosacral radiculitis with urinary retention; and in VZV infections, a sensory ganglionitis, vasculitis, or encephalitis. In a few cases of zoster myelitis, there may be evidence of an extensive inflammatory necrosis of the spinal cord with involvement of sensory and motor tracts. In other words, these conditions may at times simulate acute paraplegic and tetraplegic transverse syndromes of nonviral type. Herpes zoster is the best example. Pleocytosis in the cerebrospinal fluid and isolation of the viral DNA by the polymerase chain reaction or by direct culture from the cerebrospinal fluid (CSF) confirm the diagnosis of a primary viral infection as discussed in Chap. 33 (see Dawson and Potts).

There are other rare forms of poliomyelitic reactions of unknown, possibly viral etiology. One such condition presents as an acute febrile or afebrile meningomyelitis and leaves all the limbs paralyzed and flaccid, sparing the brainstem and affecting the diaphragm to a variable extent. Several such patients have harbored a carcinoma or Hodgkin disease, and the pathology proved to be like that of a poliomyelitic viral infection rather than the usual paraneoplastic syndromes. Also, we would emphasize that we have cared for several patients who have had destruction of anterior horn cells due apparently to an enterovirus other than poliomyelitis virus (see further on and Fig. 33-3, page 650).

Involvement of the white matter with sensory and motor palsy below the level of a lesion has also been reported in so-called dumb rabies (in contrast to the usual form of “mad” or “fu-

rious" rabies encephalitis), and in an infection transmitted by the bite of a monkey, called the *B virus*. These are decidedly rare. Far more common are the viral myelopathy of AIDS and of HTLV-1 infection. With these exceptions, one may say that any myelitis that expresses itself by dysfunction of motor and sensory tracts will usually prove not to be viral in origin but due rather to one of the disease processes in category III (noninfectious, inflammatory) of the preceding classification. The unique vacuolar myelopathy of AIDS and the myelopathy of human HTLV infections are described later and also in Chap. 33.

Vacuolar Myelopathy with AIDS (see also page 646) As the neurology of AIDS has been elucidated, this new clinical and pathologic entity has emerged. Its frequency is impressive—20 of 89 successive cases of AIDS on whom a postmortem examination was performed by Petito and colleagues. Often the clinical symptoms and signs of spinal cord disease are obscured by a neuropathy or one or more of the cerebral disorders that complicate AIDS—due either to HIV or to an opportunistic infection (CMV disease, toxoplasmosis, etc.). In five cases of severe vacuolar myelopathy in Petito's series there was leg or leg and arm weakness, often asymmetrical and developing over a period of weeks, to which the signs of sensory tract involvement and sphincteric disorder were added. A sensory ataxia has been a common early feature in our experience. The CSF shows a small number of lymphocytes, a slight elevation of protein, and, occasionally, bizarre giant cells.

The white matter of the spinal cord is vacuolated, most severely in thoracic segments. The posterior and lateral funiculi are affected diffusely. Axons are involved to a lesser degree than myelin sheaths, and lipid-laden macrophages are present in abundance. Similar vacuolar lesions may be seen in the brain in some cases. Although the lesions in the spinal cord resemble those of subacute combined degeneration, levels of vitamin B₁₂ and folic acid have been normal. A similar lesion was seen in one of our cases of chronic lupus erythematosus.

Often there are coexistent features of AIDS dementia or one of the several neuropathies that occur in the intermediate and advanced stages of the disease (discussed in Chap. 33). The antiretroviral drugs that slow the progress of AIDS, with a few exceptions, seem to have little effect on the myelopathy and one can only resort to the symptomatic treatment of spasticity.

Tropical Spastic Paraparesis due to Human T-Cell Lymphotropic Virus Type I (HTLV-I) The so-called tropical myeloneuropathies were drawn to the attention of neurologists 50 years ago through the observations and writings of Cruickshank. However, it is only relatively recently that a chronic infective-inflammatory disease of the spinal cord due to the retrovirus HTLV-I has been discovered and the connection made to tropical myelitis. The implications of this discovery are broad and extend even to the demyelinative and possibly the degenerative diseases.

Spinal cord disease of this type has been reported from the Caribbean islands, southern United States, southern Japan, South America, and Africa. The clinical picture is one of a slowly progressive paraparesis with increased tendon reflexes and Babinski signs; disorder of sphincteric control is usually an early change. Paresthesias, reduced vibratory and position senses, and ataxia are the usual features. A few patients have had an associated polyneuropathy, as in Cruickshank's early cases. The upper extremities are usually spared (except for lively tendon reflexes), as are cerebral and brainstem functions.

The CSF contains small numbers of lymphocytes of T type (10 to 50 per cubic millimeter), normal concentrations of protein and glucose, and an increased content of IgG with antibodies to HTLV-I. The diagnosis is confirmed by the detection in the serum of the antibodies to the virus. Thinness of the spinal cord is evident on MRI, and subcortical cerebral white matter lesions may be seen as well. Neuropathologic study has documented an inflammatory myelitis with focal spongiform, demyelinative, and necrotic lesions, perivascular and meningeal infiltrates of inflammatory cells, and focal destruction of gray matter. The posterior columns and corticospinal tracts are the main sites of disease, most evident in the thoracic cord. It is strongly suspected but not established that the disease is due to the cytotoxic effect of the viral infection but autoimmune damage is an alternative possibility.

Because of slow evolution, the clinical picture can easily be confused with that of progressive spastic paraparesis of the heredofamilial variety, sporadic motor neuron disease, or the chronic phase of MS. There are also similarities with the AIDS myelopathy described earlier, but the other features of HIV infection are absent. Tropical spastic paraparesis and HTLV-I are also considered in the chapter on viral disease (page 647). There are anecdotal reports of improvement with intravenous administration of gamma globulin but these have not been consistent and had no effect in two of our patients.

Myelitis Secondary to Bacterial, Fungal, Parasitic, and Granulomatous Diseases

With few exceptions, this class of spinal cord disease seldom offers any difficulty in diagnosis. The CSF usually holds the clue to causation. In most cases, the inflammatory reaction in the meninges is only one manifestation of a generalized (systemic) disease process. The spinal lesion may involve primarily the pia-arachnoid (leptomeningitis), the dura (pachymeningitis), or the epidural space, e.g., taking the form of an abscess or granuloma; in the last circumstance, damage to the spinal cord is due to compression and ischemia. In some acute forms, both the spinal cord and meninges are simultaneously affected, or the cord lesions may predominate. Chronic spinal meningitis may involve the pial arteries or veins; and as the inflamed vessels become thrombosed, infarction (myelomalacia) of the spinal cord results. Chronic meningeal inflammation may provoke a progressive constrictive pial fibrosis (so-called spinal arachnoiditis) that virtually strangulates the spinal cord. In certain instances, spinal roots become progressively damaged, especially the lumbosacral ones, which have a long meningeal exposure. Posterior roots, which enter the subarachnoid space near arachnoidal villi (where CSF is resorbed), tend to suffer greater injury than anterior ones (as happens in tabes dorsalis). Interestingly, there are cases of chronic cerebrospinal meningitis that remain entirely without symptoms until the spinal cord or roots become involved.

The infrequent but unique bacterial myelitis caused by the atypical pneumonia agent *Mycoplasma pneumoniae* has come to be viewed as a postinfectious immune disease, as discussed on page 601. However, portions of the DNA from this organism have been found in the spinal fluid early in the course of illness in some cases (using the polymerase chain reaction), suggesting instead a direct bacterial infection of the spinal cord (see Chap. 32). It is not known whether antibiotic treatment alters the course of the illness.

Syphilitic myelitis is discussed on page 618. *Bacterial abscess of the spinal cord* (acute bacterial myelitis) is rare (especially in

comparison to epidural spinal abscess) and is only beginning to be recognized by MRI. At times it stands as a single pyogenic metastasis, but more often there has been spread from a contiguous infected surgical site or a fistulous connection with a superficial paraspinal abscess or a distant infection and subsequent bacteremia. As stated, *spinal epidural abscess and granuloma* are the more important representatives of this group.

Sarcoid myelitis (see also page 613) *Sarcoid* granulomas may present as one or more intramedullary spinal cord masses, as in the cases reported by Levivier and colleagues. In our experience the granulomatous lesion, which may be focal or multifocal, simulates demyelinative disease with respect to its tendency to relapse and remit and in its notable but inconsistent response to corticosteroids (page 614). An asymmetrical ascending paraparesis and bladder disturbance have been the main features in our patients. Usually there is evidence of disseminated sarcoidosis and the CSF is abnormal (increase in cells and protein), but we have encountered several instances of sarcoid restricted to the spinal cord before it was evident in the mediastinum (i.e., chest CT failing to demonstrate hilar adenopathy). Elevation of the spinal fluid IgG concentration and the presence of oligoclonal bands are typical but not constant in these cases of neurosarcoidosis; often there are activated histiocytes in the CSF. The use of angiotensin-converting enzyme levels in the CSF to distinguish sarcoidosis from MS suffers from the lack of normative values for this test, but it is said to be elevated in two-thirds of patients. The MRI is abnormal and the conus or other portions of the cord reveal intramedullary lesions. The most characteristic finding, however, is a multifocal-subpial nodular enhancement of the meninges adjacent to a lesion of the cord or nerve roots—a picture which to some extent resembles neoplastic meningeal infiltration. The diagnosis can be confirmed by mediastinal lymph node biopsy or by the less desirable method of biopsy of the spinal meninges and affected subpial cord.

A number of other rare granulomatous conditions have on occasion caused an intrinsic or, more often, an extrinsic compressive myelopathy, including brucellosis, xanthogranulomatosis, and eosinophilic granuloma. The diagnosis may be suspected if the systemic disease is apparent at the time, but in some instances only the histology of a surgical specimen reveals the underlying process.

Spinal Epidural Abscess This condition is worthy of emphasis because the diagnosis is often missed or mistaken for another disease, sometimes with disastrous results. Children or adults may be affected. Infection of the epidural space has a wide variety of sources. *Staphylococcus aureus* is the most frequent etiologic agent, followed in frequency by streptococci, gram-negative bacilli, and anaerobic organisms. An injury to the back, often trivial at the time, furunculosis or other skin or wound infection, or a bacteremia may permit seeding of the spinal epidural space or of a vertebral body. This gives rise to osteomyelitis with extension of the purulent process to the epidural space. Occasionally, it spreads from an infected disc. One frequent source is a septicemia in a drug addict following the use of nonsterile needles or the injection of contaminated drugs. In other cases organisms may be introduced into the epidural space during spinal surgery or rarely via a lumbar puncture needle during epidural or spinal anesthesia or from epidural injections of steroid or other therapeutic agents. The localization in these latter instances is over the lumbar and sacral roots. In these cases of *cauda equina epidural abscess*, back pain may be severe and neurologic symptomatology minimal unless the infection extends

upward to the upper lumbar and thoracic segments of the spinal cord.

At first, the suppurative process is accompanied only by low-grade fever and aching local back pain, usually intense, followed within a day or several days by radicular pain in most cases. Headache and nuchal rigidity are sometimes present; more often there is just the persistent pain and a disinclination to move the back. After several more days, there is the onset of a rapidly progressive paraparesis and paraplegia or quadriplegia associated with sensory loss in the lower parts of the body and sphincteric paralysis. Percussion of the spine elicits considerable tenderness over the site of the infection. Examination discloses all the signs of a complete or partial transverse cord lesion, occasionally with elements of spinal shock if paralysis has evolved rapidly, which is rare. If a spinal puncture has been performed, the CSF contains a relatively small number of white cells (usually fewer than 100 per cubic millimeter), both polymorphonuclear leukocytes and lymphocytes, unless the needle penetrates the abscess, in which case pus is obtained. The protein content is high (100 to 400 mg/100 mL or more), but the glucose is normal. Elevation of the sedimentation rate and peripheral neutrophilic leukocytosis are important clues (often neglected) to the diagnosis (Baker et al).

Treatment The foregoing clinical findings call for immediate MRI (Fig. 44-2) or CT, the latter preferably with myelography, to demonstrate the abscess and determine its level. If not treated surgically by laminectomy and drainage at the earliest possible time, before the onset of paralysis, the spinal cord lesion, which is due in part to ischemia (compression mainly of veins), becomes more or less irreversible. Broad spectrum antibiotics in large doses must be given initially and the choice of treatment is then refined based on cultures from the abscess or the blood, or on the presumed source of bacteria. Cauda equina epidural abscess without neurologic signs may in many cases be treated solely with antibiotics, although some surgeons favor drainage, which must be undertaken in any case if osteomyelitis develops. When osteomyelitis of a vertebral body is the primary abnormality, the epidural extension may implicate only a few spinal sensory and motor roots, leaving long tracts and other intramedullary structures intact. In some cases with cervical epidural abscesses, stiff neck, fever, and deltoid-biceps weakness are the main neurologic abnormalities. Having emphasized the urgency of treatment, there are instances of small epidural abscesses that do not compress the cord and are limited to one or at most two levels for which we have avoided surgery by administering antibiotics alone. Antibiotics need to be continued for several weeks, and the patient should be examined at regular intervals and have sequential MRI scans of the affected region.

Even after apparently successful drainage and antibiotic treatment of an epidural abscess, there may be a slowly progressive and then stabilizing syndrome of incomplete cord compression. This is the result of formation of a fibrous and granulomatous reaction at the operative site. Distinguishing this inflammatory mass from residual epidural abscess may be difficult, even with enhanced MRI, but persistent fever, leukocytosis, and an elevated sedimentation rate should suggest that surgical drainage of the abscess was incomplete.

Spinal subdural bacterial infections also occur and, clinically, are virtually indistinguishable from epidural ones on clinical grounds. A clue is provided by the CT myelogram, in which the subdural lesion has a less sharp margin and a greater vertical extent. The difference in configuration is also appreciated on MRI. The epidural and subdural infections, if they smolder owing to delayed

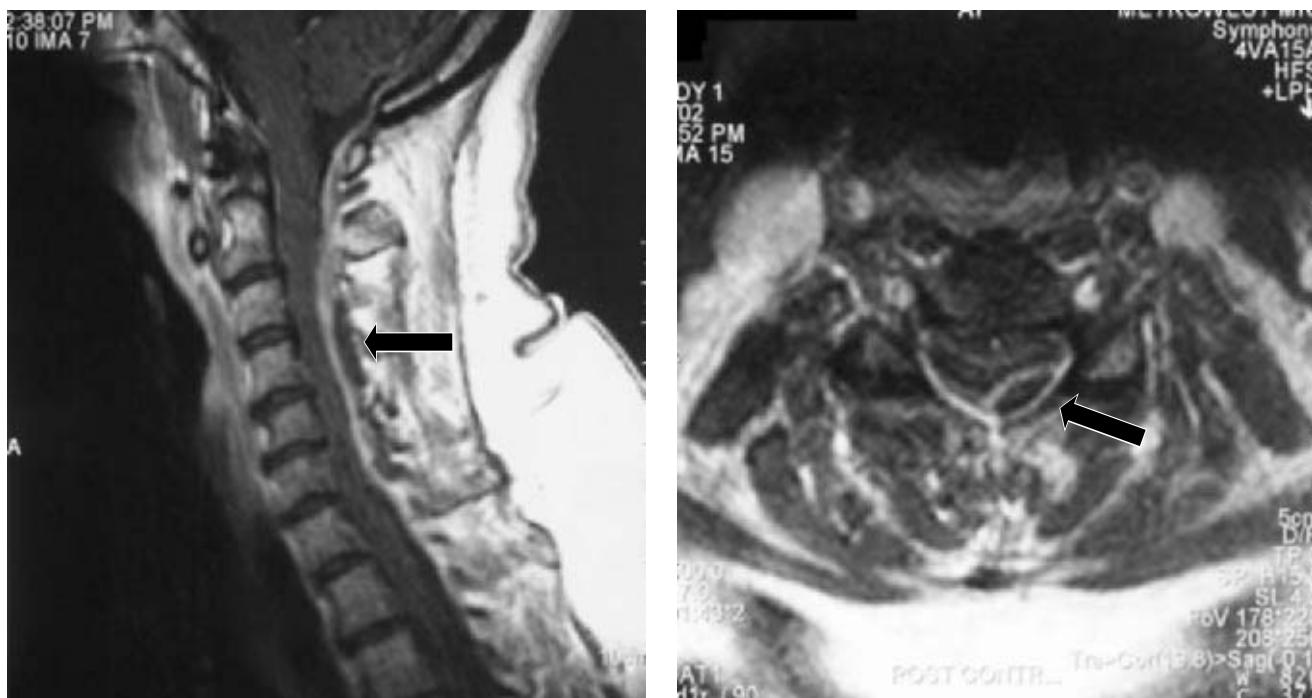

Figure 44-2. MRI of spinal epidural abscess compressing the dorsolateral cervical cord. T-1 gadolinium-enhanced images. Sagittal (left) and axial (right) images. The pyogenic collection enhances at the periphery and extends over several segments. The pyogenic collection is shown by the arrows.

diagnosis or inadequate therapy, may evolve into a local chronic adhesive meningoileitis.

Subacute pyogenic infections and granulomatous infections (tuberculous, fungal) may also arise in the spinal epidural space, as noted below.

Spinal Cord Abscess This entity was first described by Hart in 1830 and, although it is rare, 73 cases had been reported by 1994 (Candon and Frerebeau). In some instances the patient was known to have had systemic bacterial infection, septicemia, or endocarditis; in others there was a contiguous abscess in the skin or subcutaneous tissues with a fistula to the spinal cord through an intervertebral foramen. Spinal cord abscess is a rare complication of spinal dysraphism or of a developmentally open fistulous tract. The symptoms are indistinguishable from those of epidural abscess—namely, spinal and radicular pain followed by sensory and motor paralysis; the CSF findings are also the same. Woltman and Adson described a patient in whom surgical drainage of an encapsulated intramedullary abscess led to recovery, and Morrison and associates reported a similar case caused by *Listeria monocytogenes*, which was successfully drained and the meningeal infection suppressed by ampicillin and chloramphenicol. MRI is the most useful diagnostic procedure.

Tuberculous Spinal Osteomyelitis (Pott disease) Tuberculous osteitis of the spine with kyphosis (Pott disease) is well known in regions of endemic tuberculosis. Children and young adults are most often affected. The osteomyelitis is the result of reactivation of tuberculosis at a site previously established by hematogenous spread. An infectious endarteritis causes bone necrosis and collapse of a thoracic or upper lumbar (less often cervical) vertebral body resulting in a highly characteristic angulated kyphotic deformity

(Fig. 44-3); any degree of additional rotary instability produces a gibbus deformity. Most patients have some evidence of active infection as evidenced by fever, night sweats, and other constitutional symptoms; the sedimentation rate is invariably elevated. A compressive myelopathy occurs in some cases as a result of the spinal deformity, but it is surprisingly infrequent and an epidural tuberculous abscess is a more common cause of cord compression (see below). What is surprising to us about Pott disease is the excellent result that may be obtained by external stabilization of the spine and long-term antituberculous medication. While there is some controversy regarding spinal surgery, it is required only in the presence of severe deformities or a compressive myelopathy.

Tuberculous Myelitis Solitary tuberculoma of the spinal cord as part of a generalized infection is an extreme rarity. More often, pus or caseous granulation tissue may extrude from an infected vertebra and gives rise to an epidural compression of the cord (Pott paraplegia, as distinct from Pott disease). Occasionally a tuberculous meningitis may result in pial arteritis and spinal cord infarction. The paraplegia may appear before the tuberculous meningitis is diagnosed. All these forms of tuberculosis have become infrequent in the United States and western Europe but we see a new case every several years in patients who spent their earlier life in India or Africa. Additional comments can be found on page 611.

Meningomyelitis due to Fungus and Parasitic Diseases A wide variety of fungal and parasitic agents may involve the spinal meninges. Such infections are rare, and some do not occur at all in the United States or are limited to certain geographic areas, particularly among immigrant populations. *Actinomycetes*, *Blastomyces*, *Coccidioides*, and *Aspergillus* may invade the spinal epidural space via intervertebral foramina or by extension from a vertebral osteo-

Figure 44-3. MRI in Pott tuberculous spine disease. The angulated deformity of the thoracic spine is highly characteristic. (Courtesy of Dr. Randall Edgell, New York University Medical Center.)

myelitic focus. *Cryptococcus*, which causes meningoencephalitis and rarely a cerebral granuloma, in our experience seldom causes spinal lesions. Hematogenous metastases to the spinal cord or meninges may occur in both blastomycosis and coccidioidomycosis. Occasionally an echinococcal infection of the posterior mediastinum may extend to the spinal canal (epidural space) via intervertebral foramina and compress the spinal cord.

Schistosomiasis (bilharziasis) is a recognized cause of myelitis in the Far East, Africa, and South America. The spinal cord is a target for all three common forms of *Schistosoma*: *S. haematobium*, *S. japonicum*, and *S. mansoni*, but particularly the last of these (see page 627). The schistosomal ova evoke an intense granulomatous myelomeningoradiculitis. The lesions are destructive of gray and white matter, with ova in arteries and veins leading to vascular obstruction and ischemia (Scrimgeour and Gajdusek). Less often, a localized granuloma gives rise to a compressive cord

syndrome and, rarely, the disease takes the form of an acute transverse myelitis with massive necrosis of cord tissue (Queiroz et al.). A pruritic “swimmer’s itch” at the site of entry of the parasite is reported by many patients in the days prior to the myelopathy. We have cared for two patients in whom the spinal cord in the low thoracic and lumbar region was infected approximately 3 weeks after they swam in contaminated water during an African vacation. The CSF showed only a slight elevation of protein, and there was no abnormality in the myelogram. Systemic and CSF eosinophilia is variable so cannot be depended on for diagnosis. The administration of praziquantel arrested the course of the illness, but the patients were left disabled.

Myelitis of Noninfectious Inflammatory Type (Acute and Subacute Transverse Myelitis; See also Chap. 36 on Demyelinating Disease)

The spinal cord disorders that make up this category take the form mainly of a leukomyelitis based on either demyelination or necrosis of the tracts in the spinal cord. The critical factor in their pathogenesis appears to be a disordered immune response, in some cases, to an infection, and in others, idiopathic. Varied clinical syndromes are produced, and the basic disease is classified in most textbooks under headings such as *acute transverse myelitis*, *postinfectious myelitis*, *postvaccinal myelitis*, *acute MS*, and *necrotizing myelitis*. While each of these conditions may affect other parts of the nervous system (most often the optic nerves or brain), often the only manifestations are spinal. The aforementioned myelopathies are sufficiently distinct to justify their separate classification, for in most cases they are isolated syndromes; but transitional cases sharing the clinical and pathologic attributes of more than one disease are encountered in any large clinical and pathologic material.

Postinfectious and Postvaccinal Myelitides The characteristic features of these diseases are (1) their temporal relationship to certain viral infections or vaccinations (see page 791); (2) the development of neurologic signs over the period of a few days; and (3) a monophasic temporal course, i.e., a single attack of several weeks’ duration with variable degrees of recovery and no recurrence. These diseases may involve the brain as well as the spinal cord, in which case the process is properly designated as *acute disseminated encephalomyelitis* (ADEM). On the basis of the clinical features of disseminated postinfectious encephalomyelitis and the animal model of experimental allergic encephalomyelitis (EAE), postinfectious myelitis is presumed to be immunologic in nature, reflecting an attack that is more or less confined to spinal cord myelin (see Chap. 36).

The usual history in these cases is for weakness and numbness of the feet and legs (less often of the hands and arms) to develop over a few days, at times longer, and for the sensory symptoms to ascend from the feet to the trunk. Paresthesias in the feet and legs are a common early symptom. Sphincteric disturbances and backache are also common in the first days. A slight asymmetry of the symptoms and signs, a sensory level on the trunk, or a Babinski sign clearly marks the disease as a myelopathy and serves to distinguish it from a rapidly progressive polyneuropathy such as the Guillain-Barré syndrome. Back pain of varying degree and headache and stiff neck may or may not be present. In about half of cases the patient can identify a recent infectious illness, usually a mundane upper respiratory syndrome, but there is no fever when

the neurologic symptoms begin. The illness evolves over several days, sometimes a single day or on the other extreme, over one to 2 weeks. Despite the term *transverse myelitis*, fewer than half of cases demonstrate a “transverse” involvement of the cord; more often there is an incomplete corticospinal and spinothalamic syndrome affecting one side more than the other. As discussed later, after only a single episode, it is difficult to distinguish this myelitis from the first attack of MS.

Almost invariably the CSF contains lymphocytes and other mononuclear cells in the range of 10 to 100 per cubic millimeter (sometimes higher), with slightly raised protein and normal glucose content. There may be only 3 or 4 cells per cubic millimeter, or none, making the inflammatory aspect less clear. Oligoclonal bands are usually absent. In most instances that have come under our care, the MRI has shown some degree of T2 signal abnormalities and slight gadolinium enhancement extending over two or three spinal segments. The cord may be swollen in these regions (Fig. 44-4), however, several of our patients with mild and partial myelitis have had normal MRI studies.

Clinical variants of this syndrome are frequent in our experience; including: an almost pure paresthetic illness with posterior column dysfunction and the converse; a symmetrical paraparesis with analgesia below a level on the trunk but without involvement of deep sensation (a syndrome usually associated with infarction in the territory of the anterior spinal artery); a syndrome of variable sensory loss involving the leg and groin on one side or both; a purely lumbosacral or sacral myopathy (conus syndrome with saddle analgesia and sphincter disturbances); and a partial Brown-Séquard syndrome.

In the past, postinfectious myelitis was most often observed in relation to the common exanthems (rubella, rubeola, varicella). The neurologic signs appeared as the rash was fading, often with a slight recrudescence of fever. Practically all human viruses have at one time or another been found to precede acute myelitis; the large DNA viruses such as Epstein-Barr and cytomegalovirus are most common, but hepatitis B, varicella, and enter- and rhinoviruses have been detected when sought systematically. *Mycoplasma* is almost unique as a bacterial trigger of the disease, but—as noted earlier—there is some uncertainty regarding its ability to cause direct infection rather than a postinfectious immune reaction; our interpretation of the existing information still favors a postinfectious etiology. In most instances the connection to a preceding infection is presumed but cannot be proved. Only the associations with EBV, CMV, and *Mycoplasma* seem fairly certain based on the regularity of their occurrence or perhaps the relative ease with which a recent infection can be documented by serologic tests. The list of antecedent infections is otherwise much the same as that for the Guillain-Barré syndrome with the notable absence of *Campylobacter jejuni*, which has not led to myelitis. It can be reasonably assumed that pharyngitis, respiratory infection, or conjunctivitis, etc., with or without fever, was a likely trigger for myelitis if it occurred during the several days before or even in a 2- to 3-week period prior to the neurologic symptoms. Severe headache with fever and subsequent myelitis suggests *Mycoplasma*, influenza or another atypical pneumonia agent, and the finding of abnormal liver function tests or severe pharyngitis with cervical adenopathy usually indicates EBV or, less often, CMV infection.

More difficult to understand are the large number of instances

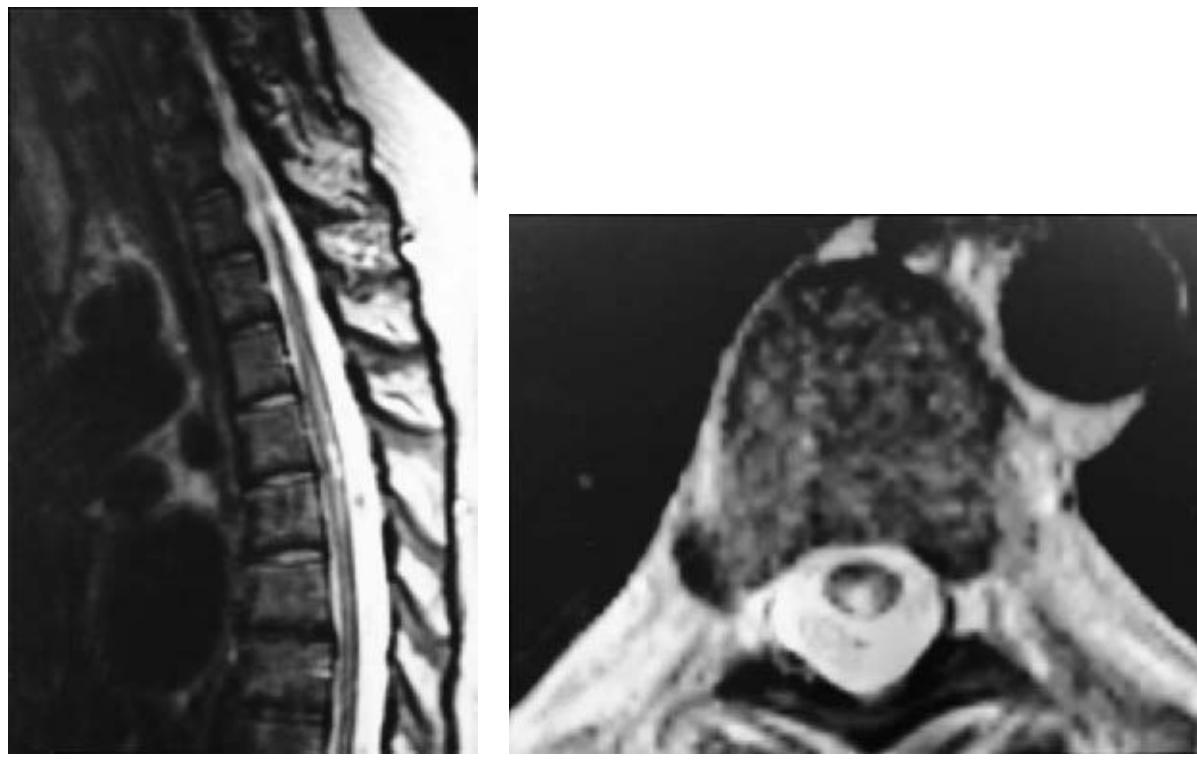

Figure 44-4. MRI of acute postinfectious myelitis in the sagittal (A) and axial (B) planes. There is T2 signal change and other images showed mild enhancement after gadolinium infusion. The cord is slightly enlarged at the involved level.

of myelitis, including autopsy proven ones, in which the disease develops without an apparent antecedent infection. There is understandable uncertainty in such cases as to whether the illness is the opening phase of MS of the type described below under "Demyelinative Myelitis." In the numerous cases of transverse myelitis under our care, fewer than half have shown other signs of MS after 10 to 20 years (this is a far lower incidence than following a bout of optic neuritis). Also, there is an isolated form of *relapsing myelitis*, sometimes but not always triggered by an infection that does not manifest lesions elsewhere in the neuraxis and therefore has an ambiguous relationship to MS. Further discussion of acute transverse myelitis in relation to other demyelinating diseases can be found below and on pages 778 and 791.

The *pathologic changes* take the form of numerous subpial and perivenular zones of demyelination, with perivascular and meningeal infiltrations of lymphocytes and other mononuclear cells, and para-adventitial pleomorphic histiocytes and microglia (page 772). Taken in isolation, these changes cannot be clearly distinguished from those of MS.

Treatment Once symptoms begin, it is doubtful if any treatment is of consistent value. One's first impulse, assuming the mechanism to be an autoimmune, is to administer high doses of corticosteroids—a practice we have followed but without conviction. Perhaps it is advisable to do so, but there is as yet no evidence that this alters the course of the illness. We have also used plasma exchange or intravenous immune globulin in several patients, with uncertain results, although this approach was seemingly helpful in a few patients who had an explosive clinical onset.

In general, the prognosis is better than the initial symptoms might suggest. Invariably, the myelitic disease improves, sometimes to a surprising degree, but there are examples in which the sequelae have been severe and permanent. Pain in the midthoracic region or an abrupt, severe onset usually indicates a poor prognosis (Ropper and Poskanzer). The authors have several times given a good prognosis for long-term recovery and assurance that no relapse will occur, only to witness a recrudescence of other symptoms at a later date, indicating that the original illness was MS.

Demyelinative Myelitis (Acute Multiple Sclerosis) The lesions of acute MS presenting as a myelitis share many of the features of the postinfectious type except that the clinical manifestations of the former tend to evolve more slowly, over a period of 1 to 3 weeks or even longer. Also, their relation to antecedent infections is less certain, and in most recorded examples such provocative events were lacking. Only the occurrence of subsequent attacks or additional lesions revealed by MRI or evoked potentials indicates that the basic illness is one of chronic recurrent demyelination, indistinguishable from the usual type of MS.

The most typical mode of clinical expression of demyelinative myelitis is with numbness that spreads over one or both sides of the body from the sacral segments to the feet, anterior thighs, and up over the trunk, with coincident but variable and usually asymmetric weakness and then paralysis of the legs. As this process becomes complete, the bladder is also affected. The sensorimotor disturbance may extend to involve the arms, and a sensory level can be demonstrated on the upper parts of the trunk. The CSF usually shows a mild lymphocytosis, as in the postinfectious variety, but it is as often normal. Oligoclonal bands may be absent with the first attack. Bakshi and colleagues have suggested that in myelitis due to MS, the changes seen on MRI occupy only a few adjacent spinal segments in comparison to the postinfectious le-

sions which have a longer vertical extent, but this has not been a consistent distinction in our experience. As a general rule, acute spinal MS is relatively painless and without fever, and the patient usually improves, with variable residual signs. Those cases with a necrotic element, Devic disease and the closely related subacute necrotic myelopathy, may stabilize but then worsen (see below).

The differential diagnosis of demyelinative myelitis is considered more fully in Chap. 36.

Treatment Corticosteroids, as outlined for the treatment of MS (page 787), may lead to a regression of symptoms, sometimes with relapse when the medication is discontinued (after 1 to 2 weeks). Other patients, however, show no apparent response, and a proportion of cases have even continued to worsen while the medication was being given. Plasma exchange and intravenous immune globulin have reportedly been beneficial in individual cases, particularly in those with an explosive onset (see later). The results in our patients have been too variable to interpret.

Acute and Subacute Necrotizing Myelitis and Devic Disease (see page 781) In every large medical center, occasional examples of this disorder are found among the many patients who present with a subacute paraparesis or quadriplegia, sensory loss, and sphincter paralysis. The neurologic signs may erupt so precipitously that a vascular lesion is assumed. In most other cases, the disease evolves at a slower and usually stepwise pace, over several months or years (Katz and Ropper). It is the saltatory progression that we have found most characteristic of the disease and, when present, that distinguishes it best from other processes such as a tumor within the cord. Necrotizing myelopathy is distinguished from the more common types of transverse myelitis by a persistent and profound flaccidity of the legs (or arms if the lesion is cervical), areflexia, and atonia of the bladder—all reflecting a widespread necrosis that involves both the gray and white matter of the spinal cord over a considerable vertical extent. This picture is unexpected for a spinal cord lesion and, therefore, is often mistakenly attributed to spinal shock or to a completely different process such as Guillain-Barré syndrome.

This combination of spinal cord necrosis and optic neuritis corresponds to the syndrome described by Devic in 1894 and named by him *neuromyelitis optica* (Devic disease, page 781). Nearly all neurologists agree that a similar clinical syndrome involving the optic nerve and spinal cord (usually without necrosis) may also be caused by postinfectious encephalomyelitis and probably more often, by MS. However, a case has been made for considering Devic disease as an entity apart from MS, as discussed in Chap. 36. It follows that subacute necrotic myelopathy without optic neuritis might also be the result of MS or even a postinfectious process; the relationship between all of these entities is ambiguous, as discussed in Chap. 36.

In both the isolated necrotic myelopathy and in Devic disease, a few or up to several hundred mononuclear cells per cubic millimeter and increased protein may be found in the CSF but oligoclonal banding is usually absent. Some cases show only an elevated protein concentration. More so than with postinfectious transverse myelitis, the MRI reveals extensive signal changes and gadolinium enhancement, usually extending over several spinal segments (Fig. 44-5). Highly characteristic on imaging studies performed weeks or more later is severe atrophy of the involved segments of cord. Persistent swelling of the affected region is more suggestive of spinal cord tumor or another type of inflammation, but the permissible duration of cord swelling in cases of necrotic myelopathy is

Figure 44-5. MRI of necrotic myelopathy in a patient without optic neuritis. Atrophy of the cord was evident several months later.

not clear. The electromyogram (EMG) after several weeks reveals denervation of several contiguous myotomes, reflecting damage to the gray matter of those segments. The finding by Lennon and colleagues of a specific serum IgG antibody in half of cases of Devic disease is notable. The antibody is directed against capillaries of the brainstem and cerebellum, but its role in the pathogenesis of the disease has not been established.

As mentioned, the characteristic feature in most of our cases of necrotic myelopathy that are not affiliated with optic neuritis, has been a subacute and relapsing course, usually with stepwise worsening and occasionally punctuated by brief and limited remissions. The neurologic deficits of necrotic myelopathy—unlike those of the demyelinative and postinfectious myelitides described earlier—tend to be profound and lasting; in a few cases, they have reached a stage of flaccid tetraparesis within several weeks or months.

In several cases coming to postmortem examination at variable times after the onset of symptoms, the lesion has proved to be a necrotizing myelitis with widespread loss of spinal cord tissue. The pattern of tissue destruction appears at least in part infarctive, i.e., not respecting the borders of gray and white matter. However,

areas of residual inflammation and demyelination are often detected at the edges of the destructive lesions. For these reasons the current authors agree with Hughes in classifying this condition with the demyelinative diseases. Older lesions may have left the spinal cord cavitated or collapsed over a vertical extent of 5 to 20 cm, with conical extensions of necrosis into the gray matter above and below the area of transverse damage. In two cases of ours, in which death occurred many years after the onset of the myelitis, there were old cavitated and demyelinated, lesions in the cerebral white matter, typical of MS. Cases of this type emphasize the overlapping relationship between the necrotizing and demyelinative processes. Also, as alluded to earlier we have been unable to make a clear distinction between the necrotic myelopathy of Devic disease and the identical process occurring without optic neuropathy. The optic nerve lesions also tend to be of demyelinative type. In the cases of pure necrotic myelopathy described by Greenfield and Turner as well as by Hughes and in our own series (Katz and Ropper), patients of all ages and both sexes were affected.

Under the title “Subacute Necrotic Myelitis,” Foix and Alajouanine and later Greenfield and Turner described a disorder of adult men characterized by amyotrophic paraplegia that ran a progressive course over several months. An early spastic paraparesis evolved after a few weeks or longer into a flaccid, areflexive state. Sensory loss, at first dissociated and then complete, and loss of sphincteric control followed the initial paresis. The CSF protein was considerably elevated but there were no cells. In most ways, therefore, this process resembles subacute necrotizing myelopathy. Postmortem examinations in two of the cases of Foix and Alajouanine and in most subsequently reported ones have shown the lumbosacral segments to be the most severely involved. In the affected areas there was severe necrosis of both gray and white matter with appropriate macrophage and astrocytic reactions. However, the characterizing feature was thought to be an increase in the number of small vessels; their walls were thickened, cellular, and fibrotic (“angiolytic”), yet their lumens were not occluded. The veins were also thickened and surrounded by lymphocytes, mononuclear cells, and macrophages. These findings have been difficult to interpret. The possibility of spinal venous thrombosis in the pathogenesis has been emphasized, but in the case of Mair and Folkerts, only one thrombosed anterior spinal vein was seen; in the cases of Foix and Alajouanine, no thrombosed vessels were found. We believe the evidence of venous or other vascular occlusion to be unconvincing and are inclined to the view of Antoni and of others, who were impressed with the prominence of large arteries and veins and have reinterpreted this pathologic process as an arteriovenous malformation (see further on). More importantly, in most cases of necrotic myelopathy that are not associated with a true vascular malformation, the vascular changes simply reflect a neovascular response to necrosis. Only when enlarged and abnormal vessels involve the surface and adjacent parenchyma of the cord does the disorder deserve to be designated as Foix-Alajouanine myelopathy; the remaining cases are of the inflammatory-necrotizing type described earlier, with a secondary neovascular response to necrosis.

Rarely, a similar syndrome is produced by an idiopathic granulomatous or necrotizing angiitis that is confined to the spinal cord (Caccamo et al). In these cases, there is a persistent and marked pleocytosis and some clinical stabilization with corticosteroids. One of our patients with a similar subacute necrotizing myelitis, responsive to corticosteroids, had mononuclear cells in the spinal fluid persistently over a year and died later as a result of inflam-

matory cerebral hemorrhages. There were multiple occlusions of small vessels surrounding the spinal cord and a mild *vasculitis* (Ropper et al). Polyarteritis nodosa and necrotizing arteritis only rarely involve the spinal cord.

Treatment None of the treatments offered in our experience has made a noticeable difference in this disease, but some authors have the impression that high-dose corticosteroids, cyclophosphamide, or plasma exchange may have been beneficial in individual cases and we continue to attempt these in our patients.

Myelitis (Myelopathy) with Connective Tissue Disease A rapidly evolving or subacute myelopathy in association with systemic lupus erythematosus must always be considered in the differential diagnosis of demyelinative myelitis. It is presumed to arise from a microvasculitis of the spinal cord. Propper and Bucknall presented such a case and reviewed 44 others in which a patient with lupus erythematosus developed a transverse myelitis over a period of days. There was back pain at the level of sensory loss (the cases we have seen have been painless). Pleocytosis and elevation of CSF protein were characteristic. The MRI revealed a segmental swelling of the spinal cord. Postmortem examinations of similar cases have disclosed widespread vasculopathy of small vessels with variable inflammation and myelomalacia, and, rarely, a vacuolar myelopathy.

Some but not all cases also have an antiphospholipid antibody; the relationship of these antibodies to the myelopathy and to microvascular occlusion is uncertain (see also page 735). The incidence of lupus myelopathy is not known, but one such case is admitted to our service every several years.

Also mentioned here is the rare occurrence of nondescript myelitis with scleroderma (systemic sclerosis). The authors of most reports acknowledge the difficulty in distinguishing between the myelopathies of various connective tissue diseases. There may be some response to corticosteroids and other immunosuppressive medications. Myopathy and neuropathy, particularly trigeminal neuritis, are more common manifestations of scleroderma.

Sjögren Syndrome with Myelopathy In addition to the well-described posterior root ganglionopathy and sensory neuritis, an inflammatory myelitis has been associated with Sjögren syndrome. In most instances, the patient has had overt symptoms of Sjögren syndrome, namely the sicca complex, and in others, the association has been established through serologic testing or by the finding of a characteristic inflammatory infiltration of minor salivary glands (from which a biopsy has been taken on the lip.) In many reported cases the myelopathy has simulated the myelitis of MS, even to the extent of including episodes of optic neuritis as in the cases described by Williams and colleagues and by de Seze and coworkers. This putative Sjögren myelitis has been in different cases acute, chronic, or relapsing and displayed MRI changes in the cord that would otherwise be considered to be postinfectious or demyelinative myelitis. The spinal fluid formula has varied but generally does not contain oligoclonal bands. Treatment with prednisone and cyclophosphamide or chlorambucil has been suggested.

The authors cannot comment authoritatively on this entity. There is little pathologic material on which to judge the association but the presence of other inflammatory lesions of the central and peripheral nervous system in Sjögren cases makes the existence of a myelitis plausible. Antibody tests (anti-SS-A and -SS-B) and possibly a biopsy of the minor salivary glands (at the junction of mucosa and epidermis of the lower lip) are justified in older women

with unusual myelopathies or those with sicca symptoms; however, screening of all cases that otherwise suggest MS may not be practical. Whether our findings relative to the insensitivity of the serologic tests in patients with Sjögren disease and polyneuropathy also hold true for those with myelopathy is not known (see page 1141).

Paraneoplastic Myelitis A subacute necrotic myelitis developing in conjunction with a bronchogenic carcinoma was first brought to notice by Mancall and Rosales in 1964. Several dozen cases have since been recorded, some in association with lymphomas, but the diseases must be rare. Actually, in cancer patients, intramedullary metastasis is more common as a cause of intrinsic myelopathy than is paraneoplastic disease and, of course, a compressive lesion is far more frequent. The clinical syndrome consists of a rapidly progressive painless loss of motor and then sensory tract function, usually with sphincter disorder. Imaging studies demonstrate an area of T2 signal change in the cord or may be normal. This is in distinction to the nodular enhancing appearance of an intramedullary metastasis or of extradural metastatic disease with cord compression. The larger problem of metastatic compression of the cord from the epidural space is discussed in a later part of the chapter.

The CSF may contain a few mononuclear cells and a slightly increased protein, or it may be normal. The lesions are essentially of necrotic type and respect neither gray nor white matter, but the latter is more affected. There is little or no evidence of an infective-inflammatory or ischemic lesion, for the blood vessels, apart from a modest cuffing with mononuclear cells, are normal. No tumor cells are visible in the CSF, meninges, or spinal cord tissue, and no virus has been isolated. Unlike the situation in most of the paraneoplastic neurologic disorders, there are no diagnostic markers by way of antineuronal antibodies. In particular, this myelopathy does not seem to be a component of the anti-Hu-associated encephalitis-neuropathy spectrum.

In some cases of paraneoplastic myelopathy, the degenerative changes are more chronic, confined to the posterior and lateral funiculi and they are often associated with a diffuse loss of cerebellar Purkinje cells. This latter syndrome has a disproportionately high association with ovarian carcinoma but has been observed with carcinoma of other types and with Hodgkin disease. All of the reported cases of these types have ended fatally. Steroids and plasmapheresis were of no clear value. A special but rare variety of anterior horn cell destruction resembling motor neuron diseases is known to occur rarely with certain lymphomas; it is discussed with the paraneoplastic syndromes in Chap. 31.

Subacute Spinal Neuronitis Whitely and colleagues have drawn attention to a rare but distinctive form of encephalomyelitis of unknown cause, characterized clinically by tonic rigidity and intermittent myoclonic jerking of the trunk and limb muscles and by painful spasms of these muscles evoked by sensory or emotional stimuli. In the late stages of the disease, signs of brainstem involvement may appear which are usually progressive over a period of several weeks, months, or a year or longer; consciousness is preserved. However, the cases we have observed remained confined to several contiguous spinal segments, usually the upper abdomen and lower thorax. The CSF may be normal or show a mild lymphocytosis and increase in protein content. This is probably the same disorder that had been described earlier by Campbell and Garland under the title of *subacute myoclonic spinal neuronitis* and

later by Howell and coworkers, as noted on page 89. The disorder under discussion must be differentiated clinically from the syndrome of *continuous muscle fiber activity* of Isaacs and the "stiff man" syndrome (see page 1279) and focal tetanus. The last of these lacks the myoclonic nature and progressive course of spinal neuronitis and, of course, typically follows clostridial infection.

The brunt of the pathologic process in fatal cases, falls on the cervical portion of the spinal cord. Widespread loss of internuncial neurons with relative sparing of the anterior horn cells, neuronophagia of internuncial neurons, reactive gliosis and microglial proliferation, conspicuous lymphocytic cuffing of small blood vessels, and scanty meningeal inflammation are the main findings. Involvement of the white matter is less marked.

The pathophysiology of the rigidity in these cases is not well understood but is presumed to be due to the impaired function (or destruction) of Renshaw cells, with the release of tonic myotatic reflexes (Penry et al). The painful spasms and dysesthesias relate in some way to neuronal lesions in the posterior horns of the spinal cord and dorsal root ganglia. Whitely and Lhermitte and their co-workers have proposed that these cases probably represent a rare and obscure form of viral myelitis.

Myoclonic jerking of the trunk and limbs in a focal or segmental distribution is probably due to neuronal damage that is limited to the spinal cord. We have seen several such cases, usually with regional abdominal or thoracic myoclonus, in otherwise healthy patients and have been unable to determine its cause. The spinal fluid has been normal. Anticonvulsants and antispasticity drugs in some combination may partially suppress the myoclonus, and local injection of botulinum toxin has improved the symptoms in some. A similar syndrome in a few cases has complicated vertebral or spinal artery angiography (see later). A paraneoplastic variety, not of the stiff-man type, has been proposed, as in the case described by Roobol and colleagues, but its nature has not been fully elucidated.

VASCULAR DISEASES OF THE SPINAL CORD

In comparison with the brain, the spinal cord is an uncommon site of vascular disease. Blackwood, in a review of 3737 necropsies at the National Hospital for Nervous Diseases, London, in the period 1903 to 1958, found only 9 cases of spinal cord infarction, but in general hospitals such as ours, the incidence (on clinical grounds) is somewhat higher. The spinal arteries tend not to be susceptible to atherosclerosis, and emboli rarely lodge there. Of all the vascular disorders of the spinal cord, infarction, dural fistula, bleeding, and arteriovenous malformation are the only ones that are encountered with any regularity, but they are rare in comparison with demyelinating myelitis or compression by tumor. In current practice, most cases of infarction have developed in relation to operations on the aorta, usually the thoracic portion, where the aorta must be clamped for some period. An understanding of these disorders requires some knowledge of the blood supply of the spinal cord.

Vascular Anatomy of the Spinal Cord The blood supply of the spinal cord is derived from a series of segmental vessels arising from the aorta and from branches of the subclavians and internal iliac arteries (Fig. 44-6). The most important branches of the subclavian are the vertebral arteries, small branches of which give rise to the rostral origin of the anterior spinal artery and to smaller posterolateral spinal arteries and constitute the major blood supply to the cervical

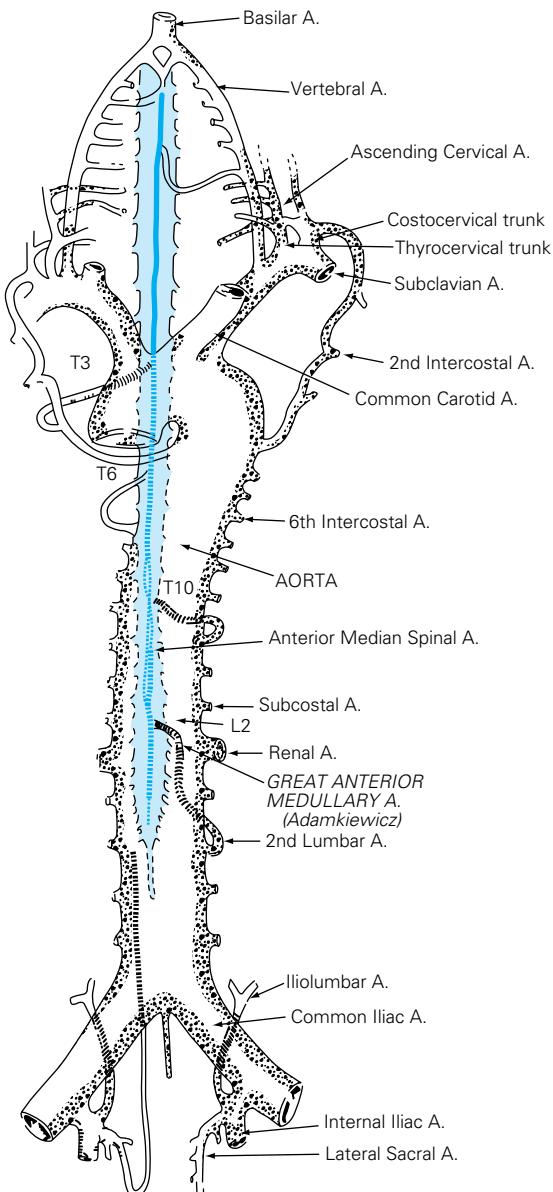

Figure 44-6. Anterior view of spinal cord with its segmental blood supply from the aorta. See text for details. (From Herrick and Mills, by permission.)

cord. The thoracic and lumbar cord is nourished by segmental arteries arising from the aorta and internal iliac arteries. Segmental branches of the lateral sacral arteries supply the sacral cord.

A typical segmental artery divides into an anterior and a posterior ramus (Fig. 44-7). Each posterior ramus gives rise to a spinal artery, which enters the vertebral foramen, pierces the dura, and supplies the spinal ganglion and roots through its anterior and posterior radicular branches. Most anterior radicular arteries are small and some never reach the spinal cord, but a variable number (four to nine), arising at irregular intervals, are much larger and supply most of the blood to the spinal cord. Tributaries of the radicular arteries supply blood to the vertebral bodies and surrounding ligaments. The venous drainage of the marrow is into the posterior veins forming the spinal plexus. Their importance relates to the pathogenesis of fibrocartilaginous embolism (see further on).

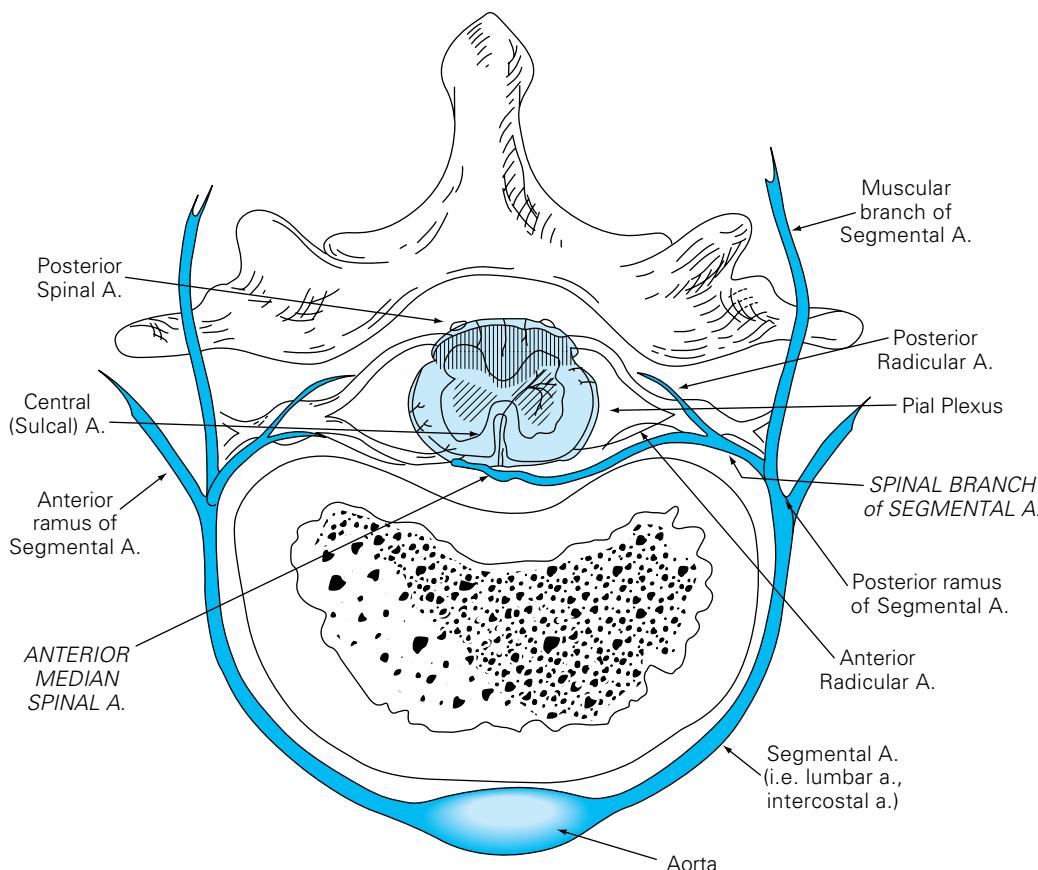

Figure 44-7. Representative cross section of lumbar vertebra and spinal cord with its blood supply at level of an anterior medullary artery. The shaded zones in the posterior part of the cord, ventral part of the cord, and margins of the ventral cord represent the regions of blood supply of the posterior spinal arteries, central (sulcal) arteries, and pial plexus, respectively. Borders of these three zones, appearing between the shaded areas in the diagram, represent watershed areas. (From Herrick and Mills, by permission.)

Lazorthes, in his thorough review of the circulation of the spinal cord, divides the radiculomedullary arteries into three groups: (1) upper or cervicothoracic, which are derived from the anterior spinal arteries and branches of thyrocervical and costovertebral arteries; (2) intermediate or middle thoracic (T3 to T8 cord segments), usually from a single T7 radicular artery; and (3) lower or thoracolumbar, from a large T10 or L1 anterior radicular artery called the *arteria radicularis magna* or the *artery of Adamkiewicz*. This artery may supply the lower two-thirds of the cord, but in any individual the precise area supplied by this or any other anterior radiculomedullary artery varies greatly and one cannot predict what proportion of cord will be infarcted if one of these vessels is occluded. The junction between the vertebral spinal and aortic circulations typically lies at the T2–T3 spinal segment, but most ischemic lesions lie well below this level.

The anterior medullary arteries form the single anterior median spinal artery, which runs the full length of the cord in the anterior sulcus and gives off direct penetrating branches via the central (sulcocommissural) arteries. These penetrating branches supply most of the anterior gray columns and the ventral portions of the dorsal gray columns of neurons (see Fig. 44-7). The peripheral rim of white matter of the anterior two-thirds of the cord is supplied from a pial radial network, which also originates from the anterior median spinal artery. *Thus, the branches of the anterior median spinal artery supply roughly the ventral two-thirds of the*

spinal cord. The posterior medullary arteries form the paired posterior spinal arteries that supply the dorsal third of the cord by means of direct penetrating vessels and a plexus of pial vessels (similar to that of the ventral cord, with which it anastomoses freely). Within the cord substance, then, there is a “watershed” area of capillaries where the penetrating branches of the anterior median spinal artery meet the penetrating branches of the posterior spinal arteries and the branches of the circumferential pial network. All spinal segments, because of the variable size of collateral arteries, do not have the same abundance of circulatory protection.

Normally there are 8 to 12 anterior medullary veins and a greater number of posterior medullary veins arranged fairly close to one another at every segmental level. They drain into radicular veins. In addition, a network of valveless veins extends along the vertebral column from the pelvic venous plexuses to the intracranial venous sinuses without passing through the lungs (Batson's plexus) and is considered a route for metastatic disease from the pelvis.

Infarction of the Spinal Cord (Myelomalacia)

Ischemic softening of the spinal cord usually involves the territory of the anterior spinal artery, i.e., a variable vertical extent of the ventral two-thirds of the spinal cord. Infarctions in this territory are

relatively uncommon, representing 1.2 percent of all strokes (Sandson and Friedman). The resulting clinical abnormalities are generally referred to as the *anterior spinal artery syndrome*, described by Spiller in 1909. Atherosclerosis and thrombotic occlusion of the anterior spinal artery is quite uncommon, as noted, and infarction in the territory of this artery is more often secondary to disease of the extravertebral collateral artery or to disease of the aorta—either advanced atherosclerosis, a dissecting aneurysm, or intraoperative surgical occlusion of the aorta—which compromises the important segmental spinal arteries at their origins. An ischemic myelopathy has been reported in cocaine users, preceded sometimes by episodes of cord dysfunction resembling transient ischemic attacks. Cardiac and aortic surgery, which requires clamping of the aorta for more than 30 min, and aortic arteriography may occasionally be complicated by infarction in the territory of the anterior spinal artery; more often in these circumstances damage to central neuronal elements is greater than that to anterior and lateral funiculi, as described below. The special ischemic myelopathy caused by a spinal dural-based arteriovenous fistula is discussed further on.

Rarely, polyarteritis nodosa may cause occlusion of a spinal medullary artery. Systemic cholesterol embolism arising from a severely atheromatous aorta may have the same effect. This latter type of embolism is prone to occur after surgical procedures, angioplasty, or cardiopulmonary resuscitation. For unexplained reasons, the spinal cord infarction sometimes follows the procedure by up to 3 weeks, as noted in Dahlberg's series. In almost all such patients, other evidence of widespread embolism can be expected. Infarction may result from systemic hypotension, the most vulnerable part being of the thoracic segments of the cord. One of our cases occurred during a bout of diabetic coma.

Among the most curious, albeit rare causes of cervical cord infarctions is *dissection of the extracranial vertebral arteries*, either unilateral or bilateral. Presumably ischemia in the territories of the anterior spinal arteries causes anterior and central cord ischemia. In two cases of this nature that have been brought to our attention there was an asymmetric brachial palsy and a suspended sensory loss, preceded by radicular and neck pain. The patients reported by Weidauer and colleagues are representative and there are numerous other case reports. A few patients have vertigo at the onset, pointing to the vertebral artery involvement. We have also seen instances of myelomalacia in adolescents and young adults in whom no aortic or spinal arterial disease could be demonstrated. Possibly, some of these were due to embolization of disc (nucleus pulposus) material into the local vasculature (see further on).

A quite different progressive ischemic necrosis of the cord occurs in the neighborhood of an arteriovenous malformation or dural fistula and is considered later in this chapter (see also the subacute necrotic myelitis of Foix and Alajouanine, described earlier).

The clinical manifestations of spinal arterial occlusion will, of course, vary with the level and portions of the cord that are infarcted, but common to practically all cases of infarction in the territory of the anterior spinal artery is pain in the neck or back and the development of motor paralysis and loss of pain and thermal sensation below the level of the lesion, accompanied by paralysis of sphincteric function. Rarely, infarction is preceded by transient spinal ischemic attacks as has been emphasized in cases related to cocaine use. The symptoms may develop instantaneously or, more often in our experience, over an hour or two, in any case, more rapidly than in the inflammatory myelitides. Radicular pain corresponding to the upper level of the lesion is sometimes a complaint.

Paralysis is usually bilateral, occasionally unilateral, and rarely complete. Also reported is a bibrachial paralysis as a fragment of the anterior spinal artery syndrome, as mentioned earlier. Except in high cervical lesions, the sensory changes are dissociated; i.e., pain and temperature sensations are lost (due to interruption of the spinothalamic tracts), but vibration and position sense are unimpaired (due to sparing of posterior columns). In this respect the syndrome differs from the myelopathy of trauma, but as mentioned earlier a similar syndrome occasionally results from myelitis. In cases that cause a complete transverse myelopathy, the limbs are initially flaccid and areflexic, as in spinal shock from traumatic lesions, followed after several weeks by the development of spasticity, and some degree of voluntary bladder control (unless sacral segments have been infarcted). Some patients regain a substantial degree motor function, mainly in the first month but extending over a year (Sandson and Friedman; Cheshire et al).

Infarction in the territory of the posterior spinal arteries is uncommon and the corresponding syndrome is not stereotyped. It may occur with surgery or trauma of the spine or rarely with vertebral artery dissections.

Most spinal cord infarctions can be detected by MRI. After a few days, there are obvious lesions on the T2 image sequences, presumably reflecting edema extending over several levels. There may be slight enhancement after infusion of gadolinium. It is notable, however, that the MRI taken in the first hours or day is often normal. The reason for this delay in the appearance of the imaging findings is not known. After several weeks there is myelomalacia, and in the chronic stages, the infarcted region collapses and is shown to be attenuated on MRI.

A dissecting aneurysm of the aorta—which is characterized by intense interscapular and/or chest pain (occasionally it is painless), widening of the aorta, and signs of impaired circulation to the legs or arms and various organs—gives rise to a number of myelopathic syndromes. This neurologic syndrome was first described by Kalischeri in 1914 and the aortic lesion leading to dissection, according to Erdheim, was a medianecrosis. Noteworthy is the fact that this vascular pathologic change has not been observed in dissection of the carotid and vertebral arteries. The most common syndromes of aortic dissection, according to Weisman and Adams, are (1) paralysis of the sphincters and both legs with sensory loss usually below T6, (2) ischemic infarction of the cord confined to the gray matter, in which case there is an abrupt onset of muscle weakness or myoclonus and spasms in the legs but no pain or sensory loss, (3) obstruction of the origin of a common carotid artery with hemiplegia, and, less commonly, (4) obstruction of a brachial artery with a sensorimotor neuropathy of the limb.

With regard to aortic aneurysm surgery, paraplegia is extremely uncommon after procedures performed on the infrarenal segment but occurs as frequently as 5 to 10 percent following repair of thoracoabdominal aneurysms. Not easily explained is the observation that up to a quarter of these instances of myelopathy do not appear for several days (one case at 8 days in our experience) postoperatively. The article by Lintott and colleagues should be consulted for further details.

In the past, aortography was sometimes complicated by an acute myelopathy; the authors had observed a number of such cases, and Killen and Foster reviewed 43 examples of this accident. The most striking examples, fortunately rare, are now observed as complications of vertebral angiography, resulting in high cervical infarction, similar in most ways to the aforementioned spinal infarction from extracranial dissection of the vertebral artery. The

onset of sensorimotor paralysis is immediate, and the effects are often permanent. The syndrome of painful segmental spasms, spinal myoclonus, and rigidity, mentioned earlier, has also been observed under these conditions. It was presumed that vascular spasm and occlusion resulted in infarct necrosis. The frequency of this complication was greatly reduced by the introduction of less toxic contrast media.

Treatment The approach to all forms of spinal cord infarction is largely symptomatic, with attention during the acute stage to the care of bladder, bowel, and skin; after 10 to 14 days, more active rehabilitation measures can be started. Whether the acute effects of infarction can be modified by high-dose corticosteroids, agents that increase blood flow, or anticoagulation is not known. There are case reports of improvement in paraplegia following aortic dissection by the use of CSF drainage, as for example in the cases reported by Blacker and colleagues and by Killen et al, but other factors may have contributed.

Hemorrhage of the Spinal Cord and Spinal Canal (Hematomyelia)

Hemorrhage into the spinal cord is rare compared with the frequency of cerebral hemorrhage. The apoplectic onset of symptoms that involve tracts (motor, sensory, or both) in the spinal cord, associated with blood and xanthochromia in the spinal fluid, are the identifying features of *hematomyelia*. Aside from trauma, hematomyelia is usually traceable to a vascular malformation or a bleeding disease and particularly to the administration of anticoagulants. Actually, most vascular malformations of the spinal cord do not cause hemorrhage, but instead produce a progressive, presumably ischemic myelopathy, as described later and mentioned in the earlier section on necrotic myelopathy.

The same causes (anticoagulation, blood dyscrasia with coagulopathy, and AVM) may underlie bleeding into the epidural or subdural space (page 1072) and give rise to a rapidly evolving compressive myelopathy. In some cases, as in those of Leech and coworkers, one cannot ascertain the source of the bleeding, even at autopsy. Epidural or subdural bleeding, like epidural abscess, represents a neurologic emergency and calls for immediate radiologic localization and, in most cases, surgical evacuation.

Advances in the techniques of selective spinal angiography and microsurgery have permitted the visualization and treatment of vascular lesions that cause bleeding with a precision not imaginable a few decades ago. These angiographic procedures make it possible to distinguish among the several types of vascular malformations, arteriovenous fistulas, and vascular tumors such as hemangioblastomas and to localize them accurately to the spinal cord, epidural or subdural space, or vertebral bodies. This subject is discussed further on.

Vascular Malformations of the Spinal Cord and Overlying Dura

These are well-known lesions, occurring not infrequently and causing both ischemic and hemorrhagic lesions. Some are true arteriovenous malformations (AVM) and others more limited fistulas, mainly in the dura, the distinctions being the size of the nidus of communication between an artery and a vein and the size and location of feeding and draining vessels. The classification of spinal AVMs has been confusing, in part because the enlarged draining veins by which the lesions were formerly identified are probably a

secondary feature. The most useful categorization reflects the appearance and location of the malformation by angiography and by surgical examination. These malformations may be divided into three groups: (1) arteriovenous malformations that are strictly intramedullary or also involve the meninges and surrounding structures such as the vertebral bodies to a limited extent; (2) a variety of intradural perimedullary fistulas that lie on the subpial surface of the cord (these probably conform most closely to the lesion described by Foix and Alajouanine discussed in the earlier section on necrotic myelopathy); and (3) purely dural fistulas. There is not sufficient pathologic material to determine whether these represent distinct pathologic entities or simply differing degrees and configurations of a common developmental process. Once recognized, treatment may be an urgent matter in cases with rapid clinical deterioration and impending paralysis.

Dural Fistula The last of the above listed malformations, spinal dural fistula, while not the classic AVM, is addressed first since it has emerged as the most common type in our practices. Increasingly, it has been recognized that arteriovenous fistulas that lie within the dura overlying the spinal cord, are capable of causing a myelopathy, sometimes several segments distant from the vascular nidus. The majority are situated in the region of the low thoracic cord or the conus, with a limited venous draining system. Some appear to be situated in a dural root sleeve and to drain into the normal perimedullary coronal venous plexus.

The presenting clinical features in our patients have included slowly progressive bilateral but asymmetric leg weakness with variable sensory loss. According to Jellema and colleagues who studied 80 patients with spinal dural fistulas, the most common initial symptoms were gait imbalance, numbness, and paresthesias. As the process progressed, the majority developed urinary problems, leg weakness, and numbness in the legs and buttocks. The degree of leg weakness varied greatly and back pain was infrequent.

The myelopathy that results is subacute or saltatory in evolution, presumably from venous congestion within the cord. A claudicatory syndrome has also been reported. Characteristically, activities that increase venous pressure (Valsalva maneuver, exercise) transiently amplify the symptoms or produce irreversible, stepwise worsening. One remarkable such case involved a baritone opera singer whose legs gave way repeatedly while singing (Khurana et al). As mentioned, some cases are painless, although most of our patients have had a moderate spinal ache or sciatica. In contrast to the classic arteriovenous lesions, these bleed only rarely. The spinal fluid is normal or shows a slight elevation of protein.

Intramedullary AVM The true AVM, previously referred to as *angioma racemosum venosum* or *dorsal extramedullary arteriovenous malformation*, is typically located on the dorsal surface of the lower half of the spinal cord and occurs most often in middle-aged and elderly men (23 of 25 of Logue's patients were male). However, this lesion may occur at any age and at any location in the cord. In a few cases has there been an overlying dermatomal nevus. The clinical picture has been well described by Wyburn-Mason. Acute cramp-like, lancinating pain, sometimes in a sciatic distribution, is often a prominent early feature. It may occur in a series of episodes over a period of several days or weeks; sometimes it is worse in recumbency. Almost always it is associated with weakness or paralysis of one or both legs and numbness and paresthesias in the same distribution. Wasting and weakness of the legs may introduce the disease in some instances, with uneven progression, sometimes in a series of abrupt episodes. Severe disability

of gait is usually present within 6 months, and half of the patients described by Aminoff and Logue were chairbound within 3 years; the average survival in the past was 5 to 6 years, but the disorder has rarely been fatal in our patients. These lesions only infrequently give rise to intramedullary or subarachnoid hemorrhage. The spinal fluid shows high protein but little or no cellular reaction.

When viewed directly, the dorsal surface of the lower cord may be covered with a tangle of veins, some involving roots and penetrating the surface of the cord. The progression of symptoms is due presumably to the chronic venous hypertension and secondary intramedullary ischemic changes, and the abrupt episodes of worsening have been attributed to the thrombosis of vessels all on uncertain grounds. However, angiographic studies sometimes show only a single or a few such dilated draining vessels. Furthermore, there is not sufficient pathologic material to determine whether some of the more prominent venous anomalies represent true venous angiomas (probably they do not). As mentioned, these lesions rarely bleed.

Intradural Perimedullary and Subpial AVM The pial fistulous arteriovenous communication that involves the superficial aspect of the cord to a variable extent is the least frequent but probably of a similar nature to the dural type, or it may be related to the vascular lesion in the earlier mentioned Foix-Alajouanine process. In contrast to dorsal arteriovenous malformations, these fistulas tend to involve the lower thoracic and upper lumbar segments or the anterior parts of the cervical enlargement. The patients are often younger, and the sexes are equally affected. The clinical syndrome may take the form of slow spinal cord compression, sometimes with a sudden exacerbation; or the initial symptoms may be apoplectic in nature, due to either thrombosis of a vessel or a hemorrhage from an associated draining vein that dilates to aneurysmal size and bleeds into the subarachnoid space or cord (hematomyelia and subarachnoid hemorrhage); the latter complication occurred in 7 of 30 cases reported by Wyburn-Mason.

Diagnosis Any of these lesions, dural or intradural, may be revealed on CT myelography or MRI by the presence of one or more fortuitously discovered enlarged and serpiginous draining vessels in the subarachnoid space; just as often, they are not visualized by these methods (Jones et al). Other features that have been emphasized include enlargement of the spinal cord at the level of the lesion and, particularly in the case of spinal dural fistulae, with venous congestion and T2-bright enhancement of the swollen cord over several segments. Because of the low-flow nature of the vascular lesion, the same region may be T1 hypointense. Some clinicians have commented on the presence of peripherally located regions of T2-hypointense signal changes (Hurst and Grossman). Many of these changes reverse with appropriate surgical or radiological interventions that ablate the malformations.

The diagnosis is established through selective angiography, which shows the fistula in the dura overlying the cord or on the surface of the cord itself, but the most conspicuous finding is often the associated early draining vein (Fig. 44-8). As with other spinal cord malformations, demonstration of the fistula requires the painstaking injection of feeding vessels at numerous levels above and below the suspected lesion, since the main vessel of origin is often some distance away from the malformation. Also, blood flow through the nidus may be so rapid and brief that it is missed. In rare instances the fistula or high-flow arteriovenous malformation lies well outside the cord—for example, in the kidney—and gives rise to a similar myelopathy, presumably by raising venous pressures within the cord.

Figure 44-8. Angiographic injection of a low lumbar radicular vessel demonstrating a vascular blush of a fistula in the dura overlying the lumbar cord (small lower arrow) and a prominent early draining vein (large upper arrow), which was barely seen on a CT myelogram and was not seen on MRI. This dural arteriovenous malformation caused a subacute myelopathy involving the lumbosacral cord.

Other Rare Vascular Anomalies of the Cord In the *Klippel-Trenaunay-Weber syndrome*, a vascular malformation of the spinal cord is associated with a cutaneous vascular nevus; when the malformation lies in the low cervical region, there may be enlargement of finger, hand, or arm (the hemangiectatic hypertrophy of Parkes Weber; neurofibromatosis is another cause of limb enlargement). Spinal segmental and tract lesions may occur at any age, but three of our patients were young adults. Vascular occlusion or hemorrhage was responsible for the myelopathy. Some of these vascular lesions have been treated by defining and ligating their feeding vessels. In a few reported cases it has been possible to extirpate the entire lesion, especially if it occupied the surface of the cord.

Other rare vascular anomalies of the spinal cord include *aneurysm of a spinal artery with coarctation of the aorta and telangiectasia of the cord*, which may or may not be associated with the hereditary hemorrhagic type of Osler-Rendu-Weber. The authors have had under their care over the years patients with the latter disease who developed acute hemorrhagic lesions of the spinal cord. Also, we have observed several *cavernous hemangiomas of the spinal cord*. In two of our cases, an angiographically negative solitary cavernous angioma had been the source of an acute partial transverse myelopathy. The lesions were clearly demonstrable only in the T2-weighted MR images. McCormick and associates have reported similar cases. Characteristically, the cord lesions cause partial syndromes and are followed by considerable recovery of function just as when they occur in the brain. There may or may not be blood in the CSF. Rarely, the same disease is responsible for one or more hemorrhagic lesions of the brain. The association of cavernous angiomas with arteriovenous fistulas of the lung is a rare finding, and the latter may be a source of brain abscess. In *coarctation of the aorta*, the circulation to the lower part of the spinal cord may be deficient, with resultant paresis of the legs, sensory loss, and sphincteric impairment. Or there may be intra-

cranial subarachnoid hemorrhage from a ruptured saccular aneurysm.

Treatment The rate of progression of the myelopathy from these various lesions varies greatly. In some cases, as already noted, it may become a matter of some urgency to reverse the venous congestion and avoid infarction of the cord. Other lesions require a more measured approach. By occluding the feeding artery of a spinal AVM or fistula, which is often single, and eliminating the pressure in veins, the course of disease can be arrested and pain reduced (Symon et al). In most of our cases, there has been post-operative improvement in the neurologic deficit over a few weeks or months. In cases of the larger racemose AVMs, stripping the enlarged veins along the dorsal cord is no longer considered necessary and may be dangerous. Increasingly, one resorts to obliteration of a fistula or a reduction of the AVM by the use of endovascular techniques, using special catheters and various types of embolic particles. The procedure is long and painstaking, for the radiologist must identify and embolize all the feeding vessels of the malformation; general anesthesia is required in most cases. This approach has certain drawbacks; recanalization occurs in many instances, as does distal occlusion of the venous drainage system. For these reasons, surgical ligation of the arterial supply is still preferred as the initial procedure for larger AVMs. Some surgeons advise a staged approach in which the size of the malformation is first reduced by endovascular techniques thereby making the surgery less complicated. Intradural fistulas are usually treated solely by endovascular methods. Interventional radiologic techniques have also been used to advantage in the intramedullary malformations, either as the sole treatment or in combination with surgery. Focused radiation has been tried but the results are difficult to evaluate since most series are small.

Fibrocartilaginous Embolism

In 1961, Naiman and coworkers described the case of an adolescent boy who died of sudden paralysis after a fall in a seated position. Postmortem examination revealed extensive myelomalacia due to occlusions of numerous spinal vessels by emboli of nucleus pulposus material. Bots and colleagues encountered three cases in one year, and we regularly see one or two such cases each year. The clinical picture is essentially one of spinal apoplexy—the patient experiences the abrupt onset of pain in the back or neck, accompanied by the signs of a transverse cord lesion affecting all sensory, motor, and sphincteric functions and evolving over a period of a few minutes to an hour or more. Occasionally, the syndrome spares the posterior columns thus simulating an anterior spinal artery occlusion. The CSF is normal. As with other types of cord infarction, the changes may not appear on MRI for a day or more.

In some of the reported instances there was said to have been no excessive activity or spinal trauma preceding the spinal cord symptoms. However, this has not been true of our patients, most of whom had been participating in some strenuous activity but often earlier in the day rather than at the time of the paraplegia. Others had fallen and injured themselves on the day of the illness or on preceding days; a direct blow to the back during contact athletic sports was the antecedent event in several others and is the one most easily understandable as a cause.

At autopsy numerous small arteries and veins within the spinal cord are occluded by fibrocartilage, with necrosis of the spinal cord over one or two segments. A ruptured disc of the usual type was not found in these patients, but high-resolution radiographs in a few of them have exposed a discontinuity of the cortical bone of

the vertebral body adjacent to a collapsed disc and herniation of disc tissue into a vertebral body (Tosi et al). The explanation suggested by Yoganandan and colleagues is that the high intravertebral pressure forces nucleus pulposus material into venules and arteries of the marrow of the vertebral body, and thence into the adjacent radicular vessels. This mechanism has probably been overlooked in many cases of acute ischemic myelopathy.

Caisson Disease (Decompression Sickness, "the Bends")

This extraordinary myelopathy is observed in persons who are subjected to high underwater pressure and then ascend too rapidly. It affects mainly the upper thoracic spinal cord as a result of nitrogen bubbles that form and are trapped in spinal vessels. There may be little or no involvement of the brain. Haymaker, who has provided the most complete account of the neuropathologic changes, observed ischemic lesions mainly in the white matter of the upper thoracic cord; the posterior columns were more affected than lateral and anterior ones. We have encountered instances in which an almost complete transverse myelopathy was evident soon after the patient resurfaced but then improved, leaving the patient with an asymmetrical and incomplete albeit permanent residual deficit. The smallest degree of damage is manifest as a minor myelopathy that affects the anterior or the posterior funiculi, leaving either spasticity or numbness of the legs. Immediate treatment consists of recompression in a hyperbaric chamber; later treatment is symptomatic, with antispasticity drugs and physical therapy.

Spinal Subdural Hemorrhage

This is an unusual process but we have had experience with a few cases that presented with excruciating thoracic back pain of such severity as to cause a bizarre, almost psychotic, reaction (Swann et al). The neck becomes slightly stiff and there may be a headache, suggesting subarachnoid hemorrhage. However, signs of a myelopathy do not appear, indicating that the bleeding is confined to the pliable subdural spaces surrounding the cord. Lumbar puncture yields a distinctive dark yellow-brown spinal fluid that resembles crank case oil (in two of our cases). The color is imparted by met-hemoglobin and reflects the presence of adjacent, walled-off blood. Usually there are also red blood cells in the CSF, suggesting seepage into the subarachnoid space from the adjacent clot. MRI or CT myelography shows a subdural collection, with characteristically smooth borders. When drained operatively, this is found to be clotted blood. Usually, no vascular malformation is demonstrable and the cause remains obscure. Trauma or anticoagulation underlie a few cases but many are spontaneous. The symptoms resolve in 1 or 2 weeks after removal of the subdural hematoma. Small collections may be managed without surgery, in which case corticosteroids may be helpful in reducing the pain.

The syndrome of spinal subarachnoid hemorrhage has been mentioned earlier and is also covered on page 728.

THE SYNDROME OF SUBACUTE OR CHRONIC SPINAL PARAPARESIS WITH OR WITHOUT ATAXIA

The gradual development of weakness of the legs is the common manifestation of several diseases of the spinal cord. A syndrome of this type—including ataxia of gait beginning insidiously in late

childhood or adolescence and progressing steadily—is usually indicative of hereditary spinocerebellar degeneration (Friedreich ataxia) or one of its variants (see Chap. 39). In early adult life, MS is the most frequent cause and AIDS myelopathy is being increasingly recognized; syphilitic meningoencephalitis, formerly of great importance, is now quite uncommon. In middle and late adult life, cervical spondylosis, subacute combined degeneration of the cord (vitamin B₁₂ deficiency), combined system degeneration of the nonpernicious anemia type, radiation myelopathy, tropical spastic paraparesis, spinal arachnoiditis, and thoracic spinal tumor, particularly meningioma, are the other important diagnostic considerations for a slowly progressive syndrome. In most forms of subacute and chronic spinal cord disease, spastic paraparesis is more prominent than posterior column ataxia, Friedreich ataxia and myelopathy due to vitamin B₁₂ deficiency being notable exceptions.

Spinal Multiple Sclerosis

(See earlier under "Demyelinative Myelitis"; also Chap. 36)

Ataxic paraparesis is among the most common manifestations of MS. Asymmetrical involvement of the limbs and signs of cerebral, optic nerve, brainstem, and cerebellar involvement usually provide confirmatory diagnostic evidence. Nevertheless, purely spinal involvement may occur, no lesions being found outside the spinal cord even at autopsy. A frequent problem in diagnosis is posed by the older adult patient who was not known to have had MS in earlier life, previous episodes having been asymptomatic or forgotten. The secondary progressive stage of the disease in this group appears to be the consequence of recurrent demyelinative attacks. There is another group, however, in which slowly advancing neurologic deterioration represents the primary manifestation of the disease. The National Hospital Research Group examined 20 cases of the secondary progressive type of spinal MS and 20 of the primary type by gadolinium-enhanced MRI of the spinal cord and brain and found new lesions in only 3 of each group (Kidd et al). They have suggested that the progression correlates better with progressive atrophy of the spinal cord than with recurrent demyelinative lesions. The clinical state must be differentiated from cervical disc disease, spondylosis, and tumor. As previously discussed, the main aids in diagnosis are the CSF findings (minor pleocytosis and oligoclonal IgG abnormalities), present in 70 to 90 percent of cases, the demonstration by evoked potential studies of lesions in the optic nerves or in the auditory and sensory tracts, and by MRI, which may disclose other unsuspected white matter lesions in the spinal cord and brain.

Cervical Spondylosis with Myelopathy

It has been stated, correctly in our opinion, that this is the most frequently observed myelopathy in general practice. Basically a degenerative disease of the spine involving the lower and midcervical vertebrae, it narrows the spinal canal and intervertebral foramina and causes progressive injury of the spinal cord, roots, or both.

Historical Note Key, in 1838, probably gave the first description of a so-called spondylotic bar. In two cases of compressive myelopathy with paraplegia, he found "a projection of the intervertebral substance and posterior ligament of the spine, which was thickened and presented as a firm ridge which had lessened the diameter of the canal by nearly a third. The ligament, where it passes over the posterior surface of the intervertebral substance, was found to be ossified." In 1892, Horsley performed a cervical laminectomy on

such a patient, removing a "transverse ridge of bone" compressing the spinal cord at the level of the sixth cervical vertebra. Thereafter, operations were performed in many cases of this sort, and the tissues removed at operation were repeatedly misidentified as benign cartilaginous tumors or "chondromata." In 1928, Stookey described in detail the pathologic effects upon the spinal cord and roots of these "ventral extradural chondromas." Peet and Echols, in 1934, were probably the first to suggest that the so-called chondromata represented protrusions of intervertebral disc material. But this idea never gained wide credence until the publication, in the same year, of the classic article on ruptured intervertebral disc by Mixter and Barr. Although their names are usually associated with the lumbar disc syndrome, 4 of their original 19 cases were instances of cervical disc disease. It was C. S. Kubik who identified the nucleus pulposus from surgical specimens obtained by Mixter and Barr's cases.

Also of historical importance is Gowers's account, in 1892, of *vertebral exostoses*, in which he described osteophytes that protrude from the posterior surfaces of the vertebral bodies and encroach upon the spinal canal, causing slow compression of the cord as well as bony overgrowth in the intervertebral foramina, giving rise to radicular pain. Gowers correctly predicted that these lesions would offer a more promising field for the surgeon than would other kinds of vertebral tumors.

For some reason, there was little awareness of the frequency and importance of spondylotic myelopathy for many years after these early observations had been made. All the interest was in the acute ruptured disc. Finally, it was Russell Brain, in 1948, who put cervical spondylosis on the neurologic map, so to speak. He drew a distinction between acute rupture and protrusion of the cervical disc (often traumatic and more likely to compress the nerve roots than the spinal cord) and chronic spinal cord and root compression consequent upon disc degeneration and associated osteophytic outgrowths (*hard disc*) as well as changes in the surrounding joints and ligaments. In 1957, Payne and Spillane documented the importance of a developmentally smaller-than-normal spinal canal in the genesis of myelopathy in patients with cervical spondylosis. These reports were followed by a spate of articles on the subject (see Wilkinson). Rowland's review of the natural history of cervical spondylosis and the results of surgical therapy is a useful modern reference, as is that of Uttley and Monro.

Symptomatology The characteristic syndrome consists of varying combinations of the following: (1) painful, stiff neck or pain in the neck, shoulders, and upper arms (brachialgia) that may be aching or radicular (stabs of sharp and radiating pain evoked by movement); asymmetric or unilateral; (2) numbness and paresthesias mainly of the hands; and (3) spastic leg weakness with Babinski signs, unsteadiness of gait, and a Romberg sign. The numbness and paresthesias are occasionally the earliest symptoms and typically involve the distal limbs, especially the hands. Variations of these symptoms are elaborated later. Each of the components may occur separately, or they may occur in several combinations and sequences.

With reference to the most common of these symptoms, the neck and shoulder pain, in any sizable group of patients beyond 50 years of age, about 40 percent will be found at times to have some clinical abnormality of the neck, usually crepitus or pain, with restriction of lateral flexion and rotation (less often of extension). Pallis and colleagues, in a survey of 50 patients, all of them over 50 years of age and none with neurologic complaints, found that 75 percent showed radiologic evidence of narrowing of the cervical

spinal canal due to osteophytosis of the posterior vertebral bodies or to narrowing of the intervertebral foramina due to osteoarthritis at the apophyseal joints; thickening of the ligaments (both the ligamentum flavum posteriorly and the posterior longitudinal ligament anteriorly) adds to the narrowing of the canal. However, only half of the patients with radiologic abnormalities showed physical signs of root or cord involvement (changes in the tendon reflexes in the arms, briskness of reflexes and impairment of vibratory sense in the legs, and sometimes Babinski signs). The occasional finding of a Babinski sign in older individuals who had never had a stroke or complained of neurologic symptoms is often explained by an otherwise inapparent cervical osteophyte (Savitsky and Madonick).

The pain is usually centered at the base of the neck or higher, often radiating to an area above the scapula. When brachialgia is also present, it takes several forms: a sharp pain in the pre- or postaxial border of the limb, extending to the elbow, wrist, or fingers; or a persistent dull ache in the forearm or wrist, sometimes with a burning sensation. Discomfort may be elicited by coughing, Valsalva maneuver, or neck extension, or neck flexion may induce electrical feelings down the spine (Lhermitte symptom). Rarely, the pain is referred substernally.

As to the sensory disorders (which may occasionally be absent), numbness, tingling, and prickling of the hands and soles of the feet and around the ankles are the most frequent complaints. Some patients complain of numbness or paresthesias, most often in one or two digits, a part of the palm, or a longitudinal band along the forearm. Slight clumsiness or weakness of a hand is another complaint. A feeling as if "wearing gloves," "swollen," or the hands "coated with glue" are common descriptions. Several of our patients complained of paresthesias in the distal limbs and trunk for months before there was any indication of motor involvement. In advanced cases there may be a vague sensory level at or just above the clavicles. Impaired vibratory sensation and diminished position sense in the toes and feet (all indicative of a lesion of the posterior columns) as well as the Romberg sign are the most conspicuous sensory findings. This imparts a "tabetic" unsteadiness to the gait in advanced cases. These sensory defects tend also to be asymmetrical (it is noteworthy that symmetric sensory symptoms and signs of identical type are seen with subacute combined degeneration due to B_{12} deficiency.) Rarely, the sensorimotor pattern takes the form of a Brown-Séquard syndrome. Less frequently, paresthesias and dysesthesias in the lower extremities and trunk may be the principal symptoms; even less often there are sensory complaints on the face, ostensibly corresponding to compression of the trigeminal sensory tract in the upper cervical cord.

The third part of the typical syndrome, spastic legs from a compressive myelopathy, most often presents as a complaint of weakness of a leg and slight unsteadiness of gait. The whole leg or the quadriceps feels stiff and heavy and gives out quickly after exercise. Mobility of the ankle may be reduced, and the advancing toe of the shoe scrapes the floor. On examination, hypertonicity is more evident than weakness, and the tendon reflexes are increased (ankle jerks may not share in this change in the elderly). Although the patient may believe that only one leg is affected, it is commonly found that both plantar reflexes are extensor, the one on the side of the stiffer leg being more clearly so. Less often both legs are equally affected. As the compression continues, walking becomes unsteady because of the addition of sensory ataxia.

The biceps and brachioradial reflexes on one or both sides may be depressed, sometimes in association with an increase in the triceps and finger reflexes. The hand or forearm muscles, may un-

dergo slight atrophy, in a few cases, the atrophy of hand muscles is severe. Interestingly, in such cases, the spondylotic compression, as judged by MRI or CT myelography, may be confined to the high cervical cord, well above the levels of the motor neurons that innervate these muscles. In patients with sensory loss, pain and thermal sensation often appear to be affected more than tactile sense. An unexpected Babinski sign has already been mentioned and a few fasciculations may be seen, especially in proximal muscles.

As the myelopathy progresses, sometimes intermittently, both legs become weaker and more spastic. Sphincteric control may then be altered; slight hesitancy or precipitancy of micturition are the usual complaints; frank incontinence is infrequent. In the more advanced form of this condition, walking requires the aid of a cane or canes or a walker; in some cases all locomotion ultimately becomes impossible, especially in the elderly patient. Abrupt worsening, even paraplegia or quadriplegia, may follow forceful flexion or extension injuries of the neck, as indicated later.

Pathologic Changes The fundamental lesion is generated initially by a fraying of the annulus fibrosus, with extrusion of disc material into the spinal canal. The disc becomes covered with fibrous tissue or partly calcified, thereby forming a transverse osteophytic "spondylitic bar" or there may be simply central bulging of the annulus without extrusion of nuclear material. The latter changes, unlike ruptured discs that occur mainly at the C5-6 or C6-7 interspace, often involve higher interspaces and almost invariably occur at several adjacent levels. The dura mater may be thickened and adherent to the posterior longitudinal ligament at affected levels. The underlying pia-arachnoid is also thickened and the adjacent ligamentous hypertrophy contributes to compression of the cord or the nerve roots. This series of pathologic changes is often ascribed to hypertrophic osteoarthritis. However, in lesser degree, the osteophyte formation and ridging are so frequently observed in patients who have no other signs of arthritic disease that this explanation is surely not totally correct. Subclinical trauma is far more likely to be the cause of spondylotic bar formation, in the authors' opinion.

When a cervical nerve root is compressed by lateral osteophytic overgrowth, the dural sleeve is thickened and occluded and the root fibers are damaged. Usually the fifth, sixth, or seventh cervical roots are affected in this way, both the anterior and posterior or only the anterior, on one or both sides. A small neuroma may rarely appear proximal to the site of anterior root compression.

The dura is ridged and the underlying spinal cord is flattened. The root lesions may lead to secondary wedge-shaped areas of degeneration in the lateral parts of the posterior columns at higher levels. The most marked changes in the spinal cord are at the level(s) of compression. There may be zones of demyelination or focal necrosis at the points of attachment of the dentate ligaments (which tether the spinal cord to the dura) and areas of rarefaction in the posterior and lateral columns as well as loss of nerve cells. Ventral gray matter lesions, often asymmetrical, are attributed by Hughes to ischemia.

Pathogenesis The particular vulnerability of the cervical spine to degenerative change has no ready explanation. Most likely it is related in some way to the high degree of mobility of the lower cervical vertebrae, which is accentuated by their location next to the relatively immobile thoracic spine.

The mechanism of spinal cord injury would seem to be one of simple compression and ischemia as mentioned. When the spinal

canal is diminished in its anteroposterior dimension at one or several points, the space available for the spinal cord becomes insufficient. A developmentally small canal (reduced anteroposterior diameter) certainly makes an individual subject to the compressive effects of spondylosis. The range of narrowing of the canal that produces symptomatic cervical spondylosis is generally from 7 to 12 mm (normal canal diameter, 17 to 18 mm). One must consider, therefore, several additional mechanisms by which the cord might be damaged. The effects of the natural motions of the spinal cord during flexion and extension of the neck are probably important in this respect. Adams and Logue confirmed the observation of O'Connell that, during full flexion and extension of the neck, the cervical cord and dura move up and down. The spinal cord is literally dragged over protruding osteophytes and hypertrophied ligaments; conceivably it is this type of intermittent trauma that causes progressive injury. It has also been shown that the spinal cord, displaced posteriorly by osteophytes, is compressed by the infolding of the posterolateral ligamentum flavum each time the neck is extended (Stoltmann and Blackwood). Segmental ischemic necrosis resulting from intermittent compression of spinal arteries or from compression of the anterior spinal artery has also been postulated. Most neuropathologists favor the idea of intermittent cord compression between osteophytes anteriorly and ligamentum flavum posteriorly, with an added vascular element accounting for the scattered lesions deep in the cord. Trauma from sudden extreme extension, as in a fall, severe whiplash injury, or chiropractic manipulation, or from a lesser degree of retraction of the head during myelography, tooth extraction, or a tonsillectomy may be operative in individual cases, particularly in patients with congenitally narrow canals. The lateral extension of the osteophyte and hypertrophy of the facet joint together compress the nerve root as it is entering its spinal foramen. Sometimes these are the main changes and cause only a radiculopathy, as discussed in Chap. 11.

Diagnosis When pain and stiffness in the neck, brachialgia, either in the form of aching or a more distinctive radicular pain, and sensorimotor-reflex changes in the arms are combined with signs of myelopathy, there is little difficulty in diagnosis. When the neck and arm changes are inconspicuous or absent, the diagnosis becomes more difficult. The myelopathy must then be distinguished from the late, progressive form of spinal MS. Since posterior vertebral osteophytes and other bony alterations are frequent in the sixth and seventh decades, the question that must be answered in any given case is whether the vertebral changes are related to the neurologic abnormality. The finding of some degree of sensorimotor or reflex change corresponding only to the level of the spinal abnormalities is a point that always favors spondylotic myelopathy. A lack of such corresponding changes and the presence of oligoclonal bands and signs of lesions in the optic nerves and brain indicate demyelinative myelopathy.

The findings on both MRI and CT myelography become critical in such cases (Fig. 44-9). The MRI tends to overestimate the degree of cord compression by an osteophyte, but clear deformation of the cord into the shape of a bean and obliteration of the surrounding CSF spaces in the transverse image support the diagnosis of spondylotic compression. Signal changes within the body of the cord are seen in advanced cases and usually indicate a degree of irreversibility of at least the sensory symptoms. Curiously, these signal changes may be one or two levels above or below the site of main compression. However, serious and reversible symptoms may occur even without intrinsic changes in the MRI signal. Con-

Figure 44-9. MRI in a patient with symptomatic cervical spondylosis. The spinal cord at C4-5 and C5-6 is flattened on its ventral surface by spondylotic bars and on its posterior surface by ligamentous hypertrophy. Axial images are required to confirm that the cord is truly compressed and that the subarachnoid space is nearly or completely obliterated.

trast myelography with the patient supine and lateral views taken during flexion and extension of the neck are useful diagnostic procedures in uncertain cases. To confidently attribute neurologic symptoms to spondylosis there should be flattening of the cord and considerable encroachment on the CSF space at that level, not simply an impingement or slight deformation of the normal oval shape of the cord.

It has been said that spondylotic myelopathy may simulate amyotrophic lateral sclerosis (amyotrophy of arms and spastic weakness of the legs). This has seldom been a diagnostic problem. While brachial and shoulder fasciculations with muscle atrophy may be combined with hyperreflexia in spondylosis, the widespread denervation and progressive course of ALS is not in evidence. We have observed only a few patients with spondylotic myelopathy who exhibited an absolutely pure motor syndrome, i.e., one in which there was no cervical or brachial pain and no sensory symptoms in the arms or impairment of vibratory or position sense in the legs. Likewise, a pure spastic paraparesis is more likely to be a manifestation of MS, hereditary spastic paraparesis, motor neuron

disease (primary lateral sclerosis type), HTLV-I myelopathy, or the carrier state of adrenoleukodystrophy or other intrinsic myelopathy.

When imbalance, both perceived by the patient and observed in tests of walking, is a major symptom, spondylosis must be differentiated from a number of acquired large-fiber polyneuropathies, particularly inflammatory or immune types and the more benign sensory neuropathy of the aged (see page 1151). Loss of tactile sensation in the feet and loss of tendon reflexes are characteristic of the latter; examination of the tendon reflexes distinguishes the two. Subacute combined degeneration of the spinal cord due to vitamin B₁₂ deficiency, combined system disease of the nonpernicious anemia type, AIDS and HTLV-I myelopathy, ossification of the posterior longitudinal ligament, and spinal cord tumor (discussed further on) are usually listed among the conditions that might be confused with spondylotic myelopathy. Adherence to the diagnostic criteria for each of these disorders and scrutiny of the radiologic studies should eliminate the possibility of error in most instances. The gait abnormality produced by spondylotic myelopathy may also be mistaken for that of normal-pressure hydrocephalus; a marked increase of imbalance with removal of visual cues (Romberg sign) is a feature of spondylosis but not of hydrocephalus. Also, the short stepped and magnetic quality of walking that is characteristic of hydrocephalus is not seen in cases of cervical myelopathy. Incontinence occurs only in advanced cases of spondylotic myelopathy, but usually follows soon after gait deterioration in hydrocephalus.

The special problems of spondylotic radiculopathy, which may accompany or occur independently of the myelopathy, are discussed on pages 184 and 186.

Treatment The slow, intermittently progressive course of cervical myelopathy with long periods of relatively unchanging symptomatology makes it difficult to evaluate therapy. Assuming that the prevailing opinion of the mechanisms of the cord and root injury is correct, the use of a soft collar to restrict anteroposterior motions of the neck seems reasonable. This form of treatment alone may be sufficient to control the discomfort in the neck and arms. Only exceptionally in our experience has arm and shoulder pain alone been sufficiently severe and persistent to require surgical decompression unless there is a laterally protruded disc or osteophytic constriction of a root foramen.

Most of our patients have been dissatisfied with this passive approach and are unable to wear a collar for prolonged periods. If osteophytes have narrowed the spinal canal at several interspaces, a posterior decompressive laminectomy with severance of the dentate ligaments helps to prevent further injury. The results of such a procedure are fairly satisfactory (Epstein and Epstein); in fully two-thirds of the patients, improvement in the function of the legs occurs, and in most of the others, progression of the myelopathy is halted. The operation carries some risk; rarely, an acute quadriplegia—due presumably to manipulation of the spinal cord and damage to nutrient spinal arteries—has followed the surgical procedure. When only one or two interspaces are the site of osteophytic overgrowths, their removal by an anterior approach has given better results and carries less risk. The surgical methods and their relative advantages are reviewed by Braakman. Newer techniques have been developed in which titanium cages are used to stabilize the adjacent vertebrae thereby obviating the need for bone grafts to fuse adjacent bodies; the conventional process using bone grafts requires many weeks or longer and stabilization in a hard collar.

Unfortunately, the long-term results after surgical treatment

are less than ideal. Ebersold and colleagues evaluated the outcomes in 84 patients in whom the median duration of follow-up was 7 years. In the group of 33 patients who had undergone anterior decompressive procedures, 18 had improved, 9 were unchanged, and 6 had deteriorated. Of the 51 patients who underwent posterior decompression, 19 had improved, 13 were unchanged, and 19 were worse at their last follow-up examinations. These results, similar to those of most other series, indicate that the long-term outcome varies and that a significant proportion, even after adequate decompression and initial improvement, have persistent symptoms or undergo some degree of later functional deterioration. Whether the new surgical appliances previously mentioned give more satisfactory results is not known but they certainly make recovery easier and more rapid.

Lumbar Stenosis This is another spondylotic abnormality, seen with particular frequency in older individuals, especially men. Usually it declares itself by numbness and weakness of the legs, sometime with poor control of sphincters. There is said to be generally little or no pain or only a spine ache that fluctuates from day to day but in our experience the majority of patients have backache and sciatica or a smiliar back or leg pain from associated osteoarthritis or discogenic disease. A notable feature is induction or aggravation of the neurologic symptoms upon standing and walking (neurologic claudication). This topic is discussed further on page 179, which should be consulted for further discussion.

Ankylosing Spondylitis This rheumatologic condition of the spine is due to inflammation at the sites of ligamentous insertions into bone that leads to an intense calcification at these and adjacent sites. The sacroiliac joints and lumbar spine are most affected, as discussed on page 180, but as the disease advances, the entire spine becomes fused and rigid. The biomechanics of the rigid spine make it susceptible to fracture. The most common complication is a spinal stenosis and cauda equina syndrome. Bartleson and associates described 14 patients (and referred to 30 others in the medical literature) who, years after the onset of spondylitis, developed sensory, motor, reflex, and sphincteric disorders referable to L4, L5, and the sacral roots. Surprisingly, the spinal canal was not narrowed but instead the caudal sac was actually dilated. Confavreux et al have presented evidence that enlargement of the lumbar dural sac is due to a defect in resorption of the CSF. There are usually arachnoidal diverticulae on the posterior root sleeves, but no other explanation can be given for the radicular symptoms and signs. Surgical decompression has not benefited the patients, nor has corticosteroid therapy. This condition occasionally occurs at higher levels and gives rise to a myelopathy. Our experience includes cases with symptoms related to the cervical roots with diverticulae of dural nerve sheaths.

The most hazardous complication of ankylosing spondylitis is compression of the cord, from seemingly minor trauma that has resulted in fracture-dislocation of the cervical (or lumbar) vertebrae. Fox and colleagues from the Mayo Clinic treated 31 such patients in a 5-year period; the majority of unstable fractures that required surgical fixation were in the cervical region, and several patients had fracture-dislocations at two levels. The instability at the upper spinal levels may be difficult to detect radiologically, and caution should be observed in allowing patients to resume full activity after a neck injury if the cervical spine is seen to be involved by spondylitis. Careful flexion and extension x-ray views usually, but not always, demonstrate the instability.

As alluded to earlier, multiple arachnoid cysts in the thoracic or lumbar region have been associated with ankylosing spondylitis and with *Marfan syndrome*.

Rheumatoid Arthritis The spinal changes of rheumatoid arthritis differ somewhat from those of ankylosing spondylitis although the latter too may be a cause of atlantoaxial dislocation (see further on under "Anomalies at the Craniocervical Junction.") The ligaments that attach the odontoid to the atlas and to the skull and the joint tissue are weakened by the destructive inflammatory process. The subsequent dislocation of the atlas on the axis may remain mobile or become fixed and give rise to an intermittent or persistent mild to moderate paraparesis or quadriplegia. Similar effects may result from a forward subluxation of C4 on C5 (see Nakano et al). Atlantoaxial dislocation is known to be a cause of collapse and sudden death. If the upper cervical cord is compressed, the odontoid process must be removed and C1–C2 decompressed and stabilized. Other levels of the spine are less frequently affected.

Ossification of the Posterior Longitudinal Ligament (OPLL) Compressive cervical myelopathy due to this unusual process occurs almost exclusively in patients of Japanese extraction and has been demonstrated to us as an almost mundane finding by colleagues in Hawaii. The clinical signs are much the same as those of cervical spondylosis, but the radiologic appearance of cancellous bone along a segment of the posterior longitudinal ligament is unique. The ligamentous calcification can be seen on plain films, CT scan, and MRI and may be mistaken for spondylotic change. The ossified areas may enlarge enough to form islands of bone marrow. Laminoplasty with enlargement of the spinal canal has been successful.

Cervical Dural Sac Myelopathy (Hirayama Disease, Juvenile Muscular Atrophy of the Distal Upper Limb) This unusual myelopathy has usually been considered with the motor neuron disorders because of its characteristic features of chronic wasting of one hand and forearm without sensory changes or long tract signs. Hirayama pointed out that in the young men who were affected, the mechanism of cord damage may be a buckling of the dorsal dural sac and intermittent anterior displacement and ligamentous compression of the cord during flexion of the neck.

The muscles innervated by C7, C8, and T1, encompassing mainly the hand and forearm, are affected on one side or bilaterally, but always asymmetrically. There are few or no fasciculations and no sensory changes; the painless loss of power and muscle bulk proceeds smoothly over several years, giving the impression of a degenerative condition. MRI or CT myelogram performed with the neck flexed, as described by Hirayama and Tokumaru, shows the cervical cord to be atrophic with signal changes in the anterior parts of the cord and confirms the diagnosis of compression by the buckled dura. We have examined three such patients in the past 5 years and can corroborate their claim from observation of MRI with the patient placed in a flexed-neck position. Presumably, this configuration causes ischemia of the anterior gray matter, but this has not been proved. Others have reported the syndrome in the absence of this structural configuration (Willeit et al). Two of our patients had long swan-like necks. What is most important about this process is the degree of recovery afforded by partial vertebrectomy and by similar surgical approaches that accomplish decompression of the lower cervical cord.

Paget Disease of the Spine (Osteitis Deformans) Enlargement of the vertebral bodies, pedicles, and laminae in Paget disease may result in narrowing of the spinal canal. The clinical picture is one of cord compression. Plasma alkaline phosphatase concentrations are high, and the typical bone changes are seen in radiographs. Usually several adjacent vertebrae of the thoracic spine are affected. Other parts of the skeleton are also involved (see later), which facilitates diagnosis. Posterior surgical decompression, leaving the pedicles intact, is indicated if there is sufficient stability of the vertebral bodies to prevent collapse. Medical management includes the use of nonsteroidal anti-inflammatory drugs for persistent pain; calcitonin to reduce pain and plasma levels of alkaline phosphatase; and cytotoxic drugs such as plicamycin and etidronate disodium to reduce bone resorption (see Singer and Krane).

Other Spinal Abnormalities with Myelopathy

The spinal cord is obviously vulnerable to any vertebral maldevelopment or disease that encroaches upon the spinal canal or compresses its nutrient arteries. Some well-known abnormalities are listed here.

Anomalies at the Craniocervical Junction Of these, congenital fusion of the atlas and foramen magnum is the most common. McCrae, who described the radiologic features of more than 100 patients with bony abnormalities at the craniocervical junction, found a partial or complete bony union of the atlas and foramen magnum in 28 cases. He noted also that whenever the anteroposterior diameter of the canal behind the odontoid process was less than 19 mm, there were signs of spinal cord compression. Fusion of the second and third cervical vertebrae is a common associated anomaly but does not seem to be of clinical significance.

Abnormalities of the Odontoid Process These were found in 17 cases of McCrae's series. There may be complete separation of the odontoid from the axis or chronic *atlantoaxial dislocation* (axis displaced anteriorly in relation to the axis). These abnormalities may be congenital or the result of injury and are known causes of acute or chronic spinal cord compression and stiffness of the neck.

In all the congenital anomalies of the foramen magnum and the upper cervical spine there is a high incidence of syringomyelia (see pages 115 and 1084). McCrae found that 38 percent of all patients with syringomyelia and syringobulbia showed such bony anomalies. All patients whose symptoms might be explained by a lesion in the cervicocranial region (particularly patients in whom MS and foramen magnum tumor are suspected) require careful radiologic examination.

In mucopolysaccharidosis IV, or the Morquio syndrome (page 823), a typical feature is the absence or severe hypoplasia of the odontoid process. This abnormality, combined with laxity or redundancy of the surrounding ligaments, results in atlantoaxial subluxation and compression of the spinal cord. Affected children refuse to walk or develop spastic weakness of the limbs. Early in life they excrete an excess of keratan sulfate, but this may no longer be detectable in adult life. In certain of the mucopolysaccharidoses, we have also seen a true pachymeningiopathy—great thickening of the dura in the basal cisterns and high cervical region with spinal cord compression. Surgical decompression and spinal immobilization has been curative.

Achondroplasia This dominantly inherited form of dwarfism is due to a mutation in one of the fibroblastic growth factors, which

causes a failure of conversion of fetal cartilage to bone at the growth plate. It occasionally results in great thickening of the vertebral bodies, neural arches, laminae, and pedicles because of increased periosteal bone formation. The spinal canal is narrowed in the thoracolumbar region, often with kyphosis, leading sometimes to a progressive spinal cord or cauda equina syndrome. Another neurologic complication, which results from a small foramen magnum, is hydrocephalus (internal, with large ventricles, or external, with widened subarachnoid spaces). In young children, a syndrome of central apnea and spasticity of the legs is characteristic. These complications may require ventricular shunting. Narrowing of the lumbar canal tends to present later in life.

Platybasia and Basilar Invagination *Platybasia* refers to a flattening of the base of the skull (the angle formed by intersection of the plane of the clivus and the plane of the anterior fossa is greater than 135 degrees). *Basilar impression or invagination* has a somewhat different meaning—namely, an upward bulging of the occipital condyles; if the condyles, which bear the thrust of the spine, are displaced above the plane of the foramen magnum, basilar invagination is present. Each of these abnormalities may be congenital or acquired (as in Paget disease); frequently they are combined. They give rise to a characteristic shortness of the neck and a combination of cerebellar and spinal signs. A normal-pressure hydrocephalus may also develop.

In the *Klippel-Feil syndrome* there is fusion of the upper cervical vertebrae or of the atlas to the occiput. The anomaly is easily identified by substantial foreshortening of the neck. There may be compression of the cervical cord after minor trauma.

Tethered Cord This developmental anomaly is discussed fully in Chap. 38. A progressive cauda equina syndrome with prominent urinary difficulties, and varying degrees of spasticity are the usual presentations.

Syphilitic Meningomyelitis

Here, as in MS, the degree of ataxia and spastic weakness is variable. A few patients have an almost pure state of spastic weakness of the legs, requiring differentiation from motor system disease and familial spastic paraparesis. Such a syndrome, formerly called Erb's spastic paraparesis and attributed to meningo-vascular syphilis, is now recognized as being nonspecific and more often due to demyelinative disease. In a minority of chronic syphilitic patients, sensory ataxia and other posterior column signs predominate. Ventral roots are involved in the chronic meningeal inflammation, giving rise to signs of segmental amyotrophy. Hence the term *syphilitic amyotrophy* of the upper extremities with spastic paraparesis. Confirmation of this now infrequent diagnosis depends on finding a lymphocytic pleocytosis, an elevated protein and gamma globulin, and a positive serologic reaction in the CSF. Other aspects of this disease and treatment are discussed on page 618.

Subacute Combined Degeneration of the Spinal Cord (SCD; see also Chap. 41, page 992)

This classic form of nutritional spinal cord disease is due to vitamin B₁₂ deficiency and is fully described on pages 992 to 996. Almost invariably it begins with bilateral symptoms and signs of posterior column involvement in the hands (paresthesias and reduced touch, pressure and joint sensibility), which, if untreated, is followed within a matter of several weeks or months by progressive spastic

paraparesis due to involvement of the corticospinal tracts to which a vague sensory level on the trunk may be added. Of particular importance is the fact that SCD is a treatable disease and that the degree of reversibility is dependent upon the duration of symptoms before specific treatment is begun.

Combined System Disease of Nonpernicious Anemia Type and Hypocupric Myopathy

This refers to an intrinsic degenerative disease of the spinal cord, probably somewhat more common than SCD and affecting the posterior and lateral columns (in this sense, also a combined system disease). There is no association with vitamin B₁₂ or folate deficiency, but low serum copper and ceruloplasmin levels are found in some cases and replacement of copper results in stabilization of the illness (Kumar et al). Posterior column signs and gait ataxia are said to predominate. The problem seems to be one of absorption of copper, for example, after bowel surgery, and there may be an anemia. In a recent case on our service, without explanation for the discovered copper deficiency, MRI of the cervical cord revealed distinctive signal changes in both the posterior and lateral columns. It is doubtful that copper depletion accounts for all cases of combined system disease that are not linked to B₁₂ deficiency, but the resemblance of the clinical syndromes is remarkable. Other cases unrelated to B₁₂ or to copper deficiency display predominantly corticospinal signs and are of unknown cause. Little is known of its pathologic basis and perhaps it is a manifestation of several processes.

Progressive spastic or spastic-ataxic paraparesis of a chronic, irreversible type may also develop in conjunction with chronic, decompensated liver disease (page 967); with AIDS; in certain cases of adrenoleukodystrophy, particularly in the symptomatic heterozygote, i.e., the female carrier (page 837); in tropical spastic paraparesis (HTLV-I); in radiation myelopathy; and in adhesive spinal arachnoiditis, which is discussed later.

Spinal Arachnoiditis (Chronic Adhesive Arachnoiditis)

This is now a relatively uncommon spinal cord disorder that was introduced in relation to the subject of low back pain (page 180). It is characterized clinically by a combination of painful root and spinal cord symptoms that may mimic intraspinal tumor. Pathologically there is opacification and thickening of the arachnoidal membranes and adhesions between the arachnoid and dura—the result of proliferation of connective tissue. The subarachnoid space is unevenly obliterated. In this sense, the term *arachnoiditis* is not entirely appropriate, although it seems likely that the connective tissue overgrowth is a reaction to an antecedent arachnoidal inflammation. Some forms of arachnoiditis can be traced to syphilis or to a subacute, therapeutically resistant meningitis of another type. Most others have followed the introduction of a variety of substances, most no longer used, into the subarachnoid space for diagnostic or therapeutic purposes. These included penicillin and other antibiotics, methylene blue, iophendylate (Pantopaque), and other contrast media and corticosteroids. At one time, many examples of adhesive arachnoiditis were observed following spinal anesthesia, occurring soon afterward or after an interval of weeks, months, or even years. Our colleagues observed more than 40 such cases. This complication was eventually traced to a detergent that had contaminated vials of procaine. If enough of the contaminant

was injected, an areflexic paralysis of the legs and sphincters of bladder and bowel and sensory loss in the legs developed within a few days, along with considerable pain. More pernicious, however, was a delayed meningo(myelopathy that developed within a few months or years, causing a spastic paralysis, sensory loss, and incontinence of sphincters. There are cases on record in which an epidural or similar catheter has accidentally penetrated the cord and caused a traumatic partial myelopathy (page 1057). Still seen is a restricted form of arachnoiditis that complicates a series of operations for lumbar discs or the spinal injection of methylene blue. Less convincing are cases attributed to closed spinal injuries. In many cases no provocative factor can be recognized. A familial form has been reported by Duke and Hashimoto, but we have had no experience with it.

Clinical Manifestations Symptoms may occur in close temporal relation to an acute arachnoidal inflammation or may be delayed for weeks, months, or even years. The most common mode of onset is with pain in the distribution of one or more sensory nerve roots, first on one side, then on both, in the lumbofemoral regions. The pain has a burning, stinging, or aching quality and is persistent. Abnormalities of tendon reflexes are common, but weakness and atrophy, the results of damage to anterior roots, are less frequent findings and tend to occur in cases involving the cauda equina. In thoracic lesions, symptoms of root involvement may antedate those of cord compression by months or years. Sooner or later, however, there is involvement of the spinal cord, manifest by a slowly progressive spastic ataxia with sphincter disturbances.

The localized lumbar arachnoiditis associated with repeated disc surgery (the common variety seen in pain clinics) is characterized by back and or leg pain with other inconstant signs of radiculopathy (loss of tendon reflexes, weakness, and variable degrees of sensory loss), usually bilateral.

The CSF is abnormal during the acute stage in practically all cases of adhesive arachnoiditis. In some there is a moderate lymphocytic pleocytosis, occurring soon after the inciting event, but the striking finding is a partial or complete obliteration of the spinal subarachnoid space, sometimes extreme in degree. In the localized lumbar arachnoiditis, referred to earlier, the CSF may be normal or show only a slight increase in protein content. The loculated myelographic appearance of arachnoiditis is characteristic (patchy dispersion of the column of dye and a "candle-guttering" appearance that was most evident with oil-based contrast media); MRI reveals a loss of the normal ring of CSF or localized loculations of CSF (see Fig. 11-6). These ancillary procedures and the CSF formula, if obtained in the acute stages, allow one to make the diagnosis with certainty. Later, the CSF shows only an elevated protein content.

Pathologic Features In advanced cases the subarachnoid space is completely obliterated and the roots and cord are strangulated by the thickened connective tissue. Subpial nerve fibers of the cord are destroyed to a varying extent, and peripherally placed fibers of the posterior and lateral columns undergo secondary degeneration. Where the pathologic process is confined to relatively circumscribed portions of the cord, the subarachnoid space may be occupied by loculated collections of yellowish, high-protein fluid (meningitis serosa circumscripta). The rare association of spinal arachnoiditis and syringomyelic cavitation of the cord is considered further on in this chapter.

Treatment In the early stages of arachnoiditis, corticosteroids have been given systemically to control the inflammatory reaction and to prevent progress of the disease, but their value is question-

able. Surgery may be effective in the rare case of localized "cyst" formation and cord compression. Severe radicular pain can be effectively relieved by posterior rhizotomy, but there is a strong tendency for the pain to return after an interval of several months or a year or two. For chronic adhesive lumbar arachnoiditis in which diffuse back and limb pain is the most distressing symptom, there is little effective surgical or medical treatment, although relief has reportedly been provided in isolated instances by painstaking microsurgical dissection of the lumbar roots. In some cases, the loculations return. Administration of corticosteroids, systemic and epidural, has not been consistently beneficial but may be tried. Immune suppressant medication such as azathioprine or interferons have been tried but not studied systematically. Transcutaneous stimulator treatment and gabapentin have also been used with inconsistent results.

Herniation of the Cord Through a Dural Tear

Violent trauma to the spinal canal or skull can cause arachnoidal and dural tears. The associated neural injury dominates the picture and the dural tear may require repair in order to minimize the development of meningitis. More difficult to understand is the occurrence of spinal cord herniation through an apparently spontaneous rent in the adjacent dura with no preceding injury. In view of the fact that we have encountered five such instances in a decade, without trauma having occurred, it is probably not rare.

In the typical case, a vertically oriented tear of limited extent occurs in the ventral dura, in the mid- or high-thoracic region, and a segment of the spinal cord protrudes through it into the epidural space. The result is a painless, subacute, and incomplete spinal cord syndrome, which reaches a plateau and leaves the patient with an asymmetrical spastic paraparesis and variable sensory loss. There are reports of a Brown-Séquard hemicord syndrome. Orthostatic headache of low-CSF pressure is not usually part of the syndrome. MRI or CT myelopathy demonstrates the protruded segment of the cord where it buckles through the dura. Presumably the herniation creates a sufficient degree of local ischemia or mechanical disturbance to account for the myelopathic symptoms. Surgical replacement of the cord in its proper position and repair of the tear has resulted in partial return of neurologic function (Vallee et al).

As to the cause, a congenital duplication of the dura membranes combined with herniation through the inner layer has been observed in some cases at operation.

Intraspinal Tumors

Compression of the spinal cord by a metastatic tumor in the vertebral column is a common occurrence in many types of cancer. Primary tumors of the spinal cord, however, are considerably less frequent. In the Mayo Clinic series of 8784 primary tumors of the CNS, only 15 percent were intraspinal (Sloof et al). In distinction to brain tumors, the majority of intraspinal ones are benign and produce their effects mainly by compression of the spinal cord rather than by invasion. Thus, a proportion of intraspinal tumors are amenable to surgical removal, and their early recognition, before irreversible neurologic changes have occurred, becomes a matter of utmost importance.

Anatomic Considerations Neoplasms and other space-occupying lesions within the spinal canal can be divided into two groups:

(1) those that arise within the substance of the spinal cord, either as a primary neural neoplasm or as a metastasis, and invade and destroy tracts and central gray structures (*intramedullary*) and (2) those arising outside the spinal cord (*extramedullary*), either from vertebral bodies and epidural tissues (*extradural*) or in the lepto-meninges or roots (*intradural*). In a general hospital, the relative frequency of spinal tumors in these different locations is about 5 percent intramedullary, 40 percent intradural-extramedullary, and 55 percent extradural, the majority of the latter being metastatic cancers, as already mentioned. This percentage of extradural lesions is higher than that encountered in more specialized neuro-surgical services (e.g., Elsberg's figures of 7, 64, and 29 percent, respectively), probably because the latter do not include as many patients with extradural lymphomas, metastatic carcinomas, etc., as are seen in general hospitals.

The most common *primary extramedullary* tumors are the neurofibromas and meningiomas (Fig. 44-10), which together constitute about 55 percent of all intraspinal neoplasms. They are more often intradural than extradural. Neurofibromas have a predilection for the thoracic region, whereas meningiomas are more evenly distributed over the vertical extent of the cord. The other primary extramedullary tumors are sarcomas, vascular tumors, chordomas, and epidermoid and similar tumors, in that order of frequency.

Primary intramedullary tumors of the spinal cord have the same cellular origins as those arising in the brain (Chap. 31), although the proportions of particular cell types differ. Ependymomas (some of which arise from the filum terminale; page 860)

Figure 44-10. Gadolinium-enhanced MRI of intraspinal meningioma that caused incontinence and leg weakness, including spastic and flaccid elements (combined conus and cauda syndrome).

Figure 44-11. T1-weighted MRI of an intramedullary thoracic ependymoma, causing expansion of the cord and edema over several segments. There is faint enhancement of the tumor with gadolinium.

make up 60 percent of the spinal cord cases (Fig. 44-11) and astrocytomas about 25 percent. The astrocytoma is the most common intramedullary tumor if one excludes tumors arising in the filum terminale. Oligodendrogliomas are much less common. The remainder (about 10 percent) consists of a diverse group of non-gliomatous tumors: lipomas, epidermoids, dermoids, teratomas, hemangiomas, hemangioblastomas, and metastatic carcinomas. The cavernous hemangioma may be a source of spontaneous hematomyelia. As indicated further on, there is a frequent association between intramedullary tumors (both gliomatous and nongliomatous) and syringomyelia. The basis of this relationship remains obscure.

Intramedullary growths invade as well as compress and distort fasciculi in the spinal cord white matter. As the cord enlarges from the tumor growing within it or is compressed by a tumor from without, the free space around the cord is eventually consumed, and the CSF below the lesion becomes isolated or loculated from the remainder of the circulating fluid above the lesion. This is indicated by a Froin syndrome (xanthochromia and clotting of CSF) and an interruption of flow of contrast medium in the subarachnoid space (by myelogram). The most informative diagnostic procedure

is an MRI, which demonstrates both the intramedullary extent of the tumor and the effect on the surrounding subarachnoid space.

Secondary spinal cord tumors can also be subdivided into intramedullary and extramedullary types. *Extradural metastases (carcinoma, lymphoma, myeloma)* are the most common of all spinal tumors. They account for the largest group of patients who develop symptoms of myelopathy while being cared for in hospital and are therefore likely to be encountered in the course of providing neurologic consultations. Extradural metastases arise from hematogenous deposits or extend from tumors of the vertebral bodies or from a paraspinal tumor extending via the intervertebral foramina (Fig. 44-12). Secondary extramedullary tumor growths are far more often extradural than intradural. The intradural type takes the form of a meningeal carcinomatosis or lymphomatosis and the rare primary melanoma of the meninges, which is considered in Chap. 31.

Intramedullary metastases are not as rare as is generally believed. In a retrospective autopsy study of 627 patients with systemic cancer, Costigan and Winkelman found 153 cases with CNS metastases, in 13

of which the metastases were located within the cord. In 9 of the 13 cases, the metastasis was deep in the cord, unassociated with leptomeningeal carcinomatosis; in 4 cases, the neoplasm seemed to extend from the pia. Bronchogenic carcinoma was the main source. Diagnosis is difficult but is aided greatly by MRI with gadolinium infusion; there is generally extensive contiguous edema (Fig. 44-13). Differentiation is from meningeal carcinomatosis, radiation myelopathy, and paraneoplastic necrotizing myelopathy, which is the rarest of these entities. Treatment is usually ineffective unless radiation therapy is begun before paraplegia supervenes (Winkelman et al).

Symptomatology Patients with spinal cord tumors are likely to present with one of three clinical syndromes: (1) a sensorimotor spinal tract syndrome, (2) a painful radicular-spinal cord syndrome, or (3) least often, an intramedullary syringomyelic syndrome. The sensory features of these syndromes are shown in Fig. 9-5 on page 140.

Pain and stiffness of the back may antedate signs of spinal cord disease or dominate the clinical picture in some cases of extramedullary tumor. The back pain is usually worse when the patient lies down or may become worse after several hours in the recumbent position and be improved by sitting up. *In children*, severe back pain associated with spasm of paravertebral muscles is often prominent initially; scoliosis and spastic weakness of the legs come later. Because of this somewhat unusual clinical presentation and the rarity of intraspinal lesions in childhood, spinal cord tumors in this age group may be overlooked.

Sensorimotor Spinal Tract Syndrome The clinical picture is related predominantly to compression and less often to invasion and destruction of spinal cord tracts. The signs of compression consist of (1) an asymmetrical spastic weakness of the legs with thoracolumbar lesions and of the arms and legs with cervical lesions, (2)

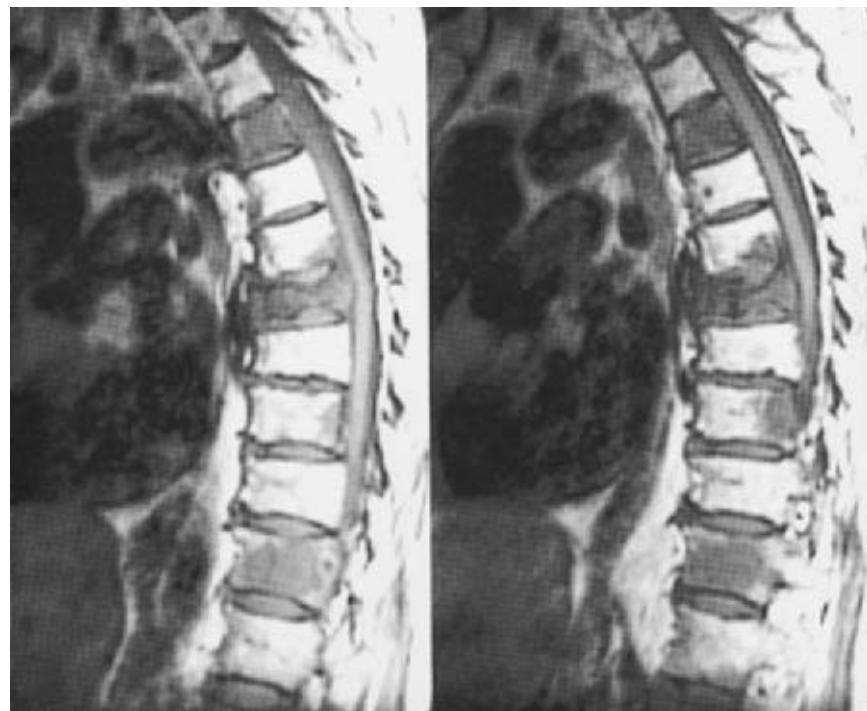

Figure 44-12. MRI of multiple spinal metastases from carcinoma of the lung. The metastases exhibit low signal intensity on T1-weighted images. An epidural mass is present, compressing the cord.

a sensory level on the trunk below which perception of pain and temperature is reduced or lost, (3) posterior column signs, and (4) a spastic bladder under weak voluntary control. The onset of the compressive symptoms is usually gradual and the course progressive over a period of weeks and months, frequently with back pain. With extradural tumors, paralysis usually develops over a period of days to several weeks, but the tempo of progression may be more rapid or more leisurely. The initial disturbance may be motor or sensory and the distribution asymmetrical. High cervical or foramen magnum lesions produce special clinical syndromes, as discussed on page 52 and below. With thoracic lesions, one leg usually becomes weak and stiff before the other one. Subjective sensory symptoms of the dorsal column type (tingling paresthesias) assume similar patterns. Pain and thermal senses are more likely to be affected than tactile, vibration, and position senses. Nevertheless, the posterior columns are frequently involved. Initially the sensory disturbance is contralateral to the maximum motor weakness, but a sharply defined Brown-Séquard hemicord syndrome is rarely observed. The bladder and bowel usually become paralyzed coincident with paralysis of the legs. If the compression is relieved, there is recovery from these sensory and motor symptoms, often in the reverse order of their appearance; the first part affected is the last to recover, and sensory symptoms tend to disappear before motor ones. **Radicular-Spinal Cord Syndrome** Here the syndrome of spinal cord compression is combined with radicular pain, i.e., pain in the distribution of a sensory nerve root. It is described as knife-like or as a dull ache with superimposed sharp stabs of pain, which radiate in a distal direction, i.e., away from the spine, and are intensified by coughing, sneezing, or straining. Segmental sensory changes (paresthesias, impaired perception of pinprick and touch) and/or motor disturbances (cramp, atrophy, fascicular twitching, and loss of tendon reflexes) and an ache in the spine, in addition to the radicular pain, are the usual manifestations. Tenderness of spinous

Figure 44-13. MRI of an intramedullary metastasis from breast cancer. The expansile lesion is at C8 and the adjacent edema extends over a great length of the spinal cord.

processes over the growth is found by percussion in about half the patients. The segmental changes, particularly the sensory radicular ones, often precede the signs of spinal cord compression by months if the lesion is benign.

Intramedullary Syringomyelic Syndrome No single symptom is unique to *intramedullary tumors*. Some degree of pain, sometimes minor, is common and is almost invariably present with tumors of the filum terminale. Ependymomas and astrocytomas, the two most common intramedullary tumors, usually give rise to a mixed sensorimotor tract syndrome. When the intramedullary tumor involves the central gray matter, a central cord, or *syringomyelic syndrome* may result (page 1084). The main features are segmental or dissociated sensory loss, amyotrophy, early incontinence, and late corticospinal weakness. Also, on sensory examination, sacral sparing may be found but is of less value in distinguishing intramedullary from extramedullary lesions. A dissociation of thermal pain and tactile sensory loss over several segments on the trunk is a more dependable sign of an intramedullary lesion. Rarely, an extramedullary tumor may give rise to a syringomyelic syndrome, possibly by causing vascular insufficiency in the central portion of the cord.

Special Spinal Syndromes Unusual clinical syndromes may be found in patients with *tumors in the region of the foramen magnum*. They produce a quadripareisis with pain in the back of the head and stiff neck, weakness and atrophy of the hands and dorsal neck muscles, marked imbalance, and variable sensory changes—or, if they spread intracranially, there may be signs of cerebellar and lower cranial nerve involvement. As noted earlier and in Chap. 3, slowly growing tumors in this region, such as meningiomas, characteristically produce an “around the clock” progression of weakness beginning in one limb and proceeding to the adjacent one. Lesions at the level of the lowermost thoracic and the first lumbar vertebrae may result in mixed cauda equina and spinal cord symptoms. A Babinski sign indicates that the spinal cord is involved above the fifth lumbar segment. *Lesions of the cauda equina* alone, always difficult to separate from those of the lumbosacral plexuses and multiple nerves, are usually attended in the early stages by sciatic and other root pain and lumbar ache, which is variously combined with a bilaterally asymmetrical, atrophic, areflexic paralysis, radicular sensory loss, and sphincteric disorder. These must be distinguished from *lesions of the conus medullaris* (lower sacral segments of the spinal cord), in which there are early disturbances of the bladder and bowel (urinary retention and constipation), back pain, symmetrical hypesthesia or anesthesia over the sacral dermatomes, a lax anal sphincter with loss of anal and bulbocavernosus reflexes, impotence, and sometimes weakness of leg muscles. Sensory abnormalities may precede motor and reflex changes by many months. Very rarely, for unclear reasons, tumors of the thoracolumbar cord (intramedullary, as a rule) may be associated with markedly elevated spinal fluid protein and hydrocephalus; these respond to shunting and removal of the spinal tumor (Feldman et al). Less often, these tumors have caused a pseudotumor cerebri syndrome.

Differential Diagnosis Several problems arise in the diagnosis of spinal cord tumors in addition to those previously mentioned. In their early stages they must be distinguished from other diseases that cause pain over certain segments of the body, i.e., diseases affecting the gallbladder, pancreas, kidney, stomach and intestinal tract, pleura, etc. Localization of the pain to a dermatome; its intensification by sneezing, coughing, and straining, and sometimes by recumbency; and the finding of segmental sensory changes and minor alterations of motor, reflex, or sensory function in the legs will usually provide the clues to the presence of a spinal cord radicular lesion. MRI will settle the diagnosis in most instances.

There is then the problem of locating the segmental level of the lesion. At first, the sensory and motor deficits may be most pronounced in those parts of the body farthest removed from the lesion, i.e., in the feet or lumbosacral segments. Later the levels of the sensory and motor deficits ascend, but they may still be at a level several segments below the lesion. In determining the level of the lesion, the location of back pain, root pain, and atrophic paralysis are of greater help than the upper level of hypalgesia.

Once vertebral and segmental levels of the lesion are settled, there remains the necessity of determining whether the lesion is extradural, intradural-extramedullary, or intramedullary and whether it is neoplastic. If there is a visible or palpable spinal deformity or radiographic evidence of vertebral destruction, one may confidently assume an extradural localization. Even without these changes, one still suspects an extradural lesion if root pain developed early and is bilateral, if pain and aching in the spine are prom-

inent and percussion tenderness is marked, if motor symptoms below the lesion preceded sensory ones, and if sphincter disturbances were late. However, to distinguish between intradural-extramedullary lesions and intramedullary lesions on clinical grounds alone is often difficult. The findings of segmental amyotrophy and sensory loss of dissociated type (loss of pain and temperature and preservation of tactile sensation) point to an intramedullary lesion.

Extradural tumors, both primary and secondary, must be differentiated from cervical spondylosis, tuberculous granuloma, sarcoidosis, arteriovenous malformations of the cord, spinal dural fistulas, and certain chronic pyogenic or fungal granulomatous lesions, from lipomas in patients receiving corticosteroids for prolonged periods, and from the necrotizing myelopathy associated with occult tumors or occurring independently of them. In the thoracic region, a ruptured disc or even traction of the cord through a dural tear is always a possibility. In the region of the lower back, i.e., over the cauda equina, one must also distinguish between tumor and protruded intervertebral disc. Here, an extradural tumor may produce mainly sciatic and low back pain with little or no motor, sensory, reflex, or sphincteric disturbances. With intradural-extramedullary lesions, the important diagnostic considerations are meningioma, neurofibroma, meningeal carcinomatosis, cholesteatoma, and teratomatous cyst, a meningomyelic process, or adhesive arachnoiditis. The cytologic study of cells in the CSF and the use of MRI are the essential laboratory aids. Intramedullary lesions are usually gliomas, ependymomas, or vascular malformations or, in the context of a known carcinoma, intramedullary metastases. The definition of vascular malformations by means of selective spinal angiography has been discussed in an earlier section of this chapter. Normal protein in the CSF and negative MRI effectively exclude intramedullary tumors and granulomatous lesions.

Treatment Treatment depends on the nature of the lesion and the clinical condition of the patient.

The main consideration in the management of epidural metastases is the need for early diagnosis, at a stage when only back pain is present and before neurologic symptoms and signs have appeared. Once neurologic signs appear, the results of treatment are poor. Epidural growths of carcinoma and lymphoma are best managed by the administration of radiation to the region of tumor involvement, endocrine therapy (for carcinoma of breast and prostate), the administration of antineoplastic drugs (for certain lymphomas and myelomas), and the early use of high-dose steroids and analgesics for pain. Seldom is operation necessary as a first resort. Gilbert and his associates have presented evidence that patients who receive high-dose corticosteroids (16 to 60 mg of dexamethasone) and fractionated radiation (500 cGy on each of the first 3 days and then spaced radiation up to 3000 cGy) do as well as surgically treated patients. Sometimes laminectomy and decompression are necessary for diagnosis and, with a rapidly growing tumor, to prevent irreversible compressive effects and infarction of the spinal cord. Cases that have been allowed to progress should probably be operated on if paraplegia has just occurred. If the maximal safe radiation dosage had previously been applied to the spinal column, surgical palliation is usually undertaken.

Intradural-extramedullary tumors should generally be removed if this can be accomplished safely, and this applies to benign extradural tumors that are symptomatic as well. Laminectomy, decompression, excision in isolated cases, and radiotherapy constitute the treatment of intramedullary gliomas. Such patients may im-

prove and lead useful lives for a decade or longer. Constantini and colleagues, based on their experience with 164 instances of intramedullary lesions, mainly gliomas, in children and young adults, recommend a radical excision of the tumor, but this approach has not been subjected to a trial.

Other Rare Causes of Spinal Cord Compression

Epidural fat deposition with spinal cord or cauda equina compression occurs in Cushing disease and after the long-term use of corticosteroids but also in the absence of these disorders. The clinical picture may suggest discogenic disease (Lipson et al). Copious amounts of normal adipose tissue are found at laminectomy, and removal of this tissue is curative. Lowering the dose of steroid and caloric restriction will help mobilize the fat and relieve the symptoms. (An intraspinal lipoma is also a component of the developmentally tethered cord, but in this process the essential problem is a conus medullaris myelopathy from stretching of the cord, rather than compression; see Thomas and Miller.)

Arachnoid diverticula—intra- or extradural outpouchings from the posterior nerve root—are rare causes of a radicular-spinal cord syndrome first described by Bechterew in 1893. They tend to occur in the thoracic or lumbosacral regions. The symptoms, in order of decreasing frequency, are pain, radicular weakness and sensory disorder, gait disorder, and sphincteric disturbances (Cilluffo et al). The frequent association of arachnoid diverticula with osteoporosis, ankylosing spondylitis, and arachnoiditis makes it difficult to interpret the role of the diverticulae themselves. Surgical obliteration of the pouches has yielded unpredictable results. They have attained clinical importance more often in our experience as the source of spontaneous CSF leaks and a low-pressure syndrome (Chap 30).

Spinal cord compression with paraplegia may be caused by *extramedullary hematopoiesis* in cases of myelosclerosis, thalassemia, cyanotic heart disease, myelogenous leukemia, sideropenic anemia, and polycythemia vera (Oustwani et al). A similar phenomenon occurs with ossification of the posterior longitudinal ligament, as described earlier.

Solitary *osteochondromas* of vertebral bodies and *multiple exostoses* of hereditary type are other reported causes of spinal cord compression. In the case reported by Buur and Mørch, the clinical syndrome was one of pure spastic paraparesis of several months' progression.

Lathyrism (See also page 1033)

From the interesting historical review of Dastur, one learns that this disease was known to Hippocrates, Pliny, and Galen in Europe, to Avicenna in the Middle East, and to the ancient Hindus. The term *lathyrism* was applied by Cantani, in Italy, because of its recognized relationship to the prolonged consumption of *Lathyrus sativus* (chickling vetch, vetch pea, or grass pea).

The disease is still common in some parts of India and Africa. In these districts, during periods of famine when wheat and other grains are in short supply, the diet may for months consist of flour made of the grass pea. In individuals so exposed there occurs a gradual weakening of the legs accompanied by spasticity and cramps. Paresthesias, numbness, formication in the legs, and frequency and urgency of micturition, impotence, and sphincteric

spasms are added. The upper extremities may exhibit coarse tremors and involuntary movements. These symptoms, once established, are more or less permanent but not constantly progressive, and most of the patients live out their natural life span.

Only two reports on the neuropathology of lathyrism were known to Dastur, one by Buzzard and Greenfield in England, the other by Filiminoff in Russia. Both of their patients had been in a stationary paraplegic state for years. Greenfield noted a loss of ascending and descending tracts in the spinal cord, particularly the corticospinal and direct spinocerebellar tracts. Filiminoff observed a loss of myelinated fibers in the lateral and posterior columns. Unlike the cases of Spencer et al, there had been a loss of pain and thermal sensation in the upper extremities. The larger Betz cells had disappeared, while anterior horn cells were unaffected. Gliosis and thickening of blood vessels was seen in the degenerated tracts.

The toxic nature of this disease, long suspected, was confirmed by Spencer and colleagues. They extracted a neuroexcitatory amino acid, beta-N-oxalylaminoalanine (BOAA), from grass peas and were able to induce corticospinal dysfunction in monkeys by giving this substance with a nutritious diet. Subsequently, Hugon and coworkers produced a primate model of lathyrism by feeding monkeys a diet of *L. sativus* in addition to an alcoholic extract of this legume. These findings tend to negate the importance of several other factors that until now had been thought to be causative—namely, malnutrition, ergot contamination, and toxins derived from *Vicia sativa*, the common vetch that grows alongside the *lathyrus* species.

The African acute spastic paraplegia called “*konzo*” has a similar toxic pathogenesis; it is caused by cyanide-like compounds in flour made from cassava.

Dysraphic Syndromes (Spina Bifida) and Tethered Cord

These are described in Chap. 38.

Familial Spastic Paraplegia (See Chap. 39 and Table 39-8)

There are several familial forms of progressive spastic paraparesis, some beginning in childhood, others in adult life. The pattern of inheritance in almost all our adult cases has been autosomal dominant. A lack of sensory symptoms and signs and sparing of sphincteric function until late in the illness are important diagnostic features. A number of adult cases are “complicated” in the sense that the spastic paraparesis is associated with cerebellar ataxia or dementia. By contrast, *primary lateral sclerosis*, a sporadic form of degenerative disease of the motor system, is characterized by a pure spastic paraparesis and bulbar spastic palsy either initially or with progression, the result of changes that are confined to the corticospinal pathways. These disorders are discussed extensively with the heredodegenerative diseases in Chap. 39, and the myelopathy associated with adrenoleukodystrophy, in Chap. 37.

SYRINGOMYELIC SYNDROME OF SEGMENTAL SENSORY DISSOCIATION WITH BRACHIAL AMYOTROPHY

This syndrome is most often attributable to developmental syringomyelia, i.e., a central cavitation of the spinal cord of undeter-

mined cause, but a similar clinical syndrome may be observed in association with other pathologic states such as intramedullary cord tumors, traumatic myelopathy, postradiation myelopathy, infarction (myelomalacia), bleeding (hematomyelia), and rarely with extramedullary tumors, cervical spondylosis, spinal arachnoiditis, and cervical necrotizing myelitis.

Syringomyelia (Syrinx; see also Chap. 38)

Syringomyelia (from the Greek *syrinx*, “pipe” or “tube”) is defined as a chronic progressive degenerative or developmental disorder of the spinal cord, characterized clinically by painless weakness and wasting of the hands and arms (brachial amyotrophy) and segmental sensory loss of dissociated type (loss of thermal and painful sensation with sparing of tactile, joint position, and vibratory sense, as described later). Pathologically there is cavitation of the central parts of the spinal cord, usually in the cervical region, but extending upward in some cases into the medulla oblongata and pons (syringobulbia) or downward into the thoracic or even the lumbar segments. Frequently there are associated developmental abnormalities of the vertebral column (thoracic scoliosis, fusion of vertebrae, or Klippel-Feil anomaly), of the base of the skull (platybasia and basilar invagination), and particularly of the cerebellum and brainstem (type I Chiari malformation). Approximately 90 percent of cases of syringomyelia have type I Chiari malformation consisting of a descent of cerebellar tonsils (see page 861). Conversely, approximately 50 percent of type I Chiari malformations are associated with syringomyelia. There is also a group of less frequent but well-described syringomyelias that derives from the acquired processes mentioned earlier such as intramedullary tumor (astrocytoma, hemangioblastoma, ependymoma) and traumatic or hemorrhagic necrosis of the spinal cord.

Wider experience with the pathology of the developmental type of syringomyelia and better understanding of the postulated mechanisms have led to the following classification, modified from Barnett and colleagues:

- Type I. Syringomyelia with obstruction of the foramen magnum and dilation of the central canal (developmental type)
 - A. With type I Chiari malformation
 - B. With other obstructive lesions of the foramen magnum
- Type II. Syringomyelia without obstruction of the foramen magnum (idiopathic developmental type)
- Type III. Syringomyelia with other diseases of the spinal cord (acquired types)
 - A. Spinal cord tumors (usually intramedullary, especially hemangioblastoma)
 - B. Traumatic myelopathy
 - C. Spinal arachnoiditis and pachymeningitis
 - D. Secondary myelomalacia from cord compression (tumor, spondylosis), infarction, hematomyelia
- Type IV. Pure hydromyelia (developmental dilatation of the central canal), with or without hydrocephalus

Historical Note Although pathologic cavitation of the spinal cord was recognized as early as the sixteenth century, the term *syringomyelia* was first used to describe this process in 1827 by Olivier d’Angers (cited by Ballantine et al). Later, following recognition of the central canal as a normal structure, it was assumed by Vir-

chow (1863) and by Leyden (1876) that cavitation of the spinal cord had its origin in an abnormal expansion of the central canal, and they renamed the process *hydromyelia*. Cavities in the central portions of the spinal cord, unconnected with the central canal, were recognized by Hallopeau (1870); Simon suggested in 1875 that the term *syringomyelia* be reserved for such cavities and that the term *hydromyelia* be restricted to simple dilatation of the central canal. Thus, a century ago, the stage was set for an argument about pathogenesis that has not been settled to the present day.

Clinical Features The clinical picture varies in the four pathologic types previously listed, the differences depending not only on the extent of the syrinx but also on the associated pathologic changes, particularly those related to the Chiari malformation. In the classic type 1 syrinx (idiopathic and Chiari developmental syringomyelia) symptoms usually begin in early adult life (20 to 40 years). Males and females are equally affected. Rarely, some abnormality is noted at birth, but usually the first symptom appears in late childhood or adolescence. The onset is usually insidious and the course irregularly progressive. In many instances the symptoms or signs are discovered accidentally, for example as a result of painless burn or atrophy of the hand, and the patient cannot say when the disease began. Rarely, there is an almost apoplectic onset or worsening; there are cases on record of an aggravation of old symptoms or the appearance of new symptoms after a violent strain or paroxysm of coughing. Trauma is a less certain precipitant. Once the disease is recognized, some patients remain much the same for years, even decades, but more often there is intermittent progression to the point of being chairbound within 5 to 20 years. This extremely variable course makes it difficult to evaluate therapy.

The precise clinical picture at any given point in the evolution of the disease depends on the cross-sectional and longitudinal extent of the syrinx, but certain clinical features are so common that the diagnosis can hardly be made without them. These classic elements are: (a) *segmental weakness and atrophy of the hands and arms*, (b) *loss of some or all tendon reflexes in the arms*, and (c) *segmental anesthesia of a dissociated type* (loss of pain and thermal sense and preservation of the sense of touch) over the neck, shoulders, and arms. The last of these leads to one of the most characteristic features of syringomyelia, painless injuries and burns of the hands. Finally, there are in cases of extensive cavitation, weakness and ataxia of the legs from involvement of the corticospinal tracts (possibly at their decussation) and posterior columns in the cervical region. Kyphoscoliosis is added in many of the cases and in nearly one-quarter of them there is an overt cervico-occipital malformation (short neck, low hairline, odd posture of the head and neck, fused or missing cervical vertebrae i.e., Klippel-Feil abnormality).

The particular muscle groups that are affected on the two sides may vary. Exceptionally, motor function is spared, and the segmental dissociated sensory loss and/or pain are the only marks of the disease. In a few of the cases, especially those with the Chiari malformation, the reflexes in the arms are preserved or even hyperactive, as might be expected with upper rather than lower motor neuron involvement. Or the shoulder muscles may be atrophic and the hands spastic. In the lower extremities the weakness, if present, is of a spastic (corticospinal) type.

The characteristic segmental sensory dissociation is usually bilateral, but a unilateral pattern affecting only one hand and arm is not unknown, and this is true of the amyotrophy as well. The sensory loss is distributed in a "cape" or hemicape pattern, often extending to back of the head or the face and onto the trunk. Al-

though tactile sensation is usually preserved, there are cases in which it is impaired, usually in the region of the densest analgesia. Exceptionally there is no sensory loss in the presence of amyotrophy, and cases have been recorded in which only a hydrocephalus and hydromyelia were present with spastic paraparesis. If tactile sensation is affected in the arms, joint position and vibratory sense tend also to be impaired. In the lower extremities there may be some loss of pain and thermal sensation proximally and over the abdomen, but more often there is a loss of vibratory and position sense which is indicative of a posterior column lesion and is the basis of ataxia. A Horner syndrome may result from ipsilateral involvement of the intermediolateral cell column at the C8, T1, and T2 levels.

Pain has been a symptom in about half of our patients with developmental types I and II syringomyelia. The pain is usually unilateral or more marked on one side of the neck, shoulder, and arm; it is of a burning, aching quality, mostly in or at the border of areas of sensory impairment. In a few patients it involves the face or trunk. An aching pain at the base of the skull or posterior cervical region—intensified by coughing, sneezing, or stooping (brief exertional pain)—is often present. But, as Logue and Edwards point out, pain of this type may be a feature of Chiari malformation without syringomyelia and in that case is probably attributable to compression or stretching of cervical roots.

Syringobulbia is the lower brainstem equivalent of syringomyelia. Usually the two coexist and the brainstem cavity is an extension of one in the upper cord, but occasionally the bulbar manifestations precede the spinal ones or, rarely, occur independently. The glial cleft or cavity is located most often in the lateral tegmentum of the medulla, but it may extend into the pons and, rarely, even higher. The symptoms and signs are characteristically unilateral and consist of nystagmus, analgesia, and thermoanesthesia of the face (numbness); wasting and weakness of the tongue (dysarthria); and palatal and vocal cord paralysis (dysphagia and hoarseness). Diplopia, episodic vertigo, trigeminal pain or facial sensory loss, and persistent hiccup are less common symptoms. For understandable reasons, the diagnosis of brainstem MS is often raised. The clinical and pathologic features of syringobulbia have been described in great detail by Jonesco-Sisesti. A most unusual keyhole-shaped syrinx, which was confined to the upper pons and midbrain and communicated with the fourth ventricle, has been described by de la Monte and colleagues.

When a Chiari malformation is associated with syringomyelia and syringobulbia, it may be difficult to separate the effects of the two disorders. Clinical features that favor the diagnosis of Chiari malformation are nystagmus, cerebellar ataxia, exertional head-neck pain, prominent corticospinal and sensory tract involvement in the lower extremities, hydrocephalus, and craniocervical malformations. In syringomyelia without a Chiari malformation but with some other type of obstructive lesion at the foramen magnum, the clinical picture is much the same, and the nature of the foramen magnum lesion can be determined only by MRI or surgical exploration.

The association of syringomyelia with an intramedullary tumor (type III) should be suspected when there is a syringomyelic type of sensorimotor abnormality extending over many segments of the body. With von Hippel-Lindau disease, the diagnosis hinges on the finding of the characteristic hereditary hemangioblastoma in the syrinx and retinal and cerebellar vascular malformations. In the posttraumatic cases, a necrosis of the spinal cord that has been stable for months or years begins to cause pain and spreading sen-

sory or motor loss, recognizable only in segments above the original lesion (Schurch et al). This occurred in approximately 3 percent of the traumatic myelopathy cases of Rossier and coworkers, more often in quadriplegics than in paraplegics. The posttraumatic syrinx is not as well defined anatomically as the usual forms of syringomyelia but consists instead of several contiguous areas of glia-lined myelomalacia with differing degrees of cavitation. In some instances of progressive spinal cord symptoms occurring several years after spinal surgery, the lesion has proved to be one of arachnoiditis and cord atrophy and not a syrinx (Avrahami et al).

Hydromyelia (Type IV) This refers to a dilation of the central canal and is considered a process distinct from developmental syringomyelia. The relationship between hydromyelia and syringomyelia has been the source of endless debate, in part the result of the lack of a coherent pathophysiologic explanation for either process. At least one hypothesis for the origin of syringomyelia includes an initial dilatation of the central canal (see later). Our impression is that a relatively nonprogressive well-defined cylindrical enlargement of the central canal over a few thoracic segments is a frequent enough occurrence in the absence of other changes that it represents an independent entity. In the few cases of true hydromyelia that have come to our attention there has sometimes been a long-standing congenital hydrocephalus complicated years later by progressive weakness and atrophy of the shoulders and the muscles of the arms and hands. More often, there is no associated obstruction at the upper cord and no hydrocephalus. It is our impression that most cases are benign and relatively nonprogressive. Proof of the existence of pure hydromyelia in the past has been based on necropsy demonstration of an enormously widened central canal, with or without hydrocephalus. Now it is easily diagnosable by MRI, however, numerous asymptomatic cases with mild dilation of the central canal are being discovered and cause unnecessary concern.

Pathogenesis Experimental work in animals indicates that there is a normal flow of CSF from the spinal subarachnoid space, through perivascular spaces, to the parenchyma of the cord and possibly into the central canal. It has been suggested that impediments to flow might then explain dilation of the central canal, but not necessarily the creation of a parallel or attached syrinx cavity.

One theory of the pathogenesis of developmental syringomyelia, of which Gardner was the most persuasive advocate, is that the normal flow of CSF from the central canal to the fourth ventricle and its outlets is prevented by an obstruction of the foramina of Luschka and Magendie. As a result, a pulse wave of CSF pressure, generated by systolic pulsations of the choroid plexuses, is transmitted into the cord from the fourth ventricle through the central canal. According to this theory, the syrinx consists essentially of a greatly dilated central canal with a diverticulum that ramifies from the central canal and dissects along gray matter and adjacent fiber tracts. The frequency with which syringomyelia is linked to malformations at the craniocervical junction, i.e., to Chiari and other lesions that could interfere with normal flow of CSF, lent credence to this theory.

There are many instances, however, where Gardner's hydrodynamic theory could not explain the syringomyelia. In some cases, for example, the foramen of Luschka and Magendie are found to be patent, and other abnormalities of the posterior fossa or foramen magnum are also not in evidence. Furthermore, in many cases, including several of our own, serial histologic sections have failed

to demonstrate a connection between the fourth ventricle and the syrinx in the spinal cord or a widening of the central canal above the syrinx (see also Hughes).

Gardner's theory has been questioned on other grounds. Ball and Dayan calculated the pulse-pressure wave transmitted into the cord to be of so low an order as to be unlikely to produce a syrinx. In their view, the CSF around the cervical cord, under increased pressure during strain or physical effort because of subarachnoid obstruction at the craniocervical junction, tracks into the spinal cord along the Virchow-Robin spaces or other subpial channels as described earlier. Over a prolonged period, abetted perhaps by traumatic lesions, small pools of fluid coalesce to form a syrinx; originally the syrinx forms independently of the central canal, but eventually the two may become connected, allowing secondary enlargement of the canal (hydromyelia *ex vacuo*). The findings of Heiss and colleagues lend strong support to the theory of Ball and Dayan. According to them, progression of syringomyelia is produced by the compressive effect of the cerebellar tonsils, which partially occlude the subarachnoid space at the foramen magnum and create pressure waves that compress the spinal cord from without and not from within; the pressure waves propagate syrinx fluid caudally with each heartbeat. This hardly exhausts the list of hypotheses, but none of them is easy to confirm, and there is no point in enumerating them all.

The authors favor the type of hydrodynamic mechanism as postulated originally by Gordon Holmes and elaborated by Ball and Dayan. In this view, a relationship exists between basal cranial, cervical spine, the cerebellospinal Chiari malformation, syringomyelia and disturbed hydrodynamics of perispinal CSF. Logue and Edwards have documented several cases of syringomyelia in which the foramen magnum was obstructed by a lesion other than a Chiari formation—dural cyst, localized arachnoiditis, atlantoaxial fusion, simple cerebellar cyst, and basilar invagination (see Williams for a review of the numerous hypotheses of causation).

Irrespective of its mode of origin, the syrinx first occupies the central gray matter of the cervical portion of the spinal cord, usually independent of the central canal but sometimes extending into it. It interrupts the crossing pain and temperature fibers in the anterior commissure at several successive cord segments. As the cavity enlarges, it extends symmetrically or asymmetrically into the posterior and anterior horns and eventually into the lateral and posterior funiculi of the cord. It may enlarge the spinal cord. The cavity is lined with astrocytic glia and a few thick-walled blood vessels, and the fluid in the cavity is clear and in our patients has had a relatively low protein content, like CSF.

The cavitation nearly always arises in the cervical portion of the cord and can only reach the thoracic and lumbar portions by extension from the cervical region. Either a cavity or a glial septum may extend asymmetrically into the medulla, usually in the vicinity of the descending tract of the fifth cranial nerve (syringobulbia).

Diagnosis The clinical picture of syringomyelia is so characteristic that diagnosis is seldom in doubt. Now one can obtain spectacular demonstrations of the syrinx, Chiari malformations, and other foramen magnum lesions by MRI in the sagittal plane of the brain and spinal cord (see Figs. 38-4 and 44-14). Hours after a CT myelogram, contrast material fills the syrinx and the central canal directly, possibly by diffusion from the surface of the cord.

In addition to acquired lesions in the central cord, certain rare polyneuropathies (amyloid, Tangier disease, and Fabry disease) that preferentially affect small fibers in the nerves of the upper

Figure 44-14. T1-weighted sagittal MRI of the cervical cord, showing a posttraumatic syrinx that led to progressive clinical worsening. At operation there proved to be glial septa within the cavity. (See Fig. 38-4 for comparison to developmental syrinx with Chiari malformation.)

extremities can reproduce the dissociated sensory loss that is characteristic of a syrinx ("pseudosyringomyelic" deficit), but syringomyelic motor abnormalities are not found in these neuropathic cases. These diseases are discussed in Chap. 46.

Treatment The only therapy of lasting value for type I syringomyelia (related to Chiari malformation) is surgical decompression of the foramen magnum and upper cervical canal. Headache and neck pain are helped most; ataxia and nystagmus tend to persist. Radiation therapy, which was formerly recommended, is of no benefit. The operation advised by Gardner, of plugging the connection between the fourth ventricle and the central canal of the cervical cord, has been abandoned. There were complications of this operative procedure, and the results were no better than those obtained from simple decompression. The decompression operation also carries some risk, especially if there is an attempt to excise the tonsillar projections of the cerebellum. In the series of Logue and Edwards, comprising 56 cases of type I syringomyelia, the occipitocervical pain was relieved by decompression in most patients, but the shoulder-arm pain usually persisted. Upper motor

neuron weakness of the legs and sensory ataxia were often improved, whereas the segmental sensory and motor manifestations of the syringomyelia were not. Hankinson has reported good results from decompression in 75 percent of type I cases of syringomyelia. In the retrospective review of 141 adult patients by Stevens and colleagues, good surgical outcome was achieved in 50 percent of those with minor degrees of descent of the cerebellar tonsils but in only 12 percent of those with major cerebellar ectopia. A distended syrinx also led to a more favorable outcome. Whether the long-term course of these diseases is altered has not been determined.

Syringostomy or shunting of the cavity has been performed in type I and some of the type II (idiopathic) cases, but the results have been unpredictable. Love and Olafson, who performed this procedure in 40 patients of both types (mainly type II), stated that 30 percent had an excellent outcome. Schurch and coworkers obtained improvement of pain and motor weakness in 5 of their 7 cases by stabilization of the spine and syringotomy with placement of a T-tube within the syrinx. In a more recent and comprehensive study of 73 patients with a developmental syrinx operated by Sgouros and Williams, one-half remained clinically stable for a 10-year period; 15 percent had serious complications of the surgery, however. Our experience with this procedure has not persuaded us of its lasting value; most of these patients, even those who reported some improvement originally, soon relapsed to their preoperative state, and the disease then progressed in the usual way. An enlarged cervical cord with progressive clinical worsening may nonetheless justify an attempt to shunt the cavity.

Surgery for the *posttraumatic cases* has given only slightly more favorable results. With incomplete myelopathy, syringostomy relieved the pain in all the 10 patients of Shannon and associates. Where they found the myelopathy to be complete, the cord was transected and the upper stump excised. Sgouros and Williams have also studied 57 such patients and recommend decompressive laminectomy and reconstruction of the subarachnoid space as the most effective of the several procedures that have been used in the management of traumatic cavities. An extensive review of surgical approaches to syringomyelia can be found in the article by Brodbelt and Stoodley. They tentatively recommend lysis of arachnoidal adhesions as preferable to shunting or filleting of the cord but they acknowledge that the current state of treatment is not satisfactory.

In the cases of syringomyelia with tumor, in which the cyst fluid may be high in protein and viscous (unlike the low-protein fluid of the usual syrinx), the tumor should be excised if possible. This has been done successfully with hemangioblastomas of the posterior columns and occasionally with ependymomas.

The infrequent symptomatic *purely hydromyelic cases* may benefit from ventriculoperitoneal shunts of hydrocephalus, and a few excellent results are reported. This procedure has also been attempted in type I developmental cases, with unimpressive results unless there is an associated hydrocephalus. Draining the central canal by amputation of the tip of the sacral cord has been unsuccessful and can be harmful. Most cases do not require treatment.

CONCLUDING REMARKS ON DISEASES OF THE SPINAL CORD

It is always well to remind oneself that of the more than 30 diseases of the spinal cord, effective means of treatment are available for many of the common ones: spondylosis, extramedullary spinal cord tumors, syphilis (meningomyelitis and tabes), epidural abscess, he-

matoma and granuloma (tuberculous, fungal, sarcoidosis), perhaps syringomyelia, and subacute combined degeneration and other forms of nutritional myelopathy among others. Some of the inflam-

matory myelopathies may respond to immune modulating measures. The physician's major responsibility is to determine whether the patient has one of these treatable diseases.

CHAPTER 45

ELECTROPHYSIOLOGIC AND LABORATORY AIDS IN THE DIAGNOSIS OF NEUROMUSCULAR DISEASE

The clinical suspicion of neuromuscular disease, disclosed by any of the symptoms or syndromes in the succeeding chapters, finds ready confirmation in the laboratory. The intelligent selection of ancillary examinations requires some knowledge of the biochemistry and physiology of muscle fiber contraction, nerve action potentials, and neuromuscular conduction. These basic subjects, with the relevant anatomy, serve as an introduction to the descriptions of the laboratory methods and the subject matter of the chapters that follow.

ELECTROLYTES AND NEUROMUSCULAR ACTIVITY

It is not possible here to review all the biochemical and biophysical data that explain nerve impulse generation and conduction. Since the early studies of Hodgkin (1951) and of Hodgkin and Huxley (1952), tomes have been written on these subjects. Suffice it to say that the nerve and muscle fibers, like other bodily cells, maintain a fluid internal environment that is distinctly different from the external or interstitial medium. The main intracellular constituents are potassium (K), magnesium (Mg), and phosphorus (P), whereas those outside the cell are sodium (Na), calcium (Ca), and chloride (Cl). In both nerve and muscle the intracellular concentrations of these ions are held within a narrow range by electrical and chemical forces, which maintain the membranes in electrochemical equilibrium ("resting membrane potential"). These forces are the result of selective permeability of the membranes to various ions and the continuous expulsion of intracellular Na through special channels by a pump mechanism ("the sodium pump"). The function of the pump is dependent on the enzyme Na-K-ATPase, which is localized in the membranes.

This resting membrane potential is therefore dependent on the differential concentrations of K and Na. The interior of the cell is some 30 times richer in K than the extracellular fluid, and the concentration of Na is 10 to 12 times greater in the extracellular fluid. In the resting state, the chemical forces that promote diffusion of K ions out of the cell (down their concentration gradient) are counterbalanced by electrical forces (the internal negativity opposes further diffusion of K to the exterior of the cell). At the resting potential, the situation of Na ions is the opposite; they tend to diffuse into the cell, both because of their concentration gradient and because of the relative negativity inside the cell. Because the resting membrane is less permeable to Na than to K, the amount of K leaving the cell exceeds the amount of Na entering the cell, thus creating the difference in electrical charge across the membrane. This discrepancy, in association with the actions of the electrogenic Na:K pump and the presence of impermeant, negatively charged intracellular proteins, creates an electrical potential across the membrane such that, in the resting

state, the intracellular compartment is 70 to 90 mV negative (the resting membrane potential).

Electrical discharge of neural and muscular tissue is predicated on a special property of excitable membranes—namely, that the permeability of the cell to Na is controlled by the electrical potential of the membrane. As the membrane is depolarized by any slight electrical or chemical change, there is an increased permeability to Na. The subsequent movement of K outward repolarizes the membrane and thereby reduces its permeability to Na. If a greater degree of depolarization occurs, a situation arises in which the outward movement of K is unable to stabilize the membrane potential. The membrane then becomes even more depolarized and progressively more permeable to Na, and an "explosive," or regenerative Na current develops; sodium rushes down its chemical and electrical gradients into the cell. With the elevation in Na permeability, the Na ions would continue to depolarize the intracellular compartment to about +40 mV (the Nernst equilibrium potential for Na). Indeed, it is this depolarization of the intracellular compartment, lasting a few milliseconds, that constitutes the action potential. However, an equilibrium is not established, because there is a rapid (within 5 ms) fall in membrane Na permeability back to baseline levels. This fall in Na permeability occurs because the initial depolarization inactivates the Na conductance.

The transient depolarization at the same time activates an increase in membrane permeability to K. The combined effects of the resulting efflux of K and a diminishing influx of Na repolarizes the membrane to a resting level. During a brief period immediately after repolarization, the nerve and muscle fibers are refractory, at first absolutely then relatively, to another depolarizing stimulus. The duration of the refractory period is determined largely by the duration of the inactivation of the Na channel.

Conduction, or propagation of the action potential along excitable nerve or muscle membranes, occurs as the current flows into the contiguous membrane, which in turn becomes depolarized. When the depolarization reaches the threshold for development of an action potential, a new zone of increased Na permeability is created. In this manner, the action potential then spreads in an all-or-none fashion, down the length of the nerve or muscle membrane (see Kuffler et al for further details). The action potentials in individual nerve fibers are too small and brief to be detected by conventional nerve conduction techniques, but a summated volley of all the fibers comprised by a nerve is large enough to be recorded, and it is this property that is utilized to study nerve function in the clinical electromyography (EMG) laboratory.

As the motor nerve impulses pass centrifugally from the axon into its terminal branches, transmission may still "break down," especially if the repetition rate is excessive and impulses arrive too frequently at branch points. Impulses may then fail to reach the myoneural junction of these fibers; or there may be failure of con-

duction at the myoneural junction, which is what occurs in myasthenia gravis.

In large motor and sensory nerves, contiguous spread of action potentials along a fiber is slow and eventually decays over long distances. In these large fibers, conduction is aided by the structure and configuration of the myelin sheaths. The sodium channels, which generate the action potential, are concentrated at short exposed segments of the axon, the nodes of Ranvier, lying between longer segments of myelinated axon. The portions of axon that are covered by myelin remain electrically insulated. This creates “flux lines” that converge on the nodes and allows current to be regenerated at each of these gaps in the myelin. The speed of electrical conduction, which jumps in a “saltatory” fashion from node to node, is many times faster than conduction through an unmyelinated axon. The largest-diameter fibers, which by reason of their size have the fastest conduction times, also have the thickest myelin sheaths and longest internodal distances.

Conventional laboratory studies of nerve conduction generally measure the speed of these fastest-conducting fibers. This dependence of nerve conduction on the myelin sheath explains a number of electrophysiologic abnormalities that are a consequence of myelin destruction. One common finding, as one might predict, is a slowing of nerve conduction due to loss of the impulses contributed by the largest-diameter and fastest-conducting fibers. When myelin destruction is severe or a circulating factor impedes the channels that regenerate a sodium current, there is a total block of electrical conduction. An intermediate state of partial demyelination slows and desynchronizes the electrical volley, leading to temporal dispersion of the action potentials that reach the muscle. The cumulative effect of these changes is to reduce the number of nerve fibers that are capable of conducting an electrical volley, leading to a graduated reduction in the amplitude of the muscle action potential over longer segments of nerve. This reduction in amplitude of the compound motor action potential (CMAP) as the stimulating electrode is moved proximally is termed *conduction block* (discussed under “Studies of Nerve Conduction,” later). Blocked conduction of this nature is the most reliable marker of an acquired demyelinating neuropathy; of all the electromyographic changes, it corresponds most closely to the degree of muscle weakness (see further on).

In contrast to these effects of demyelination of peripheral nerve, the result of loss of axon fibers is a reduction in the summed electrical activity of the attached muscle and an atrophic denervation as described further on.

THE NEUROMUSCULAR JUNCTION (MOTOR END PLATE)

This is the interface between the finely branched nerve fiber and the muscle fiber, where the electrical activity of the motor nerve is translated into muscle action (Fig. 45-1). The nerve fiber contacts the muscle membrane in a trough-like junctional space of 50 nm—the *synaptic cleft*—between the axolemma and sarcolemma (see Fig. 53-1). Within the nerve terminal, a relatively fixed number of packets, or quanta, of acetylcholine (ACh), each packet containing

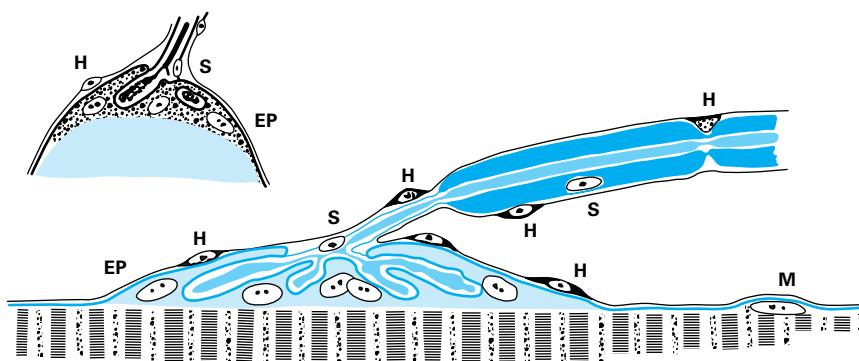

Figure 45-1. Motor end plate showing relationship between various structures in nerve and muscle. Last segment of myelin, with Schwann nucleus (S), terminates abruptly, leaving axis cylinder covered by sheaths of Schwann and Henle. End-plate nuclei (EP) of muscle fiber lie embedded in sarcoplasm and have same staining reactions as sarcolemmal nuclei (M). Ramifications of axis cylinder (telodendria) lie in grooves or pouches in granular sarcoplasm, each lined by spiny “subneurial apparatus” of Couteaux, which is continuous with membranous sarcolemma and also Schwann membrane. Nucleus (S) of sheath of Schwann commonly lies near point of branching of axon. Sheath of Henle has small nuclei (H) and fuses with endomysial sheath of muscle fiber. (Courtesy of Dr. D. Denny-Brown.)

about 10,000 molecules, are liberated through an exocytotic process by the arrival of axonal action potentials. Arrival of the electrical impulse opens calcium channels in the presynaptic membrane, which serve to bind packets of ACh to the membrane and govern their release. Molecules of ACh diffuse into the synaptic cleft and attach to receptor sites on the postsynaptic membrane. Each impulse triggers the release of approximately 200 quanta of ACh and produces a depolarization of sufficient size to initiate an action potential in the muscle through the same mechanism of a regenerative sodium current described earlier. Botulinum toxin and a high concentration of Mg ions interfere with the entry of calcium on the presynaptic side and raise the threshold for quantal release. There is also a nonquantal release of ACh through continuous leakage. This appears to play a role in the trophic influence of nerve on muscle.

The ACh molecule binds to the postsynaptic ACh receptor, a complex of five proteins that constitute the postsynaptic ion channel. Binding of Ach by this receptor causes a conformational change in the Ach receptor that leads to a local increase in the conductance of Na and K and other small ions. This produces a depolarization known as the *end-plate potential*. Small (miniature) end-plate potentials (MEPPs) are continuously formed and regenerated as the membranes repolarize, much as in the process of passive decay previously described. These potentials are too small to be recorded by routine EMG testing, although fortuitous needle placement adjacent to a synapse may detect them. The bound ACh is hydrolyzed by cholinesterase, a glycoprotein enzyme that exists in free form in the cleft. Its main function is to terminate the action potential and permit the sequential activation of muscle. The postsynaptic membrane, once depolarized, is refractory to another action potential until it is repolarized.

The calcium that entered the presynaptic nerve terminal is sequestered and then extruded and the choline from the hydrolyzed ACh enters the nerve terminal, where it is resynthesized to ACh near the release sites.

The analysis of a rapid series of electrically elicited muscle contractions is used specifically to analyze the function of the neuromuscular junction. In general, a decrement in the amplitude of

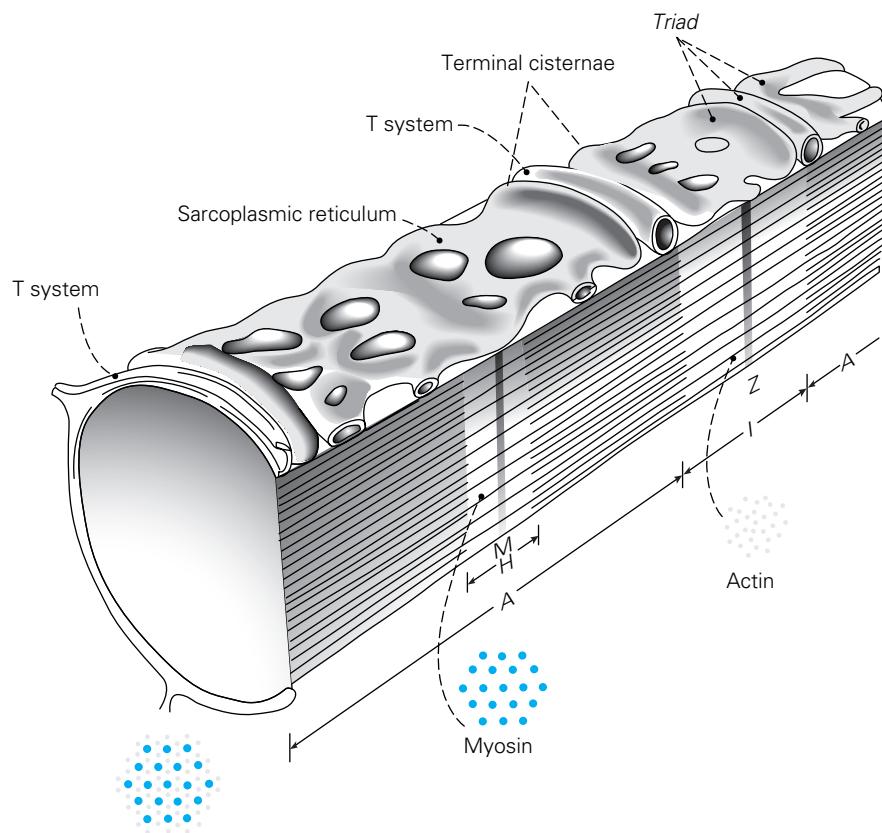

Figure 45-2. Schematic illustration of the major subcellular components of a myofibril. The transverse (T) system, which is an invagination of the plasma membrane of the cell, surrounds the myofibril midway between the Z lines and the center of the A bands; the T system is approximated to, but apparently not continuous with, dilated elements (terminal cisternae) of the sarcoplasmic reticulum on either side. Thus, each sarcomere (the repeating Z-line-to-Z-line unit) contains two “triads,” each composed of a pair of terminal cisternae on each side of the T tubule. (From Peter, by permission.)

serial muscle action potentials is typical of postsynaptic failure of conduction, and an increment in the amplitude from a train of stimuli is a reflection of presynaptic failure. *Myasthenia gravis* is the principal disease affecting the neuromuscular junction. The fundamental defect is not a deficiency of ACh or its release, but rather its failure to attach to the postsynaptic receptor, which is blocked by an antibody at the receptor site. There are several other synaptic disorders—due to botulism, aminoglycoside antibiotics, and the antibodies of the Lambert-Eaton myasthenic syndrome—which impede presynaptic release of ACh. Certain pharmacologic agents interfere with neuromuscular transmission by combining with the cholinergic (nicotinic) receptor on the postsynaptic membrane, thereby competitively blocking the transmitter action of ACh. The curariform drugs, derived from curare and termed *nondepolarizing neuromuscular blockers*, are the main examples. Other drugs, notably succinylcholine and decamethonium, cause neuromuscular blockage by producing direct depolarization of the end plate and adjacent sarcoplasmic membrane (*depolarizing neuromuscular blockers*). Agents that inactivate cholinesterase have the opposite effect, i.e., they enhance the action of ACh. The ones in clinical use for the treatment of myasthenia gravis are the carbamates neostigmine, physostigmine, and pyridostigmine, the effects of which are reversible. The organophosphates are irreversible blockers of

cholinesterase function, for which reason they are feared weapons of chemical warfare. Atropine is a potent cholinergic antagonist that is active only at muscarinic sites and therefore has no effect at the neuromuscular junction.

BIOCHEMISTRY OF MUSCLE CONTRACTION

The sarcolemma, the transverse tubules, and the sarcoplasmic reticulum each play a role in the control of the activity of muscle fibers. The structural components involved in excitation, contraction, and relaxation of muscle are illustrated in Fig. 45-2. Following nerve stimulation, an action potential is transmitted by the sarcolemma from the motor end-plate region to both ends of the muscle fiber. Depolarization spreads quickly to the interior of the fiber along the walls of the transverse tubules, probably by a conducted action potential. The transverse tubules and the terminal cisternae of the sarcoplasmic reticulum come into close proximity at points referred to as *triads*. Here, depolarization of the transverse tubules alters the conformation of a voltage-sensitive calcium channel in the transverse tubule membrane. This causes a large protein (the ryanodine receptor) in the membrane of the adjacent sarcoplasmic reticulum (SR) to open an internal calcium pore, allowing stored calcium to exit the SR and flood into the cytoplasm. The released calcium binds to the regulatory protein *troponin*, thereby removing the inhibition exerted by the tro-

ponin-tropomyosin system upon the contractile protein *actin*. This allows an interaction to take place between the actin molecules of the thin filaments and the cross-bridges of the myosin molecules in the thick filaments and enables myosin adenosine triphosphatase (ATPase) to split adenosine triphosphate (ATP) at a rapid rate, thereby providing the energy for contraction. This chemical change allows the filaments to slide past each other, thereby shortening the muscle fiber. Relaxation occurs as a result of active (energy-dependent) Ca reuptake by the sarcoplasmic reticulum.

The pyrophosphate bonds of ATP, which supply the energy for muscle contraction, must be replenished constantly by a reaction that involves interchanges with the muscle phosphagen creatine diphosphate, where high-energy phosphate bonds are stored. These interactions, in both contraction and relaxation, require the action of creatine kinase (CK). Myoglobin, another important muscle protein, functions in the transfer of oxygen, and a series of oxidative enzymes are involved in this exchange. The intracellular Ca, as noted earlier, is released by the muscle action potential and must be reaccumulated within the cisternae of the sarcoplasmic reticulum before actin and myosin filaments can slide back past one another in relaxation. This reuptake of Ca requires the expenditure of considerable energy. When there is defective generation of ATP, for example, from an enzyme deficiency, the muscle

remains shortened, as in the *contracture* of phosphorylase deficiency (McArdle disease) or of phosphofructose kinase deficiency. The same sort of shortening occurs under normal conditions in some of the “catch muscles” of certain mollusks and is the basis of rigor mortis in mammals.

Many glycolytic and other enzymes (transaminases, aldolase, CK) are utilized in the metabolic activity of muscle, particularly under relatively anaerobic conditions. Muscle fibers differ from one another in their relative content of oxidative and glycolytic enzymes; the latter determine the capacity of the muscle fiber to sustain anaerobic metabolism during periods of contraction with inadequate blood flow. Muscle cells rich in oxidative enzymes (type 1 fibers) contain more mitochondria and larger amounts of myoglobin (therefore appearing red), have slower rates of contraction and relaxation, fire more tonically, and are less fatigable than muscle fibers poor in oxidative enzymes. The latter (type 2 fibers) fire in bursts and are utilized in quick phasic rather than sustained reactions. The amount of myosin ATPase activity, which governs the speed of contraction, is low in oxidative-rich fibers and high in glycolytic-rich fibers. The myosin ATPase stain at pH 9.4 has been used to identify these two types of fibers in microscopic sections. Type 1 fibers have a low content of myosin ATPase, and type 2 (phosphorylative-rich) fibers have a high content of this enzyme; hence type 1 fibers stain lightly and type 2 darkly (the reverse reaction occurs at pH 4.6). All the fibers within one motor unit are of the same type, a feature that is used to advantage to identify the reinnervation of muscle fibers by a single motor neuron after adjacent neurons have died and denervated their constituent muscle fibers (fiber type grouping).

The chemical energy required to maintain the various activities of the muscle cell is derived mainly from the metabolism of carbohydrate (blood glucose, muscle glycogen) and fatty acids (plasma free fatty acids, esterified fatty acids, and ketone bodies). There is a lesser contribution from branched-chain and other amino acids, but this may increase during prolonged exercise.

The most readily available source of energy is glycogen, which is synthesized and stored in muscle cells. It provides over 90 percent of the energy needs of muscle under conditions of high work intensity and during the early stages of submaximal exercise. Blood glucose and free fatty acids supplement intracellular glycogen as exercise proceeds. The free fatty acids are obtained from endogenous triglycerides (found mostly in type 1 fibers), from the triglycerides released by circulating lipoproteins, and from the lipolysis of adipose tissue. Most of the energy needs of resting muscle are provided by fatty acids.

The enzymatic reactions involved in the transport of these substrates into muscle cells and their intracellular synthesis and degradation during anaerobic and aerobic cell conditions have been thoroughly investigated and most of the enzymes identified. This subject is too complicated to present in a textbook of neurology, but enough is known about these matters to state confidently that there are a number of diseases that can impair the contractile functions of muscle in different ways without destroying the fiber. Specific enzymatic deficiencies under genetic control may affect carbohydrate utilization (myophosphorylase, debrancher enzyme, phosphofructokinase, phosphoglyceromutase, and myoadenylate deaminase), fatty acid utilization (carnitine and carnitine palmitoyl transferase deficiencies), pyruvate metabolism, and cytochrome oxidase activity (in the mitochondrial diseases). These enzymatic disturbances are discussed in later chapters.

PHYSIOLOGY OF MUSCLE CONTRACTION

The contraction of a muscle fiber is to be viewed as both a series of electrochemical events and a mechanical event. The mechanical change far outlasts the electrical one and extends through the period when the muscle fiber is refractory to another action potential. When a second muscle action potential arrives, after the refractory phase of the previous action potential but before the muscle has relaxed, the contraction will be prolonged. Thus, at frequencies of anterior horn cell firing of more than 100 per second, the twitches fuse into a sustained contraction or *fused tetanus*. In most sustained contractions, there is incomplete tetanus, attained by firing rates of 40 to 50 per second. In this fashion the mechanical phenomena are smoothed into a continuous process, even though the electrical potentials present as a series of depolarizations, separated by intervals during which the muscle membrane resumes its resting polarized state.

As pointed out in Chap. 3, the physiology of muscle activity should always be considered in terms of motor units, i.e., the group of muscle fibers within the domain of a single anterior horn cell. The strength of muscle contraction is a function of the number and rates of firing of many motor units. The smoothness of contraction depends on the integrated enlistment of motor units of increasing size. The electrical signal of this summated contraction, as recorded at the skin surface over a muscle, is the main feature of the surface EMG and the basis for quantifying the size of the motor potential in the motor nerve conduction examinations.

If the motor units are stimulated by a brief electrical stimulus applied to a motor nerve, the effect is a CMAP as just described (the summated amplitude produced by all the innervating nerve fibers). The CMAP can be visualized on the screen of an oscilloscope or a computer and its onset used to measure the speed of motor nerve conduction and the summated amplitudes produced by all the innervating nerve fibers. It can also be converted into an audible noise. Further study involves the insertion into the muscle of a coaxial needle, which samples several motor units in the vicinity of the electrode. When elicited by a sustained voluntary contraction, the flurry of electrical activity from many units at different distances from the electrodes is referred to as an *interference pattern* (see further on, under “Studies of Nerve Conduction” and “Needle Examination of Muscle”).

Biochemical changes may cause not only an impairment of neuromuscular activity (paresis, paralysis) but also excessive irritability, tetany, spasm, and cramp. In the latter instances, spontaneous discharges may occur from an instability of axon polarization; hence a single nerve impulse may initiate a train of action potentials in nerve and muscle, as in the tetany of hypocalcemia and in hemifacial spasm. The common cramps of calf and foot muscles (painful, sustained contractions with motor unit discharges at frequencies up to 200 per second) may be due to increased excitability (or unstable polarization) of the motor axons. Quinine, procainamide, diphenhydramine, and warmth reduce the irritability of nerve and muscle fiber membranes, as do a number of anticonvulsant drugs that act by blocking sodium channels and thereby limiting spontaneous membrane discharges.

To summarize, the muscle fiber, which is wholly dependent on the nerve for its stimulus to contract, may be physiologically activated or paralyzed in a number of ways. The motor nerve cell or its axon may be injured or inexcitable, in which case the muscle

cannot be stimulated. On the other hand, the nerve cell may be disinhibited in the anterior horn of the spinal cord, permitting the discharge of continuous action potentials, as in tetanus and the "stiff-man" syndrome (page 1279); the nerve fiber may fail to conduct impulses (demyelinating neuropathies) or the number of fibers may be inadequate to produce a fused and sustained contraction (axonal neuropathies); the neurilemma may not distribute the nerve impulse simultaneously to all parts of the motor unit; ACh may not be released at the presynaptic region of the neuromuscular junction (as occurs in botulism and in the Eaton-Lambert syndrome) or, once released, ACh may not be inactivated by cholinesterase (physostigmine, organophosphates); the receptor zone on the postsynaptic membrane may be destroyed or blocked by antibodies or pharmacologic agents (myasthenia gravis or curariform drugs); and, finally, the metabolic or contractile elements of the muscle may not react or, once contracted, may not relax. Similarly, the mechanisms involved in fasciculations, cramps, and muscle spasms may be traced to a number of different loci in the neuromuscular apparatus. There may be an unstable polarization of the nerve fibers, as in tetany and in dehydration with salt depletion, or unexplained hyperirritability of the motor unit, as in amyotrophic lateral sclerosis. The threshold of mechanical activation or electrical reactivation of the sarcolemmal membrane may be reduced, as in myotonia, or impairment of an energy mechanism within the fiber may slow the contractile process, as in hypothyroidism; or a deficiency of phosphorylase, which deprives muscle of its carbohydrate energy source, may prevent relaxation, as in the contracture of McArdle disease. Lesions of the most peripheral branches of nerves, which allow nerve regeneration, may give rise to continuous activity of motor units. This is expressed clinically as a rippling of muscle, or *myokymia* (see pages 1104 and 1278).

In recent years, new technologies have made it possible to isolate each of the proteins and channels involved in neuromuscular transmission and the excitation-contraction-relaxation of muscle fibers. The amino acid composition of most of these proteins has also been determined. This information is being increasingly applied to the analysis of gene products in the normal state and under conditions of disease. Pertinent comments and references to this subject are found in the chapters that follow.

EFFECTS ON MUSCLE OF ABNORMALITIES OF SERUM ELECTROLYTES

Diffuse muscle weakness or muscle twitching, spasms, and cramps should always raise the question of uremia or an abnormality in serum electrolytes. These disorders reflect the concentrations of electrolytes in the intra- and extracellular fluids. If the plasma concentration of potassium falls below 2.5 mEq/L or rises above 7 mEq/L, weakness of extremity and trunk muscles results; below 2 mEq/L or above 9 mEq/L, there is almost always flaccid paralysis of these muscles and later of the respiratory ones as well; only the extraocular and other cranial muscles are spared. In addition, the tendon reflexes are diminished or absent. The normal reaction of muscle to direct percussion is also reduced or abolished, suggesting impairment of transmission along the sarcolemmal membranes themselves. Hypocalcemia of 7 mg/dL or less (as in rickets or hypoparathyroidism) or relative reduction in the proportion of ionized calcium (as in hyperventilation) causes increased muscle irritability and spontaneous discharge of sensory and motor nerve fibers (i.e., tetany) and sometimes convulsions from similar effects upon ce-

rebral neurons; frequent repetitive and finally prolonged spontaneous discharges grouped in couplets or triplets appear in the EMG, and convulsive effects are reflected in the electroencephalogram. *Hypercalcemia* above 12 mg/dL (as occurs in vitamin D intoxication, hyperparathyroidism, carcinomatosis, sarcoid, and multiple myeloma) causes weakness and lethargy, perhaps on a central basis. Extreme *hypophosphatemia*, observed most often with intravenous hyperalimentation or bone tumor, can cause acute areflexic paralysis with nerve conduction abnormalities. *Reduction in the plasma concentration of magnesium* also results in tremor, muscle weakness, tetanic muscle spasms, and convulsions; a considerable increase in magnesium levels leads to muscle weakness and depression of central nervous function. The weakness of muscle in hypermagnesemia may also be due, in part at least, to reduced release of ACh at the motor end plate. The electrocardiogram (ECG) also becomes abnormal with many of these systemic electrolyte derangements as a result of alterations of the intracellular levels of electrolytes in the myocardium; ECG patterns are most sensitive to extreme changes in serum potassium levels.

CHANGES IN SERUM LEVELS OF ENZYMES ORIGINATING IN MUSCLE CELLS

In all diseases causing extensive damage to striated muscle fibers, intracellular enzymes leak out of the fiber and enter the blood. Those measured routinely are the transaminases, lactic acid dehydrogenase, aldolase, and especially, CK. Of these, the concentration of CK in serum has proved to be the most sensitive measure of muscle damage. Since high concentrations of this enzyme are found in heart muscle and brain, raised serum values may be due to myocardial or cerebral infarction as well as to the necrotizing diseases of striated muscle (polymyositis, muscle trauma, muscle infarction, paroxysmal myoglobinuria, and the more rapidly advancing muscular dystrophies). For serum CK levels to be interpretable, one has to be certain that the enzyme released into the serum is not derived from heart or brain. This can be determined by the quantitation of serum isoenzymes of CK, referred to as MB, MM, and BB (M, muscle; B, brain); their measurement provides a sensitive means for the detection of damage to myocardium (MB), skeletal muscle (MM), and nervous tissue (BB), respectively.

The MM form of CK is found in highest concentration in striated muscle, but these muscles also contain 5 to 6 percent MB. Myocardial tissue contains 17 to 59 percent MB; hence, the diagnosis of myocardial infarction requires that the CK-MB fraction be greater than 6 percent (or that troponin, which is overrepresented in heart muscle, be elevated in the serum). Embryonic and regenerating muscle contains more CK-MB than mature normal muscle. In patients with destructive lesions of striated muscle, serum values of CK often exceed 1000 U and may reach 40,000 U or more (the upper limit of normal varies from 65 to 200 U, depending on the method of measurement). Serum of the healthy adult contains only the MM isoenzyme, but in healthy children, as much as 25 percent of serum CK may be derived from the MB fraction. Even more interesting is the rise in serum enzyme concentration in some children with progressive muscular dystrophy before there is enough destruction of fibers for the disease to be clinically manifest, at least as judged by the relatively crude tests of muscle strength. Moreover, the unaffected female carrier of Duchenne dystrophy may be identified by an elevated serum level of CK. Alterations of serum enzyme levels are nonspecific for dystrophy since they occur

in all types of disease that damage the muscle fiber. Moreover, in the more slowly evolving types of dystrophy, such as that of Landouzy-Déjerine, the serum levels of CK may be normal. It would be expected that the values would always be normal in denervation paralysis with muscular atrophy, but elevations are sometimes observed in patients with progressive spinal muscular atrophy and amyotrophic lateral sclerosis particularly if there is relatively rapid progression of muscle denervation. Even vigorous exercise or surgical operations involving muscle elevate CK, sometimes exceeding 6 percent from the MB fraction.

HyperCKemia In some individuals, CK may be persistently elevated without evidence of muscle or other diseases ("idiopathic hyperCKemia"); there is a particularly high incidence of this finding, albeit of mild degree, in African-American men. An unexplained alteration of the sarcolemma with elevated serum CK occurs in hypothyroidism and in alcoholism. Toxic myopathies, for example the type caused by the cholesterol-lowering drugs, are a common cause of elevation in CK. Among the most commonly defined causes of persistently elevated CK are underlying inherited muscle defects, usually one of the varieties of dystrophinopathy. Detailed examination will usually reveal slight proximal weakness and perhaps minimal calf enlargement characteristic of the mildest forms of Becker dystrophy. Closely related is the finding of CK elevations that occur in females who are asymptomatic carriers of Duchenne or Becker dystrophy. In these latter instances, muscle biopsy shows a mosaic pattern of dystrophin immunostaining; i.e., some fibers contain dystrophin and others do not. Several other inherited muscle diseases present as hyperCKemia including carnitine palmitoyl transferase deficiency, myoadenylate deaminase deficiency, some of the mitochondrial myopathies, sarcoid myopathy, McArdle disease, central core disease, multicore disease, and some forms of inclusion body myopathy. Miyoshi myopathy, the distal myopathy that arises in young adults with dysferlin deficiency, can also present in the late teens or early twenties as an asymptomatic but very substantial CK elevation; in this instance, as in some of the preceding disorders, the initial, seemingly benign CK elevation, is followed by progressive distal weakness. HyperCKemia has also been correlated with subclinical mutations in the genes for caveolin-3 and titin.

If other sources of an elevated CK level that persists for months or longer have been excluded, particularly those due to exercise and to drug induced muscle damage, it is appropriate to follow the patient over time in order to detect mild weakness, or to perform a biopsy in order to resolve the issue of a mild or early muscular dystrophy.

An isolated elevation of aldolase, the serum enzyme other than CK that is derived predominantly from skeletal muscle, generally has less clinical significance. Measurement in the serum of various transaminases or lactate dehydrogenase is not particularly useful for the diagnosis of muscle disease because of their ubiquitous distribution in many mammalian tissues. Nevertheless, the neurologist should be aware that unexplained elevations in all of the muscle-derived enzymes (CK, LDH, SGOT, aldolase, etc.) can be caused by evident muscle trauma and by other processes that damage the muscle membrane.

MYOGLOBINURIA

The red pigment myoglobin, responsible for much of the color of muscle, is an iron-protein compound present in the sarcoplasm of striated skeletal and cardiac fibers. Of the total body hematin com-

pounds, about 25 percent is in muscle, the remainder in red blood corpuscles and other cells. Destruction of striated muscle, regardless of the process—whether trauma, ischemia, or metabolic disease—liberates myoglobin, and because of its relatively small size, the molecule filters through the glomeruli and appears in the urine, imparting to it a burgundy red color. Because of the low renal threshold for myoglobin, excretion of this pigment is so rapid that the serum remains uncolored. In contrast, because of the high renal threshold for hemoglobin, destruction of red blood corpuscles colors both the serum and the urine. Myoglobinuria should thus be suspected when the urine is deep red and the serum is normal in color. It is estimated that 200 g of muscle must be destroyed to color the urine visibly (Rowland). As in hemoglobinuria, the guaiac and benzidine tests of urine are positive if myoglobin is present. The colored urine does not fluoresce, as it does in porphyria. On spectroscopic analysis, myoglobin shows an absorption band at 581 nm, but the most sensitive method for measuring myoglobin in the urine and serum is by radioimmunoassay (Rosano and Kenny). Hyperkalemia, hyperphosphatemia, and hypercalcemia may complicate massive rhabdomyolysis.

Some years ago, the measurement of creatine and creatinine in blood and urine was a standard method of estimating damage to striated muscle. This technique is now seldom used for clinical or research purposes, having been replaced largely by the measurement of CK and its isoenzymes.

ENDOCRINE MYOPATHIES

In a number of disorders of the endocrine glands, muscle weakness may be a prominent feature, and occasionally it may be the chief complaint. Although these diseases are discussed in detail in Chap. 51, it should be noted that such metabolic muscle weakness, acute or chronic, may occur in the absence of changes in serum electrolytes or enzymes. Specific hormone assays are then necessary for diagnosis. This is particularly true of patients with thyrotoxicosis or Cushing disease and those receiving prolonged corticosteroid therapy. In thyrotoxicosis, muscle paresis may appear without the classic signs of Graves disease.

ELECTRODIAGNOSIS OF NEUROMUSCULAR DISEASE (ELECTROMYOGRAPHY; EMG)

It was long ago discovered that muscle would contract when a pulse of electric current was applied to the skin, near the point of entrance of the muscular nerve (*motor point*). The electrical pulse required is brief, less than a millisecond, and is most effectively induced by a rapidly alternating (faradic) current. After denervation, an electrical pulse of several milliseconds, induced by a constant electrical (galvanic) stimulus, is required to produce the same response. This change, in which the galvanic stimulus remains effective after the faradic one has failed, was the basis of *Erb's reaction of degeneration*, and varying degrees of this change were later plotted in the form of *strength-duration curves*. For decades, this was the standard electrical method for evaluating denervation of muscle. Though still valid, it was replaced long ago by nerve conduction studies and by the needle electrode examination. The latter test, based on the sherringtonian concept of the "motor unit" (page 39), is accomplished by recording the firing characteristics of evoked motor unit potentials (CMAPs) and by the insertion into muscle of needle electrodes to measure spontaneous and voluntar-

ily evoked muscle fiber activity. The terms *electromyography* and *electromyogram* (EMG) were used originally to describe the needle electrode examination but are now a common shorthand designation for the entire electrodiagnostic evaluation, including the *nerve conduction studies*, described below.

Studies of Nerve Conduction

The main laboratory technique for the study of peripheral nerve function involves the transcutaneous stimulation of motor or sensory nerves and recording of the elicited action potentials in the muscle (CMAP) and the sensory nerve action potential (SNAP). The results of these *motor and sensory nerve conduction studies*, expressed as amplitudes, conduction velocities, and distal latencies, yield certain quantitative information and additional qualitative observations regarding the waveform and dispersion of electrical impulses.

Hodes and coworkers in 1948 were the first to describe nerve conduction studies in patients and the techniques used currently are not much changed. An accessible nerve is stimulated through the skin by surface electrodes, using a stimulus that is large enough to recruit all the available nerve fibers. The resulting action potential is recorded by electrodes on the skin (1) over the muscle distally in the case of motor fibers stimulated in a mixed or motor nerve (CMAP), (2) over the nerve proximally, using orthodromic techniques for sensory fibers stimulated in the digital nerves, (3) over the nerve more distally, using antidromic techniques for sensory nerve conduction studies (this has technical advantages over orthodromic techniques), and (4) over the nerve more proximally for mixed nerve conduction studies (Fig. 45-3). These techniques are the ones used most often in clinical work. An alternative but much more demanding technique uses “near nerve” needle electrodes to record action potentials as they course through the nerve. The main characteristics of the conventional nerve conduction studies are described below.

Distal (Terminal) Latencies, Conduction Times, and Conduction Velocities The conduction times from the most distal stimulating electrode to the recording site, in milliseconds, as determined by the latency from the stimulus artifact to the onset and to the peak of the CMAP, are termed the *distal* (or *terminal*) and *peak* motor latencies, respectively (see Fig. 45-3). The former is the one used more often as a reflection of conduction time in routine work. A stimulus may then be applied to the nerve at a second site more proximally (or if recording electrodes can be placed more proximally in the case of sensory fibers), and a conduction time can be measured over a longer segment of nerve. When the distance (in millimeters) between the two sites of stimulation is divided by the difference in conduction times (in milliseconds), one obtains a *conduction velocity* (in meters per second), which describes the maximal velocity of propagation of the action potentials in the largest diameter and fastest nerve fibers. These velocities in normal subjects vary from a minimum of 40 or 45 m/s to a maximum of 65 to 75 m/s, depending upon which nerve is studied (e.g., slower in the legs than in the arms; Table 45-1). Values are lower in infants, reaching the adult range by the age of 2 to 4 years and decline again slightly with advancing age. They are routinely diminished also with exposure to cold—a potentially important artifact if these recordings are taken when the patient’s skin is cool; measurement of skin temperature therefore is routinely made prior to performing the conduction tests.

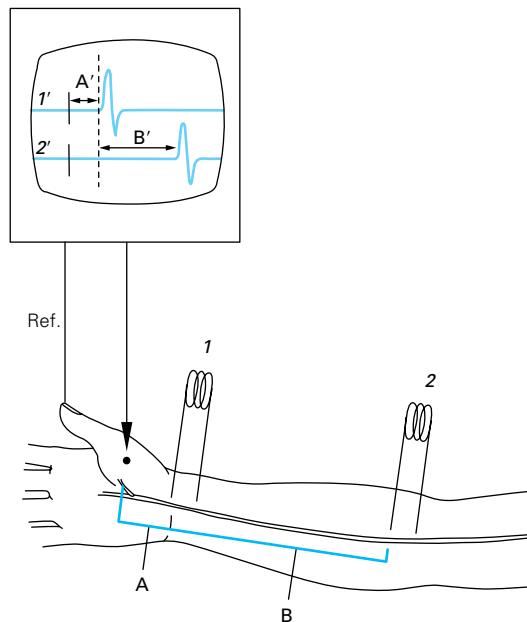

Figure 45-3. The median nerve is stimulated percutaneously (1) at the wrist and (2) in the antecubital fossa with the resultant compound muscle action potential recorded as the potential difference between a surface electrode over the thenar eminence (arrow) and a reference electrode (Ref.) more distally. Sweep 1' on the display depicts the stimulus artifact followed by the compound muscle action potential. The distal latency, A', is the time from the stimulus artifact to the take-off phase of the compound muscle action potential and corresponds to conduction over distance A. The same is true for sweep 2', where stimulation is at 2 and the time from the artifact to the response is A' + B'. The maximum motor conduction velocity over segment B is calculated by dividing distance B by the time B'.

Normal values have been established for distal latencies from the various sites of stimulation on various mixed nerves to the appropriate muscles. When one stimulates the median nerve at the wrist, for example (see electrode 1 and segment A in Fig. 45-3), the latency for motor conduction through the carpal tunnel to the median-innervated thenar muscles is always less than 4.5 ms in healthy adults. Similar normal values have been compiled for orthodromic and antidromic sensory conduction velocities and distal latencies (see Table 45-1) in all the main peripheral nerves.

Disease processes that preferentially injure the fastest-conducting, large-diameter fibers in peripheral nerves reduce the maximal conduction velocity because the remaining thinner fibers conduct more slowly. In most neuropathies, all of the axons are affected either by a fairly uniform “dying-back” phenomenon or by Wallerian degeneration as described in Chap. 46, and nerve conduction velocities are then less informative. This is true for typical alcoholic-nutritional, carcinomatous, uremic, diabetic, and other metabolic neuropathies, in which conduction velocities range from low normal to mildly slowed. In these so-called “axonal neuropathies,” the motor and sensory nerve amplitudes are diminished (see below).

By contrast, demyelinating neuropathies of the acute (Guillain-Barré, diphtheria) and chronic types such as chronic inflammatory, metachromatic leukodystrophy, Krabbe disease, and the common type of Charcot-Marie-Tooth disease show marked slowing of conduction and, in the case of the acquired demyelinating diseases, there is also dispersion of the action potential and conduction block (see later).

Table 45-1

Normal Values for Representative Nerve Conduction Values at Various Sites of Stimulation (Mean Values ± 2 SD for Adults 16 to 65 Years of Age)

MOTOR NERVE CONDUCTION STUDIES								
NERVE	DISTAL STIMULATION SITE	OTHER STIMULATION SITES	RECORDING SITE	ONSET LATENCY (ms)	AMP (mV)	CV (m/s)	DISTANCE (cm)	F-WAVE LATENCY (ms)
Median	Wrist	Elbow	APB	<4.2	>4.4	>49	6–8	<31
Ulnar	Wrist	BG, AG	ADM	<3.4	>6.0	>49	5.5–7.5	<32
Radial	Forearm	Elbow, SG	EIP	<5.2	>4.0	>50	10	NA
Peroneal	Ankle	BFH, AFH	EDB	<5.8	>2.0	>42	6–11	<58
Peroneal	BFH	AFH	TA	<3.0	>5.0	>42	10	NA
Tibial	Ankle	PF	AH	<6.5	>3.0	>41	6–8	<59 ^a

SENSORY NERVE CONDUCTION STUDIES ^b							
NERVE	DISTANCE STIMULATION SITES	RECORDING SITE	ONSET LATENCY (ms)	PEAK LATENCY (ms)	AMP (μ V)	CV (m/s)	DISTANCE (cm)
Median	Wrist	Dig2	<2.5	<3.5	>20	>52	13
Ulnar	Wrist	Dig5	<2.1	<3.0	>15	>52	11
Radial	Forearm	Wrist	<1.9	<2.8	>20	>48	10
Sural	Calf	Ankle	<3.2	<4.4	>6	>42	14

Key: AG, above ulnar groove; BG, below ulnar groove; AFH, above fibular head; BFH, below fibular head; SG, spiral groove; TA, anterior tibialis; EDB, extensor digitorum brevis; EIP, extensor indicis proprius; ADM, adductor digiti minimi; APB, abductor pollicis brevis; AH, abductor hallucis; PF, popliteal fossa.

^a Tibial H reflexes: latency <35 ms; side-to-side difference <1.4 ms.

^b Sensory studies are performed antidiromically; amplitudes are measured from baseline to negative peak of nerve potential.

Amplitude of the Compound Muscle Action Potential In addition to the study of distal latency and conduction velocity, the amplitude of the evoked muscle action potential (CMAP) yields valuable information about peripheral nerve function. These amplitudes are a semiquantitative measure of the number of nerve fibers that respond to a maximal stimulus. Demyelinative lesions or axonal loss affecting the large, fast-conducting fibers may be detected by the finding of differential slowing among various caliber fibers that causes a dispersal of the CMAP response. Reduction in motor and sensory amplitudes is a more specific and sensitive indicator of axonal loss than is slowing of conduction velocity or prolongation of distal latencies. Conversely, prolonged distal latencies and slowed motor conduction velocities—as well as conduction blocks (described later) and dispersed responses—are the hallmarks of demyelinative lesions. The range of normal amplitudes for the CMAPs that are elicited by stimulation of the main motor nerves is shown in Table 45-1.

It is usually possible to obtain a reliable motor conduction study as long as some functioning nerve fibers remain intact. The conduction velocities then reflect the status of the surviving axons, and the velocity may be normal despite widespread axonal degeneration. This is most apparent following incomplete transection of a nerve; the maximal motor conduction velocity may be normal in the few remaining fibers, although the muscle involved is almost paralyzed and the compound muscle potential recorded from it is very low.

Sensory Nerve Action Potentials When motor fibers in a mixed nerve are stimulated, an amplified CMAP of many hundreds of microvolts can easily be recorded from electrodes on the skin over the muscle. However, when one attempts to measure sensory po-

tentials, where activity must be recorded from nerve fibers themselves, the “amplification” provided by many motor units is not available and electronic amplification is required. Sensory potentials are sometimes very small or absent even when powerful computer-averaging techniques are used, and sensory conduction measurements may then be difficult to determine. Table 45-1 gives the range of normal values for sensory nerve action potential amplitudes and velocities.

Conduction Block By stimulating a motor nerve at multiple sites along its course, it is possible to demonstrate segments in which conduction is partially “blocked” or is differentially slowed. From such data one infers the presence of a multifocal demyelinative process in motor nerves. This contrasts with the findings in certain of the inherited demyelinating neuropathies, in which all parts of the nerve fiber are altered to more or less the same degree, i.e., there is uniform slowing of conduction and no conduction block.

As a technical matter, conduction block is demonstrated by a reduction in the amplitude of the CMAP elicited from the proximal site along the motor nerve, compared to stimulation at a distal site. Generally, a 40 percent reduction in amplitude over a short distance of nerve, or 50 percent over a longer distance, qualifies as a block, one exception being along the tibial nerve, in which it is difficult to stimulate all the motor nerve fibers and in which some drop in amplitude is normally expected. It is also important to be sure that any reduction in amplitude along the course of the nerve is not due solely to dispersion of the waveform. One must also keep in mind that conduction block may be attributable simply to nerve compression at common sites (fibular head, across the elbow, flexor retinaculum at the wrist, etc.) rather than to an intrinsic disease of the peripheral nerves. The presence of a conduction block can also

be inferred from the finding of poor recruitment of muscle action potentials in the absence of active denervation (see further on).

As mentioned, the finding of conduction block is a central feature of a number of acquired immune demyelinating neuropathies, including Guillain-Barré syndrome, chronic inflammatory demyelinating neuropathy, and multifocal conduction block associated with the GM₁ antibody, all of which are discussed in Chap. 46.

Focal compression of nerve, as occurs in the entrapment syndromes mentioned earlier, may produce localized slowing or blocks in conduction, perhaps because of segmental demyelination at the site of compression. The demonstration of such localized changes of conduction affords ready confirmation of nerve entrapment; for example, if the distal latency of the median nerve (see A, Fig. 45-3) exceeds 4.5 ms while that of the ulnar nerve remains normal, compression of the median nerve in the carpal tunnel is likely. Similar focal slowing or partial block of conduction may be recorded from the ulnar nerve at the elbow and from the peroneal nerve at the fibular head.

Special Electrodiagnostic Studies of Nerve Roots and Spinal Segments (Late Responses, Blink Responses, Segmental Evoked Responses)

H Reflex Information about the conduction of impulses through the proximal segments of a nerve is provided by the study of the H reflex and the F wave. In 1918, Hoffmann, after whom the H reflex was named, showed that submaximal stimulation of mixed motor-sensory nerves, insufficient to produce a direct motor response, induces a muscle contraction (H wave) after a latency that is far longer than that of the direct motor response. This reflex is based on the activation of afferent fibers from muscle spindles (the same axons that conduct the afferent volley of the tendon reflex), and the long delay reflects the time required for the impulses to reach the spinal cord via the sensory fibers, synapse with anterior horn cells, and to be transmitted along motor fibers to the muscle (see Fig. 3-1). Thus the H reflex is therefore the electrical representation of the tendon reflex circuit and is especially useful because the impulse traverses both the posterior and anterior spinal roots. The H reflex is particularly helpful in the diagnosis of S1 radiculopathy and of other polyradiculopathies. Its status generally parallels that of the Achilles reflex. However, it may be difficult to elicit an H reflex from nerves other than the tibial. Stimuli of increasing frequency but low intensity cause a progressive depression and finally obliteration of H waves. The latter phenomenon has been used to study spasticity, rigidity, and cerebellar ataxia, in which there are differences in the frequency-depression curves of H waves.

F Wave The F response, so named because it was initially elicited in the feet, was first described by Magladery and McDougal in 1950. It is evoked by a supramaximal stimulus of a mixed motor-sensory nerve. After a latency longer than that for the direct motor response (latencies of 28 to 32 ms in arms, 40 to 50 ms in legs), a second small muscle action potential is recorded (F wave). The F wave is the result of the impulses that travel antidromically in motor fibers to the anterior horn cells, a small number of which are activated and produce an orthodromic response that is recorded in a distal muscle. The response is a more reliable test than the H wave of proximal nerve and root conduction in that the F wave

traverses only the ventral root and can be elicited from any number of muscles. The combination of a normal F response and an absent H reflex is found in diseases of sensory nerves and roots. Both of these “late responses” find their main use as corroborative tests that must be interpreted in the context of the entire nerve conduction examination (see Wilbourn in References). The normal late response latencies are given in Table 45-1.

Blink Responses This special nerve conduction test is useful in the diagnosis of certain demyelinating neuropathies and in any process that affects the trigeminal or facial nerve. The supraorbital (or infraorbital) nerve is stimulated transcutaneously and the reflex closure of both orbicularis oculi muscles is recorded with surface electrodes. Two CMAP bursts are observed: the first (R1) appears ipsilaterally 10 ms after the stimulus and the second (R2) ipsilaterally at 30 ms and contralaterally up to 5 ms later. The amplitudes of the responses vary considerably and are not in themselves clinically important. The first response is not visible as a muscular contraction but may serve some preparatory function by shortening the blink reflex delay. R1 is mediated by an oligosynaptic pontine circuit consisting of one to three neurons located in the vicinity of the main sensory nucleus; R2 utilizes a broader reflex pathway in the pons. It has been established that R1 and R2 are generated by the same facial motor neurons.

The elicitation of blink reflexes establishes the integrity of the afferent trigeminal nerve, the efferent facial nerve, and the interneurons in the pons (R1) and caudal medulla (related to the bilateral R2 response). The test may be also be helpful in identifying a demyelinating neuropathy when the facial and oropharyngeal muscles are affected and those of the limbs are relatively spared, leaving conventional nerve studies normal. In such cases, the blink responses are delayed ipsilaterally and contralaterally as a result of conduction block in the proximal facial nerve. Direct facial nerve stimulation often fails to demonstrate this block because only the distal segment of the nerve is amenable to study. Although this test is rarely necessary for diagnosis, most patients with hereditary neuropathy have blink response abnormalities. In Bell’s palsy there is a delay or absence of R1 and R2 responses only on the affected side. Large acoustic neuromas may interfere with the afferent trigeminal portion of the pathway and give rise to abnormal responses on the affected side. Diseases of the brainstem have yielded inconsistent responses. It is noteworthy that the test is normal in patients with trigeminal neuralgia.

Segmental Motor, Cranial, and Somatosensory Evoked Potentials (See also Chap. 2) These techniques find use in diseases that affect spinal roots. By applying a magnetic stimulus, which induces an electrical impulse, or by a directly delivered electrical stimulus over the lower cervical or lumbar spine, it is possible to activate the motor (anterior) roots and to measure the time required to elicit a muscle contraction (Cros and Chiappa). These root stimulation tests can be quite uncomfortable for the patient because of the contraction of muscles surrounding the stimulation site.

Transcranial magnetic stimulation of the cerebral cortex permits measurement of the latency of muscle contraction after excitation of motor neurons in the cortex. Thus, the integrity of the entire corticospinal system, from the cortical motor neurons through spinal tracts, anterior horn cells, and the peripheral motor nerve can be determined. By combining this technique with the previously described root stimulation, it becomes possible to measure central and peripheral motor conduction times. These forms

of testing have their main use in the study of amyotrophic lateral sclerosis (ALS) and related disorders.

As described in Chap. 2, by applying repetitive electrical stimuli to a peripheral nerve, the sensory evoked responses can be recorded from sites along the nerve and plexus as well as in central pathways (the thalamus and somatosensory cortex). These evoked potential tests find their main use in the diagnosis of multiple sclerosis and in disorders of the sensory nerve roots as discussed in Chaps. 2 and 36. Other special nerve conduction techniques are available in many laboratories. For details of their performance and interpretation the reader is referred to specialized texts on the subject. Discussion of magnetic stimulation, collision techniques, quantitative EMG, etc., can be found in several monographs, such as the ones by Kimura, by Aminoff, and by Brown and Bolton.

Repetitive Motor Nerve Stimulation (Jolly Test)

This test of the function of the neuromuscular junction is based on Jolly's observation in 1895 that in myasthenia gravis the strength of muscular contractions progressively declines in response to a train of stimuli. By adjusting the amplitude of a stimulus over a nerve to supramaximal range, a maximal CMAP may be obtained for each stimulus. With repeated stimuli, each response will have the same waveform and amplitude until fatigue supervenes. In a healthy individual, the response follows each stimulus even with rates of stimulation up to 25 per second for periods of 60 s or more before a decrement of the CMAP appears. In certain disorders, notably myasthenia gravis, a train of 4 to 10 stimuli at rates of 2 to 5 per second (optimally 2 to 3 per second), the amplitude of the motor potentials decreases and then, after four or five further stimuli, may increase slightly (Fig. 45-4A). A progressive reduction in amplitude is most likely to be found in proximal muscles, but these are not easily stimulated for which reason the locations most commonly used for clinical testing are the accessory nerve in the posterior triangle of the neck (trapezius), the ulnar nerve (hypotenar muscle), the median nerve at the wrist (thenar muscle), and the facial nerve and orbicularis oculi muscle. A decrement of 10 percent or more denotes a failure of a proportion of the neuromuscular

junctions that are being stimulated. The sensitivity of the procedure is improved by first exercising the tested muscle for 30 to 60 s. The induced failure of neuromuscular transmission in myasthenia is similar to the one produced by curare and other nondepolarizing neuromuscular blocking agents, and both cases can be partially corrected with anticholinesterase drugs such as neostigmine and edrophonium. Similar but lesser decremental responses may occur in poliomyelitis, ALS, and certain other diseases of the motor unit or motor nerve, particularly those resulting in the growth of reinnervating nerve twigs.

The myasthenic syndrome of Lambert-Eaton, often associated with oat-cell carcinoma of the lung, is characterized by a presynaptic blockage of acetylcholine release and produces the opposite defect of neuromuscular transmission to the one recorded in myasthenia gravis. During tetanic stimulation (20- to 50-per-second repetitive stimulation of nerve), the muscle action potentials, which are small or practically absent with the first stimulus, increase in voltage with each successive response until a more nearly normal amplitude is attained (see Fig. 45-4B). Exercising the muscle for 10 s before stimulation will cause a similar posttetanic facilitation (200-fold increases are not uncommon). A less important decremental response to slow stimulation may occur, but it is difficult to discern because of the greatly diminished amplitude of the initial responses. Neostigmine has little effect on this phenomenon, but it may be reversed by guanidine and 3,4-diaminopyridine, which stimulate the presynaptic release of ACh. The effects of botulinum toxin and of aminoglycoside antibiotics are similar, i.e., being active at the presynaptic membrane, they produce an incremental response at high rates of stimulation.

The single-fiber EMG, discussed in a later section, is an even more sensitive method of detecting failure of the neuromuscular junction.

Needle Examination of Muscle (Electromyography)

This technique requires the use of monopolar or concentric bipolar needle electrodes, which are inserted into the body of the muscle to record the electrical activity generated by contraction. With concentric needle electrodes, the tip of the wire that runs in the hollow of the needle is in proximity to many muscle fibers belonging to several different overlapping motor units; this is the active recording electrode. The shaft of the needle, in contact over most of its length with intercellular fluid and many other muscle fibers, serves as the reference electrode. With monopolar electrodes, the uninsulated needle tip is the active electrode, while the reference electrode may be another monopolar needle electrode placed in subcutaneous tissue or a surface electrode on the skin overlying the muscle. Patients almost invariably find this portion of the test uncomfortable and should be prepared by a description of the procedure. Rapid and brief needle insertion by the skilled examiner makes the test more tolerable.

As the electrical impulse travels along the surface of the muscle toward the recording electrode, a positive potential is recorded on the oscilloscope, i.e., the recorded signal is deflected downward by convention (at A in Fig. 45-5). When the depolarized zone moves under the recording electrode, it becomes relatively negative and the beam is deflected upward (at B). As the depolarized zone continues to move along the sarcolemma, away from the recording electrode, the current begins to flow outward through the membrane toward the distant depolarized region, and the recording electrode

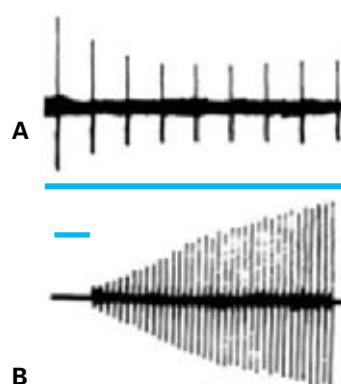

Figure 45-4. Compound action potentials evoked in hypotenar muscles by electrical stimulation of the ulnar nerve at the wrist. *A*. Patient with myasthenia gravis—typical pattern of decrement in first four responses followed by slight increment. At this rate of stimulation (4 per second), the decrement in response does not continue to zero. *B*. Patient with Lambert-Eaton syndrome and oat-cell carcinoma—typical marked increase toward normal amplitude with rapid repetitive stimulation (20 per second). Horizontal calibration: 250 ms.

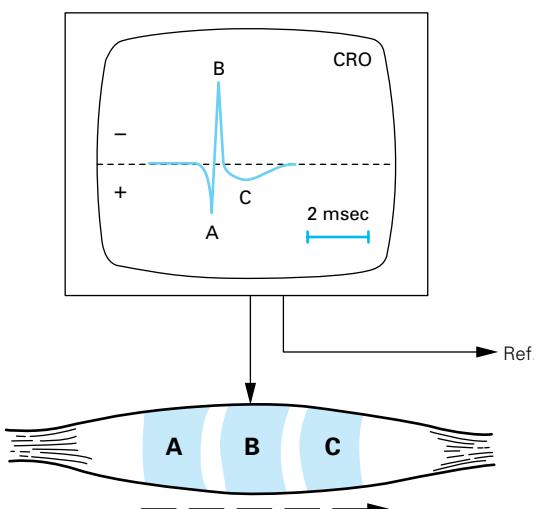

Figure 45-5. The shaded area represents the zone of the action potential, which is negative to all other points on the fiber surface. It is shown at three points in its course (*from left to right*) along the fiber. At each point, the correspondingly lettered portion of the triphasic muscle action potential displayed on the display screen reflects the potential difference between the active (vertical arrow) and reference (Ref.) electrodes. Polarity in this and subsequent figures is negative upward as depicted. The time calibration is on the screen.

becomes relatively positive again (at C). It then returns to its resting isopotential position. The net result is a triphasic action potential, as in Fig. 45-5. This configuration is typical of the firing of a single fiber.

The electrical activity of various muscles is recorded both at rest and during active contraction by the patient. As indicated earlier, muscle fibers do not normally discharge until activated together in motor unit activity. This involves the almost simultaneous contraction of all the muscle fibers innervated by a single anterior horn cell. Although the typical configuration of a motor unit potential (MUP) is triphasic, up to 10 percent of normal MUPs consist

of four or more phases (*polyphasic potentials*); an excess of polyphasic potentials beyond this is pathologic.

Normal muscle in the resting state should be electrically silent; the small tension spoken of as muscle tone has no EMG equivalent. There are, however, two closely related types of normal spontaneous activity and another that is induced by the insertion of the needle itself. One is a low-amplitude, 10- to 20-mV monophasic (negative) potential of very brief (0.5 to 1 ms) duration. These represent single or synchronized MEPPs due to the small number of ACh quanta that are being released all the time. They are normally sparse but are most evident when the recording needle electrode is placed near a motor end plate ("end-plate noise"). Fortuitous placement of the needle electrode very close to or in contact with the end plate gives rise to a second type of normal spontaneous activity. That is characterized by irregularly discharging high-frequency (50- to 100-Hz) biphasic spike discharges, 100 to 300 mV in amplitude (i.e., large enough to cause an isolated muscle action potential). These potentials have been termed *end-plate spikes* and represent discharges of single muscle fibers excited by spontaneous activity in nerve terminals. They must be distinguished from fibrillation potentials (see later). Finally, insertion of the needle electrode into the muscle injures and mechanically stimulates many fibers, causing a burst of potentials of short duration (300 ms). This is referred to as *normal insertional activity*.

When muscle is voluntarily contracted, the action potentials of motor units begin to appear. One can observe a pattern of force build up by watching the progressive recruitment of MUPs; the initial ones, representing smaller motor units, firing at rates of 5 to 10 per second. With increased force of contraction, there is recruitment of larger, previously inactive motor units as well as an increased rate of firing (40 to 50 per second; Fig. 45-6A). Since individual MUPs can no longer be distinguished during maximal voluntary contraction, this activity is referred to as a *complete interference pattern* (Fig. 45-6A, right). This is seen not only as a summated signal pattern but is also heard as a mixed high-frequency clicking when the electrical activity is made audible. As muscles relax, more and more units drop out. If a muscle is weakened by denervation or if electrical conduction is blocked, there will obviously be fewer MUPs, but the firing rate is still rapid (*reduced recruitment*, see Fig. 45-6B). In contrast, with poor voluntary effort and with upper motor neuron lesions, the MUPs fire in decreased numbers, at slower rates, and often in an irregular pattern (termed *poor activation*).

In the usual EMG examination, a plan for the study is made based on detailed knowledge of muscular innervation and focusing on the regions affected by weakness. In some patients, as in those with motor neuron diseases or polymyositis, a wider sampling of muscles is required to detect changes in asymptomatic regions.

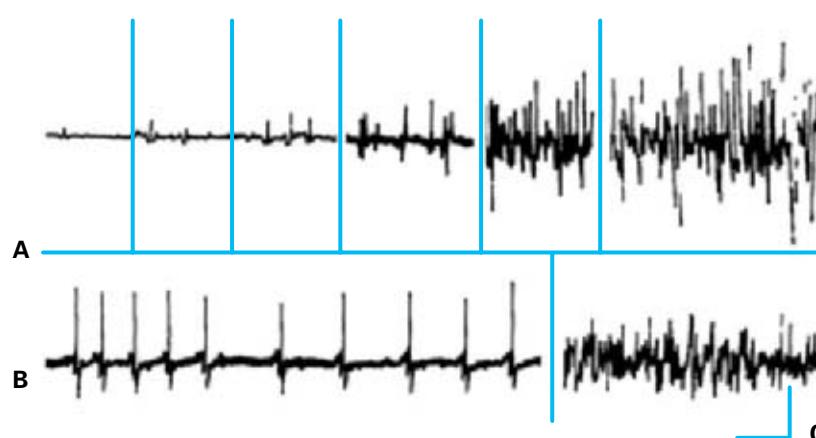

Figure 45-6. Patterns of motor unit recruitment. A. Normal. With each increment of voluntary effort, more and larger units are brought into play until, with full effort at the extreme right, a complete "interference pattern" is seen in which single units are no longer recognizable. B. After denervation, only a single motor unit is recorded despite maximal effort. It is seen to fire repetitively. C. With myopathic diseases, a normal number of units is recruited on minimal effort, though the amplitude of the pattern is reduced. Calibrations: 50 ms (horizontal) and 1 mV in A and B; 200 mV in C (vertical).

The Abnormal Electromyogram Clinically important deviations from the normal EMG include (1) increased or decreased activity upon insertion of the needle; (2) the occurrence of abnormal "spontaneous" activity during the relaxed state (fibrillation potentials, positive sharp waves, fasciculation potentials, cramp potentials, myotonic discharges, myokymic potentials); (3) abnormalities in the amplitude, duration, and shape

of single MUPs; (4) a decrease in the number of MUPs and changes in their firing pattern; (5) variation in amplitude and number of phases of MUPs during voluntary contraction of muscle; and (6) the demonstration of special phenomena, such as electrical silence during obvious shortening of the muscle (physiologic contracture).

Insertional Activity At the moment the needle is inserted into muscle, there is a brief burst of action potentials that ceases once the needle is stable, provided that it is not in a position to irritate a nerve terminal. Increased insertional activity is seen in most instances of denervation as well as in many forms of primary muscle disease and in disorders that dispose to muscle cramps. In cases of advanced denervation or myopathy, in which muscle fibers have been largely replaced by connective tissue and fat, insertional activity may be decreased and there is a palpable increase in mechanical resistance to the insertion of the needle.

Abnormal "Spontaneous" Activity With the muscle at rest, spontaneous activity of single muscle fibers and of motor units, known respectively as *fibrillation* potentials and *fasciculation* potentials, is abnormal. The two phenomena are often confused. *Fibrillation* is the spontaneous contraction of a *single muscle fiber*. It occurs when the muscle fiber has lost its nerve supply and is ordinarily not visible through the skin (but may be visible in the tongue). *Fasciculation* represents the spontaneous firing of an entire motor unit, causing contraction of a group of muscle fibers, and may be visible through the skin. The irregular firing of a number of motor units, seen as a rippling of the skin, is called *myokymia*.

Fibrillation Potentials When a motor neuron is destroyed by disease or its axon is interrupted, the distal part of the axon degenerates, a process that takes several days or more. The muscle fibers formerly innervated by the branches of the dead axon—that is, the motor unit—are disconnected from the nervous system. For reasons that are still obscure, the chemosensitive region of the sarcolemma at the motor end plate “spreads” after denervation to involve the entire surface of the muscle fiber. Then, 10 to 25 days after death of the axon, the denervated fibers develop spontaneous activity; each fiber contracts at its own rate and without relation to the activity of neighboring fibers. This spontaneous activity is associated with a totally random conglomeration of brief di- or triphasic fibrillation potentials (Fig. 45-7A) having a duration of 1 to

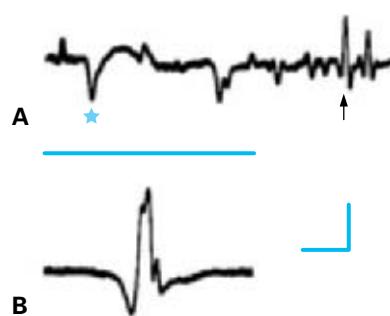

Figure 45-7. A. Fibrillations and positive sharp waves. This spontaneous activity was recorded from a totally denervated muscle—no motor unit potentials were produced by attempts at voluntary contraction. The fibrillations (above arrow) are 1 to 2 ms in duration, 100 to 300 mV in amplitude, and largely negative (upward) in polarity following an initial positive deflection. A typical positive sharp wave is seen above the star. B. Fasciculation. This spontaneous motor unit potential was recorded from a patient with amyotrophic lateral sclerosis. It has a serrated configuration and it fired once every second or two. Calibrations: 5 ms (horizontal) and 200 mV in A; 1 mV in B (vertical).

5 ms and rarely exceeding 300 mV in amplitude. When brief spontaneous fibrillation potentials of this sort are observed firing regularly at two or three different locations (outside the end-plate zone) of a resting muscle, one may conclude that the fibers are denervated. Usually, fibrillation potentials discharge at an almost regular rate. In some early lesions (less than 6 to 8 weeks), irregularly firing fibrillation potentials may be observed.

Diseases such as poliomyelitis, which damage spinal motor neurons, or injuries of peripheral nerves or anterior spinal roots frequently produce only partial denervation of the involved muscles. In such muscles, one electrode placement may record fibrillation potentials at rest from denervated fibers and normal potentials during voluntary contraction from nearby healthy fibers. Fibrillation potentials continue until the muscle fiber is reinnervated by progressive proximal-distal regeneration of the interrupted nerve fiber or by the outgrowth of new axons from nearby healthy nerve fibers (collateral sprouting), or until the atrophied fibers degenerate and are replaced by connective tissue, a process that may take many years. In addition, fibrillation potentials may take the form of positive sharp waves, i.e., spontaneous, initially positive diphasic potentials of longer duration and slightly greater amplitude than the spikes of fibrillation potentials (see Fig. 45-7A).

Fibrillation potentials, while characteristic of neurogenic denervation, are not altogether specific; for example, they are seen in muscle diseases such as polymyositis and inclusion body myositis, which presumably damage the neural innervation to small regions of muscle or isolate segments of a muscle fiber from its end plate.

Fasciculation Potentials As stated earlier, a fasciculation is the spontaneous or involuntary contraction of a motor unit or part of a motor unit. Such contractions may cause a visible dimpling or twitching under the skin, though ordinarily they are of insufficient force to move a joint. Large distal fasciculations, however, can briefly displace a finger or toe; they occur irregularly and infrequently, and prolonged inspection of the skin overlying a muscle may be necessary to detect them. The accompanying electrical form of an individual fasciculation potential is relatively constant. Typically, a fasciculation potential will have three to five phases (i.e., they are “polyphasic” as described later, in contrast to normal biphasic muscle activity), a duration of 5 to 15 ms (longer than normal but somewhat less in the facial muscles), and an amplitude of several millivolts (see Fig. 45-7B). Fasciculation potentials are evidence of motor nerve fiber irritability, most often the result of reinnervation following nerve or motor neuron damage. Thus, the combination of fibrillations and fasciculations indicates active denervation combined with more chronic reinnervation of muscle; i.e., a long-standing but still ongoing process.

The precise source of fasciculation is still contested. Forster and colleagues, in the 1940s, challenged the original belief that the discharge originated in anterior horn cells by demonstrating that fasciculations persisted after nerve block in ALS and ceased only with the appearance of fibrillation potentials, signifying Wallerian (axonal) degeneration. These observations favored a distal site of generation. Other physiologic and pharmacologic evidence pointed to the first segment of the motor axon, or to the distal axon, or even to the motor point (the site of insertion of the nerve into muscle), involving elements of the postsynaptic muscle membrane (particularly in the case of benign fasciculations) as the source of the spontaneous electrical activity. It seems that several regions of the axon are capable of spontaneous impulse generation, depending on the underlying disease. Most of the diseases that produce fasciculations involve the anterior horn cell or the motor root, but more

distal sites in the motor axon are active in cases of nerve compression and polyneuropathy.

Occasional fasciculation potentials—particularly in the calves, hands, and periocular or paranasal muscles—occur in many normal persons. They can be almost constant for days or weeks on end, or even for years in some individuals, without weakness or wasting; therefore they need not be taken as evidence of disease (benign fasciculations). Certain quantitative features of fasciculations, such as brief duration and a consistent pattern and location of firing, favor benign over pathologic discharges. Shivering induced by low temperature and twitches associated with low serum calcium levels are other forms of fasciculatory activity.

Fasciculation potentials occur with great frequency in chronic, slowly advancing, destructive diseases of the anterior horn cells, such as ALS and progressive spinal muscular atrophy. In these diseases, both voluntary MUPs and fasciculation potentials may be of long duration (more than 15 ms) and of increased amplitude, indicating chronic denervation and reinnervation. They are seen often in the early stages of poliomyelitis but only occasionally in the chronic phase of the disease, perhaps because the affected cells die rapidly. When anterior horn cells degenerate once again in older individuals who had had poliomyelitis (postpolio syndrome), fasciculations may return. Occasionally, they are seen in one muscle as a result of a compressive anterior root lesion, such as those caused by a protruded intervertebral disc; large numbers of axons may be affected, with the result that the fasciculations (or even cramps) may be more prominent than with disease of anterior horn cells. Fasciculation potentials in lesser numbers are also observed with chronic nerve entrapments, e.g., ulnar neuropathy at the elbow and other peripheral nerve lesions and some polyneuropathies. In all these cases, the damaged neuron or its axon seems to leave intact axons in a state of hyperirritability. The blocking of axon conduction by local anesthesia does not abolish the fasciculation, but curare-like drugs do so.

Less Common Types of Spontaneous Electrical Activity (See Chap. 55) One of these is *myokymia* (pages 1194 and 1278), a persistent quivering and rippling of muscles at rest (“live flesh”). The EMG picture is distinctive. The spontaneously firing MUPs are called *myokymic potentials* or *discharges* and consist of groups of repetitive discharging units, each firing at its own rate, quasi-rhythmically, usually several times per second, followed by an even briefer period of silence. The small motor unit discharges may occur singly or as doublets, triplets, or multiplets. The site of generation of this activity has also been contested, possibly because it may arise from several sites, but always the site is peripheral, not central, and is believed to correspond to an alteration in the calcium concentration in the microenvironment of the motor axon. Spontaneous discharges arising in large myelinated fibers have been implicated in the genesis of myokymia; indeed, demyelinating polyneuropathies are among the conditions that give rise to this phenomenon. Myokymia is also caused by peripheral nerve hyperexcitability due to both potassium channel mutations and antibodies against the channels. This activity may be blocked by lidocaine infusion around the peripheral nerve and may be diminished by carbamazepine or phenytoin.

In the *syndrome of continuous muscle fiber activity* or *Isaacs syndrome* (page 1278), which is actually a generalized form of myokymia, EMG discloses high-frequency (up to 300-Hz) repetitive discharges of varying waveforms.

Focal and segmental myokymias differ in small ways from the generalized form of myokymia with regard to the timing and du-

ration of the discharges. The focal types refer mainly to facial myokymia, seen most often in multiple sclerosis, Guillain-Barré syndrome, large cerebellopontine angle tumors, or compression of the facial nerve by a small aberrant blood vessel, but it may follow any peripheral nerve injury and regeneration. The EMG patterns are complex, either high-frequency (30- to 100-Hz) recurrent bursts or brief lower-frequency bursts. Segmental myokymia is a common occurrence in radiation injuries of the brachial plexus. The EMG bursts tend to be longer and less frequent than in generalized myokymia, and the interburst frequency is highly variable. The origin of these discharges (also referred to as *neuromyotonia*) is probably in the distal peripheral nerve, where activity of afferent fibers, possibly via ephaptic transmission, irregularly excites distal motor terminals. *Segmental myokymia* refers to similar activity in the distribution of one or more adjacent motor roots. This activity persists during sleep and general anesthesia.

The phenomenon of *myotonia*, which denotes a failure of voluntary relaxation of muscle because of sustained firing of the muscle membrane (see pages 1265 and 1270), is characterized by high-frequency repetitive discharges generally having a positive sharp waveform. These myotonic discharges wax and wane in amplitude and frequency, producing a “dive-bomber” sound on the audio monitor. The discharges can be elicited mechanically by percussion of the muscle or movement of the needle electrode and are also seen following voluntary contraction or electrical stimulation of the muscle via its motor nerve. The MUPs may appear normal during voluntary contraction, but they are not followed by the silence that normally occurs on relaxation; instead, there is a “prolonged afterdischarge” consisting of long trains of fibrillation-like potentials that may take as long as several minutes to subside (Fig. 45-8A). These EMG findings can be seen with any myotonic disorder. If the muscle is activated repeatedly at short intervals, the late discharge becomes briefer and briefer and eventually disappears (see Fig. 45-8B), as the patient becomes able to relax the exercised muscle (“warm-up” effect). In the paradoxical myotonia

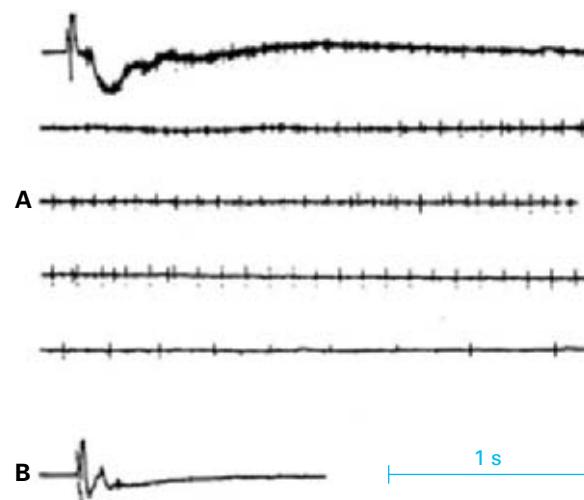

Figure 45-8. A. Myotonia congenita (Thomsen disease). The five lines are a continuous record of activity in the biceps brachii following a tap on the tendon. The initial response is within normal limits, but it is followed by a prolonged burst of rapid activity, gradually subsiding over a period of many seconds or minutes. B. Same electrode placement as in A. Response to the fifth of a series of tendon taps. “Warm-up” has occurred, and the characteristic prolonged myotonic activity is no longer evident. (See Chap. 54 for a description of the disease.)

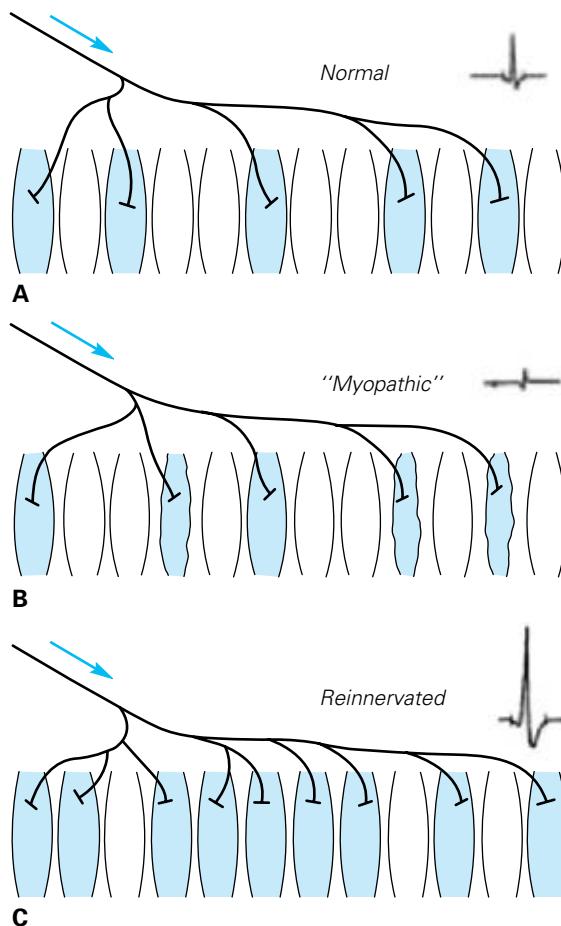

Figure 45-9. The shaded muscle fibers are functional members of one motor unit, whose axon enters from the upper left and branches terminally to innervate the appropriate muscle fibers. The action potential produced by each motor unit is seen in the upper right: its duration is measured between the two vertical lines. The normal-appearing but unshaded fibers belong to other motor units. *A*. Hypothetical situation, with five muscle fibers in the active unit. *B*. In this myopathic unit, only two fibers remain active; the other three (shrunken) have been affected by one of the primary muscle diseases. *C*. Four fibers which originally belonged to other motor units and had been denervated have now been reinnervated by terminal sprouting from an undamaged axon. Both the motor unit and its action potential are now larger than normal. Note that only under these abnormal circumstances do fibers in the same unit lie next to one another.

observed in some cases of Eulenberg paramyotonia, Nielsen and colleagues have found a decreasing recruitment pattern and increasing activity after each of a succession of voluntary contractions. This is the converse of what happens in congenital myotonia (Thompson disease). As shown by the single-fiber EMG studies of Denny-Brown and Nevin, myotonia is generated by single muscle fibers, and the mechanism of the membrane instability, at least in some forms, seems to involve changes in the chloride conductance. These disorders are discussed in subsequent chapters.

In the *stiff-man syndrome*, painful muscle spasms and stiffness are generated by a spinal mechanism; the EMG potentials resemble normal motor units but are abnormal by virtue of continuous firing at rest (see page 1279).

Complex repetitive discharges—formerly referred to as bizarre high-frequency discharges and, even earlier, as *pseudomyotonia*—consist of repetitive spontaneous potentials often having

an erratic configuration and starting and stopping abruptly. They are seen in some myopathies, in hypothyroidism, and in certain denervating disorders and are a mark of chronicity (lesions over 6 months old). High-frequency coupling of action potentials into doublets, triplets, or higher multiples of single units, indicating instability in repolarization of the nerve fiber to a muscle, occurs in tetany and in the early stages of myokymia.

The *cramp-like contracture* of McArdle disease and phosphofructokinase deficiency is associated with electrical silence of contracting muscle. This feature is an important part of the definition of true physiologic muscle contracture (as distinguished from chronic shortening of a muscle and its tendon which, strictly speaking, is a pseudocontracture).

Abnormalities in Amplitude, Duration, and Shape of Motor Unit Potentials Figures 45-9 (schematically) and 45-10 depict the ways in which disease processes affect the motor unit and the appearance of the MUP in the EMG.

Motor Unit Potentials in Denervation Early in the course of denervation, many motor units with functional connections to the spinal cord are unaffected, and though the number of MUPs appearing during contraction is reduced, the configurations of the remaining ones are quite normal. In time, the remaining MUPs often increase in size and in electrical amplitude, perhaps two to three times normal, and become longer in duration and sometimes *polyphasic* (more than four phases).

Such large and sometimes *giant potentials* (see Figs. 45-9C and 45-10B) are believed to arise from motor units containing more than the usual number of muscle fibers that are spread out over a greatly enlarged territory within the muscle. Presumably, new nerve twigs have sprouted from nodal points and terminals of undamaged axons and have reinnervated previously denervated muscle fibers, thus adding them to their own motor units. Soon after reinnervation, the MUPs generated will be low in amplitude, extremely prolonged, and polyphasic, findings that constitute a transitional configuration of early reinnervation. These amplitudes disappear as the motor unit is reestablished. Increased amplitude is usually associated with very chronic, proximal axon loss, e.g., with remote poliomyelitis and chronic cervical radiculopathy. These MUPs are to be differentiated from (1) polyphasic potentials of

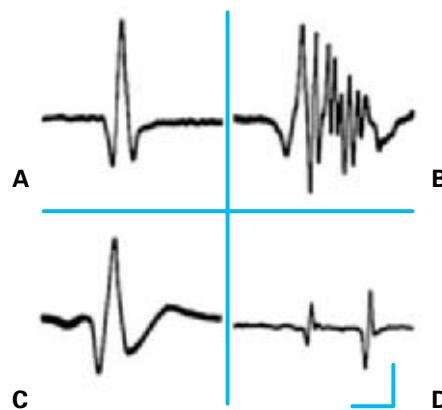

Figure 45-10. Single voluntary motor unit potentials. *A*. Normal. *B*. Prolonged polyphasic potential seen with reinnervation. *C*. "Giant unit"—normally shaped but of much greater amplitude than normal. *D*. Brief, low-amplitude "myopathic" units. Calibrations: 5 ms (horizontal) and 1 mV in *A* and *B*; 5 mV in *C*; 100 mV in *D* (vertical).

normal duration, which, as has been mentioned, make up as much as 10 percent of the total number of MUPs in normal muscle, and (2) polyphasic MUPs of short duration and low amplitude, which are characteristic of most myopathies and of myasthenia gravis and other disorders of neuromuscular transmission.

The Motor Unit Potential in Myopathy Diseases such as polymyositis, the muscular dystrophies, and other myopathies that randomly destroy muscle fibers or render them nonfunctional obviously reduce the population of muscle fibers per motor unit, as shown in Fig. 45-9B. Therefore, when such a unit is activated, its potential is of lower voltage and shorter duration than normal, and it may also appear polyphasic as the compound MUP becomes fragmented into its constituent single-fiber potentials. Slowing of the propagated muscle fiber action potential in affected muscle fibers is also believed to contribute to the changes in the "myopathic" MUP. When most of the muscle fibers are affected, the MUPs are very small and of short duration and are recruited out of proportion to the tension generated—so-called *increased recruitment*. Both types of alterations produce a characteristic high-pitched crackling sound from the audio monitor that has been likened to rain falling on a tin roof. They occur in all forms of chronic myopathies. Identical MUP changes are seen occasionally with other processes that cause disintegration of the motor unit, e.g., early Guillain-Barré syndrome (due to conduction block along some of the terminal nerve fibers), and rarely with disorders of neuromuscular transmission (myasthenia gravis, other myasthenic syndromes), but they are most characteristic of primary muscle disease.

As mentioned earlier, fibrillation potentials, while typical of denervation, are sometimes seen in the myositides, inclusion-body myopathy, and the rapidly progressive muscular dystrophies, perhaps because of segmental necrosis of muscle fibers that isolates a segment of the fiber from its nerve supply. In myasthenia gravis, where transmission of impulse fails at the neuromuscular junction, a single MUP may vary in amplitude during sustained weak contraction and some fibers cease to function. Electromyographic recordings of single muscle fibers belonging to the same motor unit disclose varying interpotential intervals on successive discharges; this phenomenon is called "jitter" and increases to the point of actual block, with deficits in neuromuscular transmission within a motor unit (see below and Chap. 53).

Abnormalities of the Interference Pattern Diseases that reduce the population of functional motor neurons or axons within the peripheral nerve decrease the number of motor units that can be recruited in the affected muscles. The decreased number of motor units available for activation then produce an incomplete interference pattern, which is manifest by a decreased number of units firing at a moderate to rapid rate. A severe reduction in the interference pattern may result in the recruitment of only a single unit (see Fig. 45-6B). Structural damage to nerve as well as demyelinating block can produce this pattern of reduced recruitment; indeed a reduced recruitment pattern coupled with the absence of denervation indicates a conduction block.

If muscle power is reduced in diseases such as polymyositis or muscular dystrophy, in which individual muscle fibers are affected, there may be little or no reduction in the number of motor units available for recruitment until the process is far advanced and entire MUPs have been lost due to random loss of all their constituent muscle fibers. Nonetheless, each motor unit will consist of fewer muscle fibers than normal, so more motor units must be activated to reach a certain degree of force. A modest effort can thus produce a full interference pattern despite marked weakness

(increased recruitment). Because fewer muscle fibers are firing, the amplitude of the pattern will be reduced from normal. This type of full, highly complex interference pattern of less than usual amplitude in the face of dramatic weakness is the hallmark of myopathy (see Fig. 45-6C).

Motor Unit Counting This experimental technique, developed by McComas and colleagues, estimates the size of motor units and is thus exquisitely sensitive to changes of denervation and reinnervation. It is carried out by applying a weak stimulus to a motor nerve or motor point and increasing it gradually as the evoked muscle response is recorded. Each quantal increase in the compound evoked response is presumed to be due to the addition of a single motor unit. In reinnervated muscles the additional units are reduced in number and are abnormally large. The technique is used mainly for the investigation of motor neuron disorders. When a normal number and configuration of motor units is found, it has been helpful in distinguishing benign fasciculations from those of serious diseases.

Single-Fiber Electromyography (SF-EMG) This is a special technique for the recording of single-muscle-fiber action potentials and is used to measure fiber density and so-called jitter. *Fiber density* is an index of the number and distribution of muscle fibers within a motor unit. *Jitter* is the variability of the interpotential interval of successive discharges of two single-muscle-fibers belonging to the same motor unit. This phenomenon is due largely to the very slight variability of delay at the branch points in the distal axon and by synaptic delay at the neuromuscular junction. For this reason, SF-EMG is particularly useful in the detection of disorders of neuromuscular transmission, especially myasthenia gravis where it has found its main clinical use. Fiber density and jitter may, however, also be increased in neuropathic disorders that cause denervation with reinnervation. They are usually normal or only slightly increased in myopathic disorders.

Testing for jitter is carried out by having the patient voluntarily contract a muscle to the slightest degree possible in order to activate only one motor unit (requiring a great deal of cooperation by the patient) or by stimulating an intramuscular nerve twig (requiring great patience on the part of the examiner). The EMG needle is advanced until two muscle fibers from the same motor unit are recorded. If the oscilloscope sweep is triggered by the firing of the first fiber, a fluctuating latency of the second fiber potential can be seen on the screen as a movement (jitter) of the second peak. The degree of jitter can be quantitated by measuring the interval between the activation of the two muscle fibers (the result of slightly differing lengths of the terminal axons) from which a mean interpeak interval is determined. Approximately 20 fiber pairs are sampled, and an average of the mean consecutive intervals can be derived. In a muscle such as the extensor digitorum communis, the average variation should be no more than 34 ms. The acceptable average is lower for large proximal muscles. Also, in disease of the neuromuscular junction one muscle fiber in a pair may fail to fire intermittently as a result of a blocking of conduction. Further details of this technique and its clinical applications are discussed fully by Stålberg and Trontelj.

Imaging of Muscle and Nerve

Imaging techniques—computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound—enable one to measure

muscle volume and to recognize qualitative changes in muscle structure (see review of deVisser and Reimers). Such methods are finding increasing clinical and research use in the diagnosis of disorders of muscle and in gauging the effects of treatment. CT scans of dystrophic muscle show foci of decreased attenuation, representing masses of fat cells. The fatty masses spread gradually from multiple foci and eventually replace muscle fibers. The original shape of the muscle is retained; indeed, an enlarged weak muscle containing mostly fat confirms the clinical impression of pseudohypertrophy. In denervative atrophy, the muscles are obviously small and contain multiple punctate areas of decreased attenuation, which represent interstitial fat. Eventually, large portions of chronically denervated muscle may be replaced by fat. Blood, blood products, and calcium deposits are expressed by increased attenuation in CT. This may be helpful in the diagnosis of muscle trauma, myositis ossificans, and polymyositis.

In MR images, fat and bone marrow have a high signal intensity, while fascia, ligaments, and cortical bone lack signal intensity. In T1-weighted images, normal muscle has a low signal and dystrophic muscle, a slightly increased signal; in T2-weighted images, dystrophic muscle has a slightly enhanced signal. Given its sensitivity to these dystrophic changes in muscle, MRI is particularly effective in determining the distribution of muscle involvement in a dystrophy. Transverse MR sections, for example, can help distinguish the topographic patterns of such disorders as the proximally predominant Becker dystrophy and the distally predominant Miyoshi myopathy or subtle subtypes of Emery-Dreifuss dystrophy (Mercuri). Spectroscopic MRI in metabolically determined myopathies has the capacity to quantitate levels of selected biochemical constituents of muscle, including intracellular pH and levels of metabolic intermediates such as phosphocreatine. This is particularly effective in demonstrating subnormal generation of intracellular acidosis after a limb is exercised in disorders of glycogenolysis and of glycolysis. Some individuals with mitochondrial disease of muscle will demonstrate rapid depletion of energy supplies and profound delays in recovery that can be quantified and used as an endpoint for treatments.

New magnetic resonance techniques are also being developed that allow the imaging of nerves. This may be an aid in traumatic nerve injury and in demonstrating neuromas, hypertrophy or atrophy of a nerve trunk, as well as neural tumors.

BIOPSIES OF MUSCLE AND NERVE

Muscle biopsy can be of great diagnostic value, but both surgical and microscopic techniques must be exacting. The muscle chosen for study should be accessible; there should be evidence that it has been affected but not totally destroyed by the disease in question; and it should not have been the site of a recent injection or EMG study, since the trauma of the needles produces focal necrotizing and inflammatory lesions. Muscle biopsy is helpful in distinguishing the following basic disorders in patients with neuromuscular disease.

Muscle Biopsy

1. *Denervation atrophy.* Reduction in the size of muscle fibers with an accompanying enlargement of intact motor units (due to collateral reinnervation) and degenerative changes in some fibers are the main changes of denervation atrophy.

Group atrophy denotes enlarged motor units where all the fibers in the group are reduced to the same size; this is typical of progressive denervation. Normally, the fibers of each motor unit are not clustered, so that when grouping occurs it means that some fibers of a denervated unit have been adopted by an adjacent intact motor unit. This change typifies axonal neuropathies and many spinal cord diseases that affect the anterior horn cell. A related change is particularly well shown in histochemical stains for ATPase, phosphorylase, and oxidases, where the normal mosaic pattern of fiber types is altered. The use of these stains reveals fiber type grouping, the most specific histologic evidence of denervation and reinnervation. Here, muscle fibers of similar histochemical type form groups of 15 or more fibers as a result of reinnervation by a single motor neuron. The diagnosis of denervation atrophy can usually be made from the clinical and EMG examinations; seldom is biopsy necessary for this purpose, but it is still utilized in cases of possible ALS, for example, where the diagnosis remains uncertain after other testing.

2. *Segmental necrosis of muscle fibers with myophagia and various manifestations of regeneration.* These are the typical changes in idiopathic polymyositis (in combination with infiltrates of inflammatory cells), and infective polymyositis (in the presence of *Trichinella*, *Toxoplasma*). These changes may also be observed in more limited form in Duchenne and other rapidly progressive muscular dystrophies.
3. *Inflammation and vasculitis.* Lymphocytic infiltration of the endomysium is most characteristic of polymyositis and in dermatomyositis it may be predominantly perimysial. The lymphocytic infiltrate is often florid in these two processes, whereas it tends to be less intense in inclusion body myositis. Lesser degrees of inflammation are common in the myopathies associated with Sjögren syndrome, mixed connective tissue disease, and scleroderma. Numerous other processes—including the infections mentioned earlier and some dystrophies (especially the fascioscapulohumeral type)—may be associated with an inflammatory reaction. There is usually acute myofibrillar destruction in regions of maximal lymphocytic infiltration.

The muscle is a frequent site of inflammatory vascular destruction (vasculitis) in systemic diseases such as polyarteritis nodosa, and for this reason it is often useful to obtain a small sample of muscle adjacent to a nerve biopsy. The finding of a granulomatous myopathy may indicate the presence of systemic sarcoidosis.

4. *Alterations in the protein and histochemical composition of muscle fibers* may be shown by special stains for enzymes, glycogen, and structural proteins that are implicated in disease. For example, it has become possible to detect the absence or deficiency of specific structural proteins of the muscle membrane that define each of the muscular dystrophies: dystrophin, sarcoglycan, laminin, as discussed in Chap. 50. These tests require rapid freezing (in a cryostat) rather than formalin fixation. Also, a number of enzymatic deficiencies and intrafiber glycogen storage that lead to weakness and muscle fatigue may be detected by appropriate histochemical staining (Chap. 51).
5. *Unusual changes of muscle fibers.* Included here are sarcoplasmic masses and disorganized ring or serpentine collections of myofibrils and myofilaments (*Ringbinden*) in myo-

- tonic dystrophy; glycogen masses in glycogen storage diseases, rods (nemaline), central cores, aggregates of lipid bodies, and other cytoplasmic changes in certain congenital myopathies; and nuclear and cytoplasmic inclusions (and other changes) that characterize inclusion-body myositis. Application of histochemical methods and electron microscopy are the important techniques in the diagnosis of these disorders. These are discussed in relation to each of these specified diseases in the following chapters.
6. *Abnormalities of mitochondria.* Several distinctive abnormalities are readily visualized in muscle biopsies and are virtually diagnostic of an entire class of mitochondrial diseases. Light microscopy of frozen sections of muscle stained with the Gomori trichrome stain show the main feature, so-called ragged red fibers, which are accumulations of subsarcolemmal mitochondria.
 7. *Disorders of the neuromuscular junctions in which nerve fibers and muscle fibers appear to be intact.* Here an abnormality may be revealed by performing the demanding procedure of motor point biopsy (to include the motor end plate), and using electron microscopy and special staining techniques for nerve terminals, cholinesterase, and the outlining of acetylcholine receptors. Myasthenia gravis, botulism, Lambert-Eaton syndrome, and myasthenic syndrome with motor end-plate cholinesterase deficiency fall into this category. Biopsy is rarely necessary for the diagnosis of these disorders but it has added considerably to our understanding of them.

As a rule, the muscle biopsy procedure requires no more than a small cleanly excised block of muscle, 1.0 to 2.0 cm, which is prevented from contracting by a clamp or by tying at full length to a tongue depressor. As an alternative to the standard surgical technique, percutaneous needle biopsies are now being done routinely in neuromuscular clinics and may be adequate for the diagnosis of certain muscle dystrophies and for their study over time and for a number of other muscle diseases and denervation atrophy. Unfortunately, the erratic distribution of lesions in many of the common disorders of muscle lessens the diagnostic yield of all types of biopsy, but in general the needle biopsy is less satisfactory than an open biopsy. The study of the muscle biopsy requires special care in removal, transport, and fixation techniques. These are discussed in detail by Engel.

Nerve Biopsy

Nerve biopsies are processed for study by conventional histologic methods and by thin-section phase and electron microscopy. These methods, sometimes supplemented by study of teased fiber preparations and immunologic studies, can provide valuable histopathologic data. With ordinary microscopy and staining, one may find evidence of focal inflammation, vasculitis, amyloidosis, leprosy, or sarcoid. These procedures are most valuable in the diagnosis of

inflammatory, vasculitic, and amyloid neuropathies. In children, the nerve biopsy may reveal the histologic features of metachromatic or globoid leukodystrophy, giant axonopathy, or neuroaxonal dystrophy. However, nerve biopsy is relatively unhelpful in most other polyneuropathies and should be used prudently because the procedure is not without complications, such as the occasional occurrence of wound infections, painful stump neuromas, persistent dysesthesias of the lateral foot or heel, and thrombophlebitis. Indeed, in a prospective study of 50 consecutive cases with sural nerve biopsy reported by Gabriel and colleagues, nerve biopsy served only to confirm the clinical diagnosis in 70 percent of cases and altered the diagnosis in only 14 percent. Nevertheless, in some instances of idiopathic polyneuropathy that are not clarified by clinical and electrophysiologic testing, and particularly if a treatable chronic inflammatory polyneuropathy is suspected, many neuro-muscular experts resort to sural nerve biopsy as a final diagnostic step. Although the sural nerve is typically chosen for biopsy, the superficial peroneal nerve and the adjacent peroneus brevis muscle gives a higher yield in cases of vasculitis (see Collins et al.).

In diseases that involve only the motor nerves, it is sometimes useful to sample a fascicle of the superficial radial nerve or the nerve to the extensor digitorum brevis, which may be taken with the muscle itself. Chronic inflammatory neuropathy and vasculitic neuropathy may be disclosed by this type of biopsy when the sural nerve is unaffected. Also, in selected circumstances we have undertaken biopsy of small radicles of upper lumbar roots (L1 or L2) to establish the diagnosis of an infiltrative lymphoma. Little deficit occurs from the removal of nerves from these alternative sites if the procedure is done by an experienced surgeon.

Additional techniques that are utilized in the study of muscle biopsies and specific pathologic findings that characterize the many individual diseases, of both muscle and peripheral nerve, are discussed in the chapters that follow.

Other Laboratory Tests in the Study of Muscle and Nerve Disease None of the diagnostic procedures previously described may be taken as an infallible diagnostic index of a specific disease of muscle or nerve. Each procedure is subject to technical error and the findings to misinterpretation. A biopsy specimen may be taken from an unaffected muscle or portion of a muscle, and such a sampling error causes the sample to be normal in the face of obvious clinical evidence of disease. This is particularly true of the inflammatory myopathies that affect muscle in heterogeneous and spotty manner.

Rough excision and improper fixation and staining may produce artifacts that may be misinterpreted as marks of disease when, in fact, the muscle (and nerve) is microscopically normal. Similarly, EMG study may fail to record fibrillations in obviously denervated muscle, particularly in slowly progressive disorders. Also, in some of the muscles of the feet, fibrillations and fasciculations may be found in normal asymptomatic older individuals (Falck and Alaranta). As in the study of all disease, laboratory data have significance only if evaluated in the light of the clinical findings.

CHAPTER 46

DISEASES OF THE PERIPHERAL NERVES

In this single chapter, an attempt is made to provide an overview of the very large and difficult subject of peripheral nerve disease. Since the structure and function of the peripheral nervous system are relatively simple, one might suppose that our knowledge of its diseases would be complete. Such is not the case. For example, when a group of patients with chronic polyneuropathy were investigated intensively in a highly specialized center for the study of peripheral nerve diseases several decades ago, a suitable explanation for their condition could not be found in 24 percent (Dyck et al, 1981) and only slightly less discouraging figures prevail in our clinics today. Moreover, the physiologic basis of many neuropathic symptoms continues to elude experts in the field, and in many of the neuropathies the pathologic changes have not been fully determined.

There has, however, been a recent surge of interest in diseases of the peripheral nervous system, which promises to change this state of affairs. Electron-microscopic studies, new quantitative histometric methods, and refined physiologic techniques have already expanded our knowledge of the structure and function of peripheral nerves, and rapidly advancing techniques in the fields of immunology and molecular genetics are beginning to clarify entire categories of neuropathic disease. Also, in recent years, effective forms of treatment for several peripheral neuropathies have been introduced, making accurate diagnosis imperative. For these reasons, clinicians now find the peripheral neuropathies among the most challenging and gratifying categories of neurologic disease.

GENERAL CONSIDERATIONS

It is important to have a clear concept of the extent of the peripheral nervous system (PNS) and the mechanisms whereby it can be affected by disease. The PNS includes all neural structures lying outside the pial membrane of the spinal cord and brainstem with the exception of the optic nerves and olfactory bulbs, which are but special extensions of the brain. The parts of the PNS within the spinal canal and attached to the ventral and dorsal surfaces of the cord are called the *spinal nerve roots*; those attached to the ventrolateral surface of the brainstem are the *cranial nerve roots*, or just cranial nerves.

The dorsal or posterior (afferent or sensory) roots consist of central axonal processes of the spinal sensory ganglia and the cranial ganglia. On reaching the spinal cord and brainstem, they extend for variable distances into the dorsal horns and posterior columns (funiculi) of the cord and into the spinal trigeminal and other tracts in the medulla and pons before synapsing with secondary neurons as described in Chap. 9. The peripheral axons of the dorsal root ganglion cells are the sensory nerve fibers. They terminate as freely branching or specialized corpuscular endings—i.e., the sensory receptors—in the skin, joints, and other tissues. The sensory nerve fibers vary greatly in size and in the thickness of their myelin covering; based on these dimensions, they are classified as type A, B, or C as discussed in Chap. 8. The ventral, or anterior (efferent, or motor), roots are composed of the emerging axons of anterior

and lateral horn cells and motor nuclei of the brainstem. Large, heavily myelinated fibers terminate on muscle fibers and smaller unmyelinated ones terminate in sympathetic or parasympathetic ganglia. From these autonomic ganglia issue the axons that terminate in smooth muscle, heart muscle, and glands. Traversing the subarachnoid space, where they lack well-formed epineurial sheaths, the cranial and spinal roots (both sensory and motor) are bathed in and are susceptible to substances in the cerebrospinal fluid (CSF), the lumbosacral roots having the longest exposure (Fig. 46-1).

The vast extent of the peripheral ramifications of cranial and spinal nerves is noteworthy, as are their thick protective and supporting sheaths of perineurium and epineurium and their unique vascular supply through longitudinal arrays of richly anastomosing nutrient arterial branches that run in the epineurium and perineurium. The perineurium comprises the connective tissue sheaths that surround and separate each bundle of nerve fibers (fascicles) of varying size, each fascicle containing several hundred axons. The sheath that binds and surrounds all the fascicles of the nerve is the epineurium. As the nerve root approaches the cord, the epineurium blends with the dura (see Fig. 46-1). The fine connective tissue covering of individual nerve fibers is the endoneurium. The nerves traverse narrow foramina (intervertebral and cranial) and a few pass through tight channels peripherally in the limbs (e.g., the median nerve between the carpal ligament and tendon sheaths of flexor forearm muscles; the ulnar nerve in the cubital tunnel). These anatomic features explain the susceptibility of certain nerves to compression and entrapment and also to ischemic damage. The axons themselves contain a complex internal microtubular apparatus for maintaining the integrity of their membranes and for transporting substances such as neurotransmitters over long distances between the nerve cell body and the distant reaches of the nerve fiber.

Nerve fibers (axons) are coated with short segments of myelin of variable length (250 to 1000 μm), each of which is enveloped by a Schwann cell and its membrane. Indeed, the Schwann cell membrane surrounding an axon is the myelin sheath. In fact, the PNS may be accurately defined as the part of the nervous system that is invested by the cytoplasm and membranes of the Schwann cells. Each myelin segment and Schwann cell has a symbiotic relationship to the axon but is always morphologically independent. The structure of the axonal membrane in the gaps between segments of the myelin sheaths (nodes of Ranvier) is specialized, containing a high concentration of sodium channels and permitting the saltatory electrical conduction of nerve impulses, as described in Chap. 45. Unmyelinated fibers, more numerous in peripheral nerves than myelinated ones, also arise from cells in dorsal root and autonomic ganglia. Small bundles of these naked (unmyelinated) axons are enveloped by a single Schwann cell; delicate tongues of Schwann cell cytoplasm partition these bundles and separate individual axons. Each sensory nerve fiber terminates in a specialized ending which is designed to be especially sensitive to certain natural stimuli as discussed in Chaps. 8 and 9.

Pathogenic Mechanisms in Peripheral Nerve Disease

The anatomic features previously mentioned enable one to conceptualize the possible avenues by which disease may affect the peripheral nerves. Pathologic processes may be directed at any one of the several groups of nerve cells whose axons constitute the nerves, i.e., the cells of the anterior or lateral horns of the spinal cord, the dorsal root ganglia, or sympathetic and parasympathetic ganglia. Each of these cell types exhibits specific vulnerabilities to disease processes, and if destroyed—as, for example, the motor nerve cells in poliomyelitis—there results a secondary degeneration of the axons and myelin sheaths of the peripheral fibers of these cells. Neuropathic symptoms may also be induced by alterations of function and structure of the ventral and dorsal columns of the spinal cord, which contain the fibers of exit and entry of anterior horn and dorsal root ganglion cells, respectively. The myelin of these centrally located fibers is constituted differently from that of the peripheral nerves, being enveloped by oligodendrocytes rather than Schwann cells, and the fibers are supported by astrocytes rather than fibroblasts.

Because of the intimate relation of the nerve roots to the CSF and to specialized arachnoidal cells (the arachnoidal villi), a pathologic process in the CSF or leptomeninges may damage the exposed spinal roots. Disease of the connective tissues may affect the peripheral nerves that lie within their sheaths. Diffuse or localized arterial diseases may injure nerves by occluding their nutrient arteries. In a large category of immune-mediated neuropathies, damage is the result of a cellular or humoral attack on various components of myelin. A subset of these is characterized by the binding of circulating antibodies to the specialized regions at the nodes of Ranvier, causing a block of electrical conduction. Also, a complement-dependent, humoral immune reaction against the radicular or peripheral axon is known. Toxic or immunologic agents that selectively damage the Schwann cells or their membranes, cause demyelination of peripheral nerves leaving axons relatively intact, or a toxin may specifically affect axons by poisoning their cell bodies, the axolemma, or the lengthy and complex axonal transport apparatus. Finally, one might correctly suppose that axons of the motor or sensory nerves, sympathetic fibers of varying diameter and length, or the end organs to which they are attached would each have its own particular liability to disease.

Some of this is theoretical and somewhat speculative. At present we can cite only a few examples of diseases or toxins that cause disease through these mechanisms exclusively: e.g., diphtheria, in which the bacterial toxin acts directly on the membranes of the Schwann cells near the dorsal root ganglia and adjacent parts of motor and sensory nerves (the most vascular parts of the peripheral nerve); polyarteritis nodosa, which causes widespread occlusion of vasa nervorum, resulting in multifocal nerve infarction; tabes dorsalis, in which there is a treponemal meningoradiculitis of the posterior roots (mainly of the lumbosacral segments) that lie next to the arachnoidal villi where CSF is resorbed; doxorubicin intoxication, wherein protein synthesis of dorsal root ganglion cells

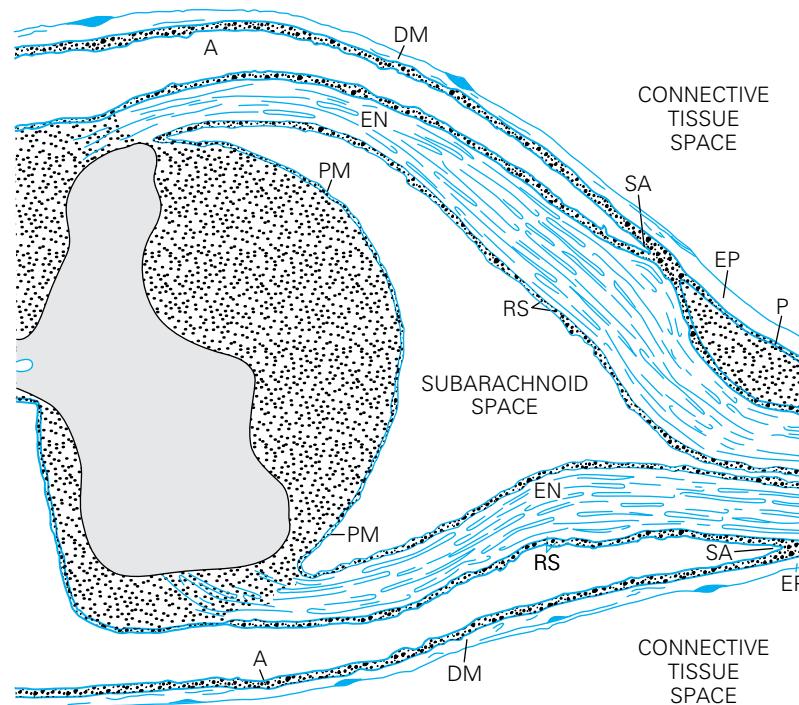

Figure 46-1. Diagram showing the relationships of the peripheral nerve sheaths to the meningeal coverings of the spinal cord. The epineurium (EP) is in direct continuity with the dura mater (DM). The endoneurium (EN) remains unchanged from the peripheral nerve and spinal root to the junction with the spinal cord. At the subarachnoid angle (SA), the greater portion of the perineurium (P) passes outward between the dura mater and the arachnoid (A), but a few layers appear to continue over the nerve root as part of the root sheath (RS). At the subarachnoid angle, the arachnoid is reflected over the roots and becomes continuous with the outer layers of the root sheath. At the junction with the spinal cord, the outer layers of the root sheath become continuous with the pia mater (PM). (From Haller FR, Low FM: Am J Anat 131:1, 1971, by permission.)

is blocked, with subsequent neuronal destruction; poisoning with arsenic, which combines with the axoplasm of the largest sensory and motor nerves via sulfhydryl bonds; and vincristine toxicity, which damages the microtubular transport system. Analogous anatomic pathways are probably implicated in other diseases by mechanisms that remain to be discovered.

Among the genetically determined neuropathies, the altered gene products are now known in some cases to lead to defective myelination, which greatly slows conduction along nerves. In other genetic diseases it is speculated that structural components of the axon are disrupted, leading to axonal degeneration and impaired electrical conduction.

Pathologic Reactions of Peripheral Nerve

Pathologically, several distinct processes are recognized in the peripheral nerve, although they are not disease-specific and may be present in varying combinations in any given case. The classic ones are *segmental demyelination*, *wallerian degeneration*, and *axonal degeneration* (diagrammatically illustrated in Fig. 46-2).

The myelin sheath is the most susceptible element of the nerve fiber, for it may break down as part of a primary process involving the Schwann cells or the myelin sheath itself, or it may be damaged secondarily, as a consequence of disease affecting its axon. Focal degeneration of the myelin sheath with sparing of the axon is called

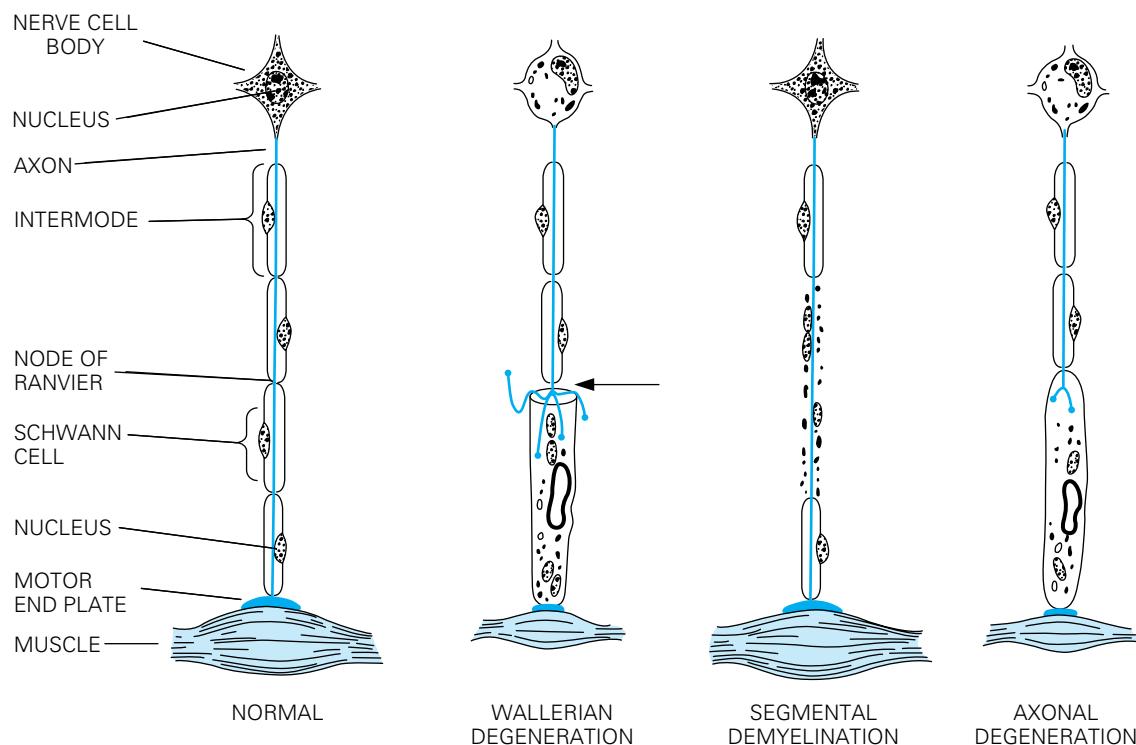

Figure 46-2. Diagram of the basic pathologic processes affecting peripheral nerves. In wallerian degeneration, there is degeneration of the axis cylinder and myelin distal to the site of axonal interruption (arrow), and central chromatolysis. In segmental demyelination, the axon is spared. In axonal degeneration, there is a distal degeneration of myelin and axis cylinder as a result of neuronal disease. Both wallerian and axonal degeneration cause muscle atrophy. Further details in text. (Courtesy of Dr. Arthur Asbury.)

segmental demyelination. The characteristic change of segmental demyelination is the disappearance of the sheath over segments of variable length, bounded on each end by a preserved segment of myelin. This exposes long segments of the axon to the interstitial environment. Myelin may also degenerate secondary to axonal disease in a general process that may occur either proximal or distal to the site of axonal interruption. Common to many lesions of the peripheral nerve is the type of reaction of both the axon and myelin *distal to axonal disruption* called *wallerian degeneration*. Wallerian degeneration might be described as “dying forward,” a process in which the nerve degenerates from the point of axonal damage outward. In contrast, when the axon degenerates as part of a “dying-back” phenomenon in a more generalized metabolically determined polyneuropathy, it is termed *axonal degeneration*. Here, the axon is affected from the distal-most site to the proximal, with dissolution of myelin that occurs in parallel with the axonal change. One possible explanation for this process is that the primary damage is to the neuronal perikaryon, which fails in its function of synthesizing proteins and delivering them to the distal parts of the axon. There is also the possibility that certain toxic and metabolic processes affect axons uniformly along their length or impair anterograde axonal transport to the periphery; the functional impairment would then be proportional to the size and length of the blocked axons.

Destruction of an anterior horn cell or proximal motor root results in a gradual dissolution of the distal motor nerve and its myelin sheath (a form of wallerian degeneration). Similar destruction of the dorsal root produces a secondary wallerian degeneration of the posterior columns of the spinal cord, but not of the peripheral

sensory nerve since the dorsal root ganglion cells maintain the integrity of the distal axon. In other words, destruction of axons results within several days in a wallerian degeneration of all the myelin distal to the point of injury. The myelin breaks down into blocks or ovoids in which lie fragments of axons (digestion chambers of Cajal). The myelin fragments are then converted, through the action of macrophages, into neutral fats and cholesterol esters and carried by these cells to the bloodstream.

Certain diseases affect the neuron primarily rather than the axon and cause either a motor or sensory *neuronopathy*. In the former case the anterior horn cell is affected by a disease process (motor neuron disease, or motor neuronopathy), and in the latter, the sensory ganglion cell (ganglionopathy) is destroyed. Degeneration of the respective nerve fibers follows.

These pathologic reactions are more easily understood if one considers certain features of cytoskeletal structure and function of nerve cells and their axons. The axon contains longitudinally oriented neurofilaments and microtubules, which are separated but interconnected by cross-bridges. Their main function involves the transport of substances from nerve cell body to axon terminal (anterograde transport) and from the distal axon back to the cell body (retrograde transport). Thus, when the axon is severed, organelles cannot be transmitted to the distal axon for the purpose of renewing membrane and neurotransmitter systems. By means of retrograde axonal transport, the cell bodies receive signals to increase their metabolic activity and to produce growth factors and other materials needed for axonal regeneration. In some incompletely defined way the axon creates a local environment that allows the Schwann cell to maintain the integrity of the adjacent myelin sheath. Loss

of this trophic signal leads to dissolution of the sheath, but not of the Schwann cell itself.

There are also highly characteristic histopathologic changes in the nerve cell body termed *chromatolysis* or *axonal reaction* that are a secondary consequence of axonal interruption. These retrograde changes consist of swelling of the cell cytoplasm and marginalization and dissolution of the Nissl substance. The important point is that despite the destructive changes in the nerve fibers, the nerve cells, while altered in histologic appearance, are left intact and reactive.

In segmental demyelination, recovery of function may be rapid because the intact but denuded axon needs only to become remyelinated. The newly formed internodal segments are initially thinner than normal and of variable length. By contrast, recovery is much slower with wallerian or axonal degeneration, often requiring months to a year or more because the axon must first regenerate and then reinnervate the muscle, sensory organ, blood vessel, etc., before function returns. When the regenerating axon first becomes myelinated, the internodal myelin segments are short, the length of one normal internode being replaced by three or four shorter new ones. Recurrent demyelination and remyelination lead to "onion bulb" formations and enlargement of nerves, the result of proliferating Schwann cells and fibroblasts that encircle the axon and its thin myelin sheath. If nerve cells are destroyed, no recovery of function is possible except by collateral regeneration from axons of intact nerve cells.

In the most extreme circumstances, interruption of a nerve by severing or crude destruction, the continuity is interrupted and may not be reestablished. Regenerating axonic filaments take aberrant courses and, with fibroblastic scar formation at the end of the central portion of the interrupted nerve, they form a pseudoneuroma.

These relatively few pathologic reactions cannot in themselves differentiate the hundred or more diseases of the peripheral nerves; but when they are considered in relation to the selective effects on various types and sizes of fibers, the topography of the lesions, and the time course of the process, they furnish criteria whereby many diseases can be distinguished. Moreover, the identification of these basic reactions of nerve is of great value in the inspection of pathologic material obtained from biopsy or autopsy.

There are in addition special pathologic changes, not specifically neural in nature, that characterize certain diseases of the peripheral nervous system. These involve inflammatory or vascular changes or deposition of material in the interstitium of the nerve. For example, acute demyelinative polyneuritis of the Guillain-Barré type is characterized by endoneurial infiltrations of lymphocytes and other mononuclear cells in the nerves, roots, and sensory and sympathetic ganglia; frequently the infiltrates and destruction of myelin have a perivenous distribution. In polyarteritis nodosa, a characteristic necrotizing panarteritis with thrombotic occlusion of vessels and focal infarction of peripheral nerves are the dominant findings. Deposition of amyloid in the endoneurial connective tissue and walls of vessels affecting the nerve fibers secondarily by a toxic effect are the distinctive features of inherited and acquired amyloid polyneuropathy. In one of the inherited polyneuropathies of childhood, the axons are enlarged by tightly packed masses of neurofilaments. Diphtheritic polyneuropathy is typified by the predominantly demyelinative character of the nerve fiber change, the location of this change in and around the roots and sensory ganglia, the subacute course, and the lack of inflammatory reaction. Other polyneuropathies (paraneoplastic, nutritional, porphyric, arsenical, and uremic) are topographically symmetrical and all represent

forms of axonal degeneration but at the present time cannot be distinguished from one another on histopathologic grounds. A number of neuropathies are characterized by the deposition of antibodies and complement on the myelin sheath or on elements of the axon. These changes can be demonstrated by immunohistopathologic techniques.

Concerning the pathology of the *mononeuropathies*, our knowledge is somewhat more complete. Compression of nerve or nerve roots, producing local or segmental ischemia, stretch, and laceration of nerves are understandable mechanisms, and their pathologic changes have been reproduced experimentally. Tumor infiltration and vasculitis with ischemic infarction of nerve account for some cases. Of infections and granulomas localized to single nerves, only leprosy, sarcoid, and herpes zoster represent identifiable disease states. For most of the acute mononeuropathies, the pathologic changes have yet to be defined, since they are usually benign reversible states that provide no opportunity for complete pathologic examination.

SYMPTOMATOLOGY OF PERIPHERAL NERVE DISEASE

There are a number of motor, sensory, reflex, autonomic, and trophic symptoms and signs that are more or less typical of peripheral nerve disease. Grouping them into syndromes based on their temporal and topographic features has proved to be of value in clinical diagnosis. The topographic patterns are detailed further on under "Approach to the Patient with Peripheral Neuropathy." Here the primary symptoms of peripheral nerve disease are described.

Impairment of Motor Function Persistent impairment of motor function over days, weeks, or months in a topographic pattern that implicates peripheral nerves, signifies either segmental demyelination, axonal interruption, or destruction of motor neurons. The degree of weakness is proportional to the number of axons or motor neurons affected, although pain and kinesthetic loss may add to the functional impairment.

Polyneuropathies are generally marked by a symmetric distribution of the weakness or paralysis. In cases of diffuse axonal damage, the muscles of the feet and legs are affected earlier and more severely than those of the hands and forearms. In milder forms of axonal disease, only the feet and lower legs are involved. Truncal and cranial muscles are usually the last to yield, and then only in severe cases. This represents the "length dependent" pattern of axonal degeneration. The nutritional, metabolic, and toxic neuropathies assume the more common, predominantly distal, axonal pattern. The pathologic changes in such cases begin in the far distal parts of the largest and longest nerves and advance along the affected fibers toward their nerve cell bodies (dying-back neuropathy, "distal axonopathy").

The typical distally predominant pattern is not generally found in the acute and chronic demyelinating inflammatory neuropathies, where the multifocal nature of lesions and blockage of electrical conduction leads to weakness of proximal limb and facial muscles before or at the same time as distal parts are affected. Another exception to the pattern of distally predominant weakness is porphyria, an axonal process in which there may be mainly proximal weakness.

Another characteristic pattern of neuropathic weakness is one in which all the muscles of the limbs, trunk, and neck are involved,

often including respiratory paralysis. The best known is the Guillain-Barré syndrome (GBS). Less common causes of such a pattern of *generalized paralysis* include diphtheria, tick paralysis, and certain toxic polyneuropathies. Fatalities, when they occur, are usually due to respiratory failure.

A predominantly *bibrachial paralysis* is an unusual presentation of neuropathic disease but may occur in the inflammatory-demyelinating polyneuropathies as well as in the Sjögren syndrome, chronic immune or paraneoplastic neuropathies, lead neuropathy, Tangier disease, and from familial brachial neuritis. (A more frequent cause of bibrachial palsy is disease of the motor neurons themselves, specifically, motor system disease, as discussed on page 939 or a lesion placed centrally in the cervical cord that damages these same neurons.) *Paraparesis* is not typical of the generalized polyneuropathies, but may be observed with infections and inflammations of the cauda equina, as occurs with Lyme disease, cytomegalovirus, herpes simplex, and with neoplastic nerve root infiltrations. Bifacial and other cranial nerve paralyses are likely to occur in GBS, with neoplastic invasion, and also with connective tissue diseases, human immunodeficiency virus (HIV) and herpes virus infection, sarcoidosis, Lyme disease, or one of the rare metabolic neuropathies (Refsum, Bassen-Kornzweig, Tangier, and Riley-Day). These are discussed in Chap. 47 on diseases of the cranial nerves and in respective chapters on infections and metabolic diseases of the nervous system.

Atrophy of weak or paralyzed muscles is highly characteristic of disease of the motor neuron or motor axon. It proceeds slowly over several months, the degree being proportional to the number of damaged motor nerve fibers. The maximum degree of denervation atrophy occurs in 90 to 120 days and reduces muscle volume by 75 to 80 percent. Atrophy may also be a consequence of disuse; it occurs over many weeks but in itself does not reduce muscle volume by more than 25 to 30 percent. Atrophy, therefore, does not coincide with or correspond to acute paralysis and is least prominent in the acute demyelinative neuropathies in which the nerve fiber is relatively less affected than is the myelin. In chronic axonal neuropathies, the degrees of paralysis and atrophy tend to correspond. Ultimately there is degeneration and loss of the denervated muscle fibers. This process begins in 6 to 12 months; in 3 to 4 years, most of the denervated fibers will have degenerated. If reinnervation takes place within a year or so, motor function and muscle volume may be restored.

Tendon Reflexes The rule is that diminution or loss of tendon reflexes is invariably a sign of peripheral nerve disease (an exception is areflexia in spinal shock described in Chap. 44). In the *small-fiber neuropathies*, however, tendon reflexes may sometimes be retained, even with marked loss of perception of painful and thermal stimuli and loss of autonomic function. This discrepancy is attributable to the fact that the afferent arc of the tendon reflexes utilizes the large, heavily myelinated fibers that originate in muscle spindles. Conversely, in neuropathies that affect the largest diameter, heavily myelinated fibers, the tendon reflexes are diminished early and out of proportion to weakness. Slowing of conduction in sensory fibers may also abolish the reflex by dispersing the afferent volley of impulses initiated by the tendon tap. There is generally a concordance between areflexia and a loss of proprioceptive and joint-position senses; i.e., the large nerve fibers from spindle afferents are of the same type and size as those mediating these forms of sensation. Furthermore, loss of sensory functions that are dependent on these large fibers in the presence of preserved reflexes

implicates the central projections of the sensory ganglion cells i.e., a lesion in the posterior columns of the spinal cord. Regional loss of a reflex is usually a sign of a radiculopathy.

Sensory Loss (See also pages 138 to 142) Most polyneuropathies cause impairment of both motor and sensory functions, but one may be affected more than the other. In most of the toxic and metabolic neuropathies, sensory loss exceeds weakness; and in sensory neuronopathy, there is no motor deficit. By contrast, in GBS paralysis is more prominent than sensory loss. These differences are emphasized in the descriptions of individual peripheral nerve diseases in the later parts of the chapter.

In the polyneuropathies, sensation is affected symmetrically in the distal segments of the limbs, and more in the legs than in the arms. In most types, all sensory modalities (touch-pressure, pain and temperature, vibratory and joint position senses) are impaired or eventually lost, although one modality may be affected out of proportion to the others, or superficial sensation may be impaired more than deep sensation. Vibratory sense is often affected more than position and tactile senses. In extreme cases, as the neuropathy worsens, there is spread of sensory loss from the distal to more proximal parts of the limbs and, eventually, to the anterior abdomen, thorax, and the face. An "escutcheon" pattern of sensory loss over the abdomen and thorax in severe axonal neuropathy may be mistaken for the sensory level of a spinal cord lesion. Another characteristic form of sensory loss affects the trunk, scalp, and face; this is the pattern of a sensory ganglionopathy that is the result of simultaneous affection of distal and proximal parts of the sensory nerve.

A pattern that is the converse of the large fiber sensory may be manifest in some diseases—namely, a loss of pain and temperature sensation with either sparing or lesser impairment of touch-pressure, vibratory, and position senses. This pattern resembles the dissociated sensory disturbance of syringomyelia (pages 140 and 1084). In some types of polyneuropathy it may be found predominantly in the lumbosacral region (it was originally referred to as "lumbosacral syringomyelia"). This "*pseudosyringomyelic*" dissociation of sensation may extend over the arms, trunk, and even cranial surfaces. Thévenard was the first to question its spinal basis, and it is now generally agreed that most such examples are due to hereditary or certain acquired small-fiber sensory neuropathies (amyloidosis, toxins such as chemotherapy, in congenital absence of pain, Riley-Day syndrome, and Tangier disease). Exceptionally, as in one of the families studied by Adams and associates, all forms of sensation may be lost over the entire body, while motor power and autonomic functions are preserved. Most often, *universal sensory loss* is attributable to an acquired disease affecting the sensory ganglia (sensory neuronopathy); usually this is a paraneoplastic process, but certain toxic or immune diseases do the same (e.g., Sjögren disease, scleroderma).

Paresthesias, Pain, and Dysesthesias These sensory symptoms have been described in Chap. 9. They tend to be especially marked in the hands and feet. "Pins and needles," stabbing, tingling, prickling, electrical, and "Novocain-like" feeling, are the adjectives chosen by patients to describe these abnormalities. In some sensory neuropathies paresthesias and numbness are the only demonstrable features; objective sensory loss is lacking. Certain neuropathies cause pain, which may be described as burning, aching, sharp and cutting, or crushing, and at times may resemble the lightning pains of tabes dorsalis. Perversion of sensation (allodynia) is common-

place—e.g., tingling, burning, stabbing pain, or just an uncomfortable dysesthesia is induced by tactile stimuli. Under these conditions, a given stimulus induces not only an aberrant sensation but also one that radiates and persists after the stimulus is withdrawn. As remarked on pages 118 and 133, the patient's reaction may seem to indicate a hypersensitivity ("hyperesthesia"), but more often the sensory threshold is actually raised and it is the sensory experience or response that is exaggerated (*hyperpathia*).

Painful paresthesias and dysesthesias are particularly common in certain types of diabetic, alcoholic-nutritional, and amyloid neuropathies. Mainly they affect the feet ("burning feet") and less often the hands. In herpes zoster they are confined to limited regions of the body. They may be a prominent feature in some cases of diabetic and other types of vascular neuropathy, and in a fairly common sensory neuropathy of obscure nature in elderly individuals. A particularly intense form of burning pain typifies the *causalgia* of a partial nerve lesion (usually traumatic) of the ulnar, median, posterior tibial, peroneal, or occasionally some other nerve (pages 120 and 1172).

The mechanism of thermal and painful dysesthesias is not fully understood. It has been theorized that a loss of large touch-pressure fibers disinhibits the pain-receiving nerve cells in the posterior horns of the spinal cord. An argument against this explanation is the lack of pain in Friedreich ataxia, in which the larger neurons degenerate, and also in certain purely sensory polyneuropathies, where only the perception of tactile stimuli (large fibers) is lost. A more likely explanation, supported by microneurographic recordings is that dysesthetic pain results from autogenic ectopic discharges arising at many sites along surviving intact or regenerating nociceptive nerve fibers or their terminal receptors. In contrast to dysesthetic pain, it has been postulated, on uncertain grounds, that the deep, aching neuropathic pain of sciatica or brachial neuritis (nerve trunk pain) arises from irritation of the normal endings (*nervi nervorum*) in the sheaths of the nerve trunks themselves (Asbury and Fields). These considerations are discussed in Chap. 8.

Sensory Ataxia and Tremor Proprioceptive deafferentation with retention of a reasonable degree of motor function may give rise to ataxia of gait and of limb movement, as discussed in Chap. 9. Probably, dysfunction of the spinocerebellar fibers of the peripheral nerves is the source of the ataxia. Some of the most severe ataxias of this type occur with sensory ganglionopathy, as commented further on.

Ataxia without weakness is characteristic of tabes dorsalis, a purely posterior root affection, but this syndrome can be essentially duplicated by diabetic polyneuropathy, which affects posterior roots as well as nerves (diabetic pseudotabes), and by a variant of the GBS (Fisher syndrome) as well as by certain sensory neuropathies (ganglionopathies). While the ataxia in some instances is indistinguishable from that caused by cerebellar disease, other features of cerebellar dysfunction such as dysarthria and nystagmus are, of course, lacking. In the chronic sensory neuropathies with ataxic features, all movements, though strong, are rendered ineffective by virtue of the deep sensory loss. Characteristic of the sensory (tabetic) ataxic gait are brusque, flinging, slapping movements of the legs. Loss of proprioception may also give rise to small wavering, fluctuating movements of the outstretched fingers—called *pseudoathetotic*, or "dancing fingers."

An action tremor of fast-frequency type may also appear during certain phases of a polyneuropathy. Shahani and coworkers had the impression that it is due to loss of input from the muscle-spindle

afferents. Corticosteroid therapy enhances this fast tremor. A particularly severe form of slower tremor is combined with clumsiness of movement in certain neuropathies that affect large afferent fibers, specifically in the autoimmune, antimyelin-associated glycoprotein (MAG) polyneuropathy and in some cases of chronic inflammatory demyelinating polyneuropathy (CIDP). During action, the tremor may at times be so coarse as to resemble the intention tremor of cerebellar disease.

Deformity and Trophic Changes In a number of chronic polyneuropathies, the feet, hands, and spine become deformed. This is most apt to occur when the disease begins during childhood. Austin pointed out that foot deformity is found in 30 percent of patients with hereditary polyneuropathy, and spine curvature in 20 percent. In early life, the feet are pulled into a position of talipes equinus (plantar deviation) because of the disproportionate weakness of the pretibial and peroneal muscles and the unopposed action of the calf muscles. Atrophic paralysis of the intrinsic foot muscles while the bones are forming allows the long extensors of the toes to dorsiflex the proximal phalanges and the long flexors to shorten the foot, heighten the arch, and flex the distal phalanges. The result is the *claw foot*—*le pied en griffe* or pes cavus (high arches) when the process is less severe. These changes in the foot are valuable diagnostic indicators that a neuromuscular disease originated in early childhood or during intrauterine development. A congenital claw hand has a similar basis. In early childhood, unequal weakening of the paravertebral muscles on the two sides of the spine leads to kyphoscoliosis.

Denervation atrophy of muscle can be considered the main trophic disturbance resulting from interruption of the motor nerves. However, there are numerous other changes. In particular, analgesia of distal parts makes them susceptible to burns, pressure sores, and other forms of injury that are easily infected and heal poorly. In an anesthetic and immobile limb, the skin becomes tight and shiny, the nails curved and ridged, and the subcutaneous tissue thickened ("trophic changes"). Hair growth is diminished in denervated areas. If the autonomic fibers are interrupted, the limb is warm and pink. Repeated injuries and chronic subcutaneous and osteomyelitic infections may result in a painless loss of digits and the formation of plantar ulcers (*mal perforant du pied*). These are prominent features of the recessive form of hereditary sensory neuropathy, and we have observed them in dominant forms as well. In tabes dorsalis and syringomyelia as well as certain familial and other chronic polyneuropathies, analgesic joints, when chronically traumatized, may first become deformed and then actually disintegrate in a process called Charcot arthropathy (Charcot joint).

The pathogenesis of the trophic changes is not fully understood. Apart from analgesia, a critical factor may be inappropriate neural regulation of the distal vasculature, which interferes with normal tissue responses to trauma and infection. Ali and colleagues relate the ulcer formation to loss of C fibers, which mediate both pain and autonomic reflexes. However, paralyzed limbs, even in hysteria, if left dependent, are often cold, swollen, and pale or blue. These are probably secondary effects of immobilization, as pointed out long ago by Lewis and Pickering. Erythema and edema, burning pain, and cold sensations surely can be evoked by peripheral nerve irritation, particularly of C and A- δ fibers as discussed in Chap. 8.

Autonomic Dysfunction Anhidrosis and orthostatic hypotension, two of the most frequent manifestations of autonomic dys-

function, predominate in certain types of polyneuropathy. They occur most frequently in amyloidosis and certain other hereditary small-fiber polyneuropathies, especially diabetic, and several congenital types. In addition, they are among the main features of an acute autonomic polyneuropathy called *pandysautonomia* (Young, Adams, et al, Low et al) and can be prominent in some cases of GBS. These dysautonomic conditions are described in detail in Chap. 26 and later in this chapter.

Other manifestations of autonomic paralysis are small or medium-sized unreactive pupils that are unusually sensitive to certain drugs (pages 241 and 462); lack of sweat, tears, and saliva; sexual impotence; weak bowel and bladder sphincters with urinary retention or overflow incontinence; and weakness and dilatation of the esophagus and colon. As a result of vagal and other parasympathetic dysfunction, the normal variability of heart rate with respiration (sinus arrhythmia) is lost and there may be paralytic ileus or dyscoordinated peristalsis, as well as achlorhydria and hyponatremia. Some of these abnormalities are found in diabetic and amyloid polyneuropathy. In general these autonomic disturbances correspond to degeneration of unmyelinated fibers in the peripheral nerves.

In any neuropathy involving sensory nerves, there is loss of autonomic function in the same zones as sensory loss. *This is not true of radicular diseases* because the autonomic fibers join the spinal nerves more distally. Such changes in sweating and cutaneous blood flow may be demonstrated by a number of special tests, as described in Chap. 26.

Fasciculations, Cramps, and Spasms (See also Chap. 55) Fasciculations and cramps, while not uncommon, are typically not prominent features in most polyneuropathies and in this respect there is a difference from diseases of the anterior horn cells where they are important features. There are exceptions, however. Chronic root compression can lead to fasciculations or painful spasms in the innervated muscles. Occasionally one observes a state of mild motor polyneuropathy that, upon recovery, leaves the muscles in a state variably referred to as myokymia, continuous muscular activity, and neuromyotonia as discussed in Chaps. 45 and 54. All the affected muscles ripple and quiver and occasionally cramp. Use of the muscles increases this activity, and there is a reduction in their contractile efficiency, which the patient senses as a stiffness and heaviness. In some instances this apparently constitutes the entire neuropathic syndrome and may be relieved by carbamazepine or phenytoin. Other closely related phenomena are spasms or involuntary movements of the toes and feet. The latter, referred to by Spillane and colleagues as the syndrome of painful legs and moving toes, is attributed by Nathan to ectopic discharges in sensory roots, ganglia, or nerves, evoking both pain and organized movements. This is one cause of a nocturnal restless leg syndrome, the more common type being idiopathic and not associated with features of peripheral nerve disease. Other possible mechanisms for cramps and spasms are ephaptic cross-transmission, segmental hyperactivity from deafferentation, and neuronal sprouting during reinnervation. In yet other instances, the muscle activity induces odd postures or slow writhing movements that Jankovic and van der Linden have likened to dystonia. The precise pathophysiology of these spontaneous and asynchronous activities of motor neurons is not known. Stimulation of a motor nerve, instead of causing a brief burst of action potentials in the muscle, results in a prolonged or dispersed series of potentials lasting several hundred milliseconds. Evidently, branched axons involved in

collateral innervation have an unstable polarization that may last for years.

APPROACH TO THE PATIENT WITH PERIPHERAL NEUROPATHY

In this field, the clinician is faced with several problems: (1) establishing the existence of disease of the peripheral nervous system; (2) distinguishing by clinical tests which of the main topographic syndromes it represents; (3) determining if the problem is predominantly of a motor or sensory nature, or is of mixed type and whether the myelin sheath or the axon is the main target of disease; and (4) establishing the temporal course of disease. When taken together, these features greatly limit the diagnostic possibilities and determine the underlying disease and possible treatment.

Topographic and Clinical Patterns of Neuropathy (Table 46-1)

At the outset it must be determined whether the neurologic findings correspond to one of the following syndromic patterns:

1. Polyneuropathy
2. Radiculopathy or polyradiculopathy
3. Neuronopathy—motor or sensory
4. Mononeuropathy
5. Multiple mononeuropathies (mononeuropathy, or mononeuritis multiplex)
6. Plexopathy (involvement of multiple nerves in a plexus)

A discussion of these patterns is given in Chap. 9 but the main facts are repeated here:

In *Polyneuropathy*, a generalized process affecting the peripheral nerves, weakness is relatively symmetrical from the beginning and progresses bilaterally; reflexes are lost in affected parts, but particularly at the ankles; sensory complaints and loss of sensation are most pronounced distally, and in the feet before the hands in most cases.

Polyradiculopathy, a disease of multiple spinal roots, differs from polyneuropathy in that the neurologic signs are asymmetrical, and with an erratic distribution that may, for example, be proximal in one limb and distal in another. Always, weakness and zones of sensory loss can only be explained on the basis of involvement of one or more roots. Pain in the sensory distribution of the roots is a common feature. A *single radiculopathy*, most often the result of root compression by disease of the spinal column, is identified by the presence of pain, sensory, motor, and reflex change solely in the distribution of a spinal nerve root. The distinction from mononeuropathy (see later) is not always apparent, and one must resort to a reference or to memorized knowledge of the motor and sensory innervation patterns of each. (The reader should refer to Figs. 9-1, 9-2, and 9-3.) Most helpful is the limitation of sensory loss to one of the dermatomes but it so happens that there is adequate overlap between adjacent dermatomes that such a pattern is not easily discerned. Some of the specific patterns of weakness that arise from a mononeuropathy as compared to radiculopathy are mentioned later.

In *sensory neuronopathy*, the ganglion cells rather than the peripheral sensory nerves are predominantly affected. This gives rise to symptoms and signs of sensory loss in both a proximal and distal distribution, including the scalp, thorax, abdomen, and but-

tocks as well as the extremities; sensory ataxia is a common accompaniment. There is no weakness but movements may be awkward as a result of a sensory ataxia. *Motor neuronopathy* is essentially the opposite condition, a disorder of the anterior horn cells causing weakness, fasciculations, and atrophy in a widespread distribution and, therefore, not properly a process of the peripheral nerves.

Mononeuropathy is the most circumscribed form of peripheral nerve disease. It is reflected by weakness and sensory loss in the territory of a single peripheral nerve. Certain specific features serve to differentiate mononeuropathy from a radiculopathy—for example, weakness in dorsiflexion and eversion of the foot is referable to the peroneal nerve or to the L5 nerve root; however, inversion of the foot, innervated by the tibial nerve, is affected, only with L5 root lesions. The distribution of sensory loss also aids in distinguishing the two processes; for example, in the aforementioned case the region of sensory change corresponding to the L5 root extends almost up to the knee on the anterior surface of the foreleg, whereas it ends a limited distance above the ankle in the case of a peroneal nerve lesion (see the sensory maps on pages 129, 130, and 132). The cumulation of multiple mononeuropathies, termed *mononeuritis multiplex*, may at times be difficult to differentiate from polyneuropathy as discussed further on.

Plexopathies (brachial or lumbosacral) create the most confusing patterns of motor and sensory involvement; only one limb is affected but the motor, sensory, and reflex loss do not conform to a pattern of several adjacent nerve roots or nerves. Knowledge of the innervation of the involved muscles at the level of the plexus usually clarifies the situation.

The apparent complexity of peripheral nerve disease is greatly simplified by recognizing that, of the multitude of diseases, each manifests itself by one or another of above-described topographic and sensory-motor patterns for which reason *the pattern of neuropathy sets limits on the etiologic possibilities*.

In the analysis of a *polyneuropathy* it is of further value to determine whether the process is predominantly motor with less sensory involvement (motor-sensory), or the converse (sensorimotor), or purely sensory, motor, or autonomic. The *time course* of the disease is also extremely informative. An acute onset (i.e., rapid evolution) is nearly always diagnostic of an inflammatory, immunologic, toxic, or vascular etiology. The other extreme, a polyneuropathy evolving slowly over many years, is indicative of a hereditary or, rarely, a metabolic disease. Most of the toxic, nutritional, and systemic diseases of nerve develop subacutely or are of an “early chronic” or subacute nature, appearing over several weeks and months. In addition to the patient’s report of the progress of symptoms, signs such as muscle atrophy signify a process of relatively long-standing, at least several months in duration.

The etiologic diagnosis of polyneuropathy is further aided by attempting to deduce whether the myelin sheath or the axon is primarily involved (i.e., *demyelinative* or *axonal*). Sometimes the neurologic examination alone is sufficient to make this distinction, but greater precision is attained from nerve conduction studies and needle examination of muscles [electromyogram (EMG)]. The latter test also helps to detect primary disorders of muscle (myopathies) and separate them from neurogenic denervation or neuromuscular block. The electrical examinations of nerve and muscle described in Chap. 45, therefore, clarify the type of abnormality in each of the main categories of neuropathic disease and greatly reduce the number of possible diagnoses. In a few instances, the EMG abnormalities are so characteristic as to virtually define a

neuropathy, e.g., chronic demyelinative motor neuropathy with multifocal conduction block. Other useful laboratory procedures are (1) biochemical tests to identify metabolic, nutritional, or toxic states; (2) CSF examination (increase in protein and in cells that indicate radicular or meningeal involvement); (3) nerve and muscle biopsy; (4) measurement of immunoglobulins and antineuronal antibodies that relate to immune-mediated neuropathies; (5) genetic testing for several of the inherited neuropathies; and (6) nerve biopsy.

Once having established that the patient has a disease of the peripheral nerves and having ascertained its clinical and electrophysiologic pattern and time course, one is usually able to determine its nature. This is accomplished most readily by allocating the case in question to one of the categories in Table 46-2, wherein the peripheral nerve diseases are classified syndromically according to their mode of evolution and clinical presentation. Again, by categorizing the neuropathic syndrome in this way by topography and time course and by motor or sensory predominance, only a limited number of diagnoses are possible. These are discussed in the sections that follow.

Our use of the terms *acute*, *subacute*, and *chronic* neuropathy must be explained. By *acute* we mean evolution in terms of days and by *subacute*, weeks. *Chronic* is divided into two groups: one in which the neuropathy has progressed for a period of several months to a few years, and another in which progression is over several years, most of which prove to have a genetic cause. It can be restated that these temporal properties are, with the topographic pattern, the main determinants in the categorization of neuropathy.

Diseases of the peripheral nerves are considered in a more comprehensive fashion in the two-volume monograph *Peripheral Neuropathy*, edited by Dyck and colleagues. Also recommended are more concise monographs on this subject by Schaumburg and associates and by Asbury and Thomas and the atlas on the pathology of peripheral nerve by King.

SYNDROME OF ACUTE MOTOR PARALYSIS WITH VARIABLE DISTURBANCE OF SENSORY AND AUTONOMIC FUNCTION

A number of subtle differences separate the polyneuropathies comprising this category: (1) acute inflammatory demyelinating or axonal polyneuropathy (GBS), (2) vasculitic polyneuropathies, (3) porphyria, (4) certain toxic polyneuropathies, and (5) acute sensory and autonomic polyneuropathies. Of these various acute polyneuropathic diseases, the Guillain-Barré demyelinative syndrome, because of its frequency and gravity, is most demanding of the physician’s attention.

Guillain-Barré Syndrome (Landry-Guillain-Barré-Strohl Syndrome, Acute Inflammatory Polyneuropathy, AIDP)

This acute condition, generally referred to as GBS, is the most common cause of acute or subacute generalized paralysis. (It was at one time rivaled by polio in frequency.) It occurs in all parts of the world and in all seasons, affecting children and adults of all ages and both sexes. A mild respiratory or gastrointestinal infection precedes the neuropathic symptoms by 1 to 3 weeks (sometimes longer) in about 60 percent of cases. Typical is a nondescript upper respiratory infection but almost every known febrile infection and

Table 46-1
Actions of the principal muscles and their nerve root supply^a

ACTION TESTED	ROOTS	NERVES	MUSCLES
<i>CRANIAL</i>			
Closure of eyes, pursing of lips, exposure of teeth	Cranial 7	Facial	Orbicularis oculi Orbicularis oris
Elevation of eyelids, movement of eyes	Cranial 3, 4, 6	Oculomotor, trochlear, abducens	Levator palpebrae, extraocular
Closing and opening of jaw	Cranial 5	Motor trigeminal	Masseters
Protrusion of tongue			Pterygoids
Phonation and swallowing			Lingual
Elevation of shoulders, anteroflexion and turning of head			Palatal, laryngeal, and pharyngeal
<i>BRACHIAL</i>			
Adduction of extended arm	C5, C6	Brachial plexus	Pectoralis major
Fixation of scapula	C5, C6, C7	Brachial plexus	Serratus anterior
Initiation of abduction of arm	C5, C6	Brachial plexus	Supraspinatus
External rotation of flexed arm	C5, C6	Brachial plexus	Infraspinatus
Abduction and elevation of arm up to 90°	C5, C6	Axillary nerve	Deltoid
Flexion of supinated forearm	C5, C6	Musculocutaneous	Biceps, brachialis
Extension of forearm	C6, C7, C8	Radial	Triceps
Extension (radial) of wrist	C6	Extensor carpi radialis longus	Extensor carpi radialis longus
Flexion of semipronated arm	C5, C6	Radial	Brachioradialis
Adduction of flexed arm	C6, C7, C8	Brachial plexus	Latisimus dorsi
Supination of forearm	C6, C7	Posterior interosseous	Supinator
Extension of proximal phalanges	C7, C8	Posterior interosseous	Extensor digitorum
Extension of wrist (ulnar side)	C7, C8	Posterior interosseous	Extensor carpi ulnaris
Extension of proximal phalanx of index finger	C7, C8	Posterior interosseous	Extensor indicis
Abduction of thumb	C7, C8	Posterior interosseous	Abductor pollicis longus and brevis
Extension of thumb	C7, C8	Posterior interosseous	Extensor pollicis longus and brevis
Pronation of forearm	C6, C7	Median nerve	Pronator teres
Radial flexion of wrist	C6, C7	Median nerve	Flexor carpi radialis
Flexion of middle phalanges	C7, C8, T1	Median nerve	Flexor digitorum superficialis
Flexion of proximal phalanx of thumb	C8, T1	Median nerve	Flexor pollicis brevis
Opposition of thumb against fifth finger	C8, T1	Median nerve	Opponens pollicis

	Extension of middle phalanges of index and middle fingers	C8, <i>T1</i>	First, second lumbricals
	Flexion of terminal phalanx of thumb	C8, <i>T1</i>	Flexor pollicis longus
	Flexion of terminal phalanx of second and third fingers	C8, <i>T1</i>	Flexor digitorum profundus
	Flexion of distal phalanges of ring and little fingers	C7, <i>C8</i>	Flexor digitorum profundus
	Adduction and opposition of fifth finger	C8, <i>T1</i>	Hypothenar
	Extension of middle phalanges of ring and little fingers	C8, <i>T1</i>	Third, fourth lumbricals
	Adduction of thumb against second finger	C8, <i>T1</i>	Adductor pollicis
	Flexion of proximal phalanx of thumb	C8, <i>T1</i>	Flexor pollicis brevis
	Abduction and adduction of fingers	C8, <i>T1</i>	Interossei
<i>CRURAL</i>			
	Hip flexion from semiflexed position	L1, <i>L2, L3</i>	Iliopsoas
	Hip flexion from externally rotated position	L2, <i>L3</i>	Sartorius
	Extension of knee	L2, <i>L3, L4</i>	Quadriceps femoris
	Adduction of thigh	L2, <i>L3, L4</i>	Adductor longus, magnus, brevis
	Abduction and int. rotation of thigh	L4, <i>L5, S1</i>	Gluteus medius
	Extension of thigh	L5, <i>S1, S2</i>	Gluteus maximus
	Flexion of knee	L5, <i>S1, S2</i>	Biceps femoris
			Semitendinosus
			Semimembranosus
<i>PERINEAL</i>			
	Hip flexion from semiflexed position	L4, <i>L5</i>	Peroneal (deep)
	Hip flexion from externally rotated position	L5, <i>S1</i>	Peroneal (deep)
	Extension of knee	L5, <i>S1</i>	Peroneal (superficial)
	Adduction of thigh	S1, <i>S2</i>	Peroneal (superficial)
	Abduction and int. rotation of thigh	L4, <i>L5</i>	Tibial
	Extension of thigh	L5, <i>S1, S2</i>	Tibial
	Flexion of knee	S1, <i>S2</i>	Tibial
		S1, <i>S2</i>	Tibial
		S1, <i>S2</i>	Tibial
	Dorsiflexion of foot (medial)	L5, <i>S1, S2</i>	Tibial
	Dorsiflexion of toes (proximal and distal phalanges)	S1, <i>S2</i>	Tibial
	Dorsiflexion of great toe	S1, <i>S2</i>	Tibial
	Eversion of foot	S1, <i>S2</i>	Tibial
	Plantar flexion of foot	L5, <i>S1, S2</i>	Tibial
	Inversion of foot	S1, <i>S2</i>	Tibial
	Flexion of toes (distal phalanges)	S1, <i>S2</i>	Tibial
	Flexion of toes (middle phalanges)	S1, <i>S2</i>	Tibial
	Flexion of great toe (proximal phalanx)	S1, <i>S2</i>	Tibial
	Flexion of great toe (distal phalanx)	L5, <i>S1, S2</i>	Tibial
	Contraction of anal sphincter	S2, <i>S3, S4</i>	Pudendal

^a Predominant root(s) supplying a particular muscle are indicated in bold italic type.

Table 46-2**The principal neuropathic syndromes and their causes**

- I. Syndrome of acute motor paralysis with variable disturbance of sensory and autonomic function
 - A. Guillain-Barré syndrome (GBS; acute inflammatory polyneuropathy; acute autoimmune neuropathy); see also Table 46-3
 - B. Acute axonal form of GBS
 - C. Acute sensory neuropathy and neuronopathy syndrome
 - D. Diphtheritic polyneuropathy
 - E. Porphyric polyneuropathy
 - F. Certain toxic polyneuropathies (thallium, triorthocresyl phosphate)
 - G. Rarely, paraneoplastic
 - H. Acute pandysautonomic neuropathy
 - I. Tick paralysis
 - J. Critical illness polyneuropathy
- II. Syndrome of subacute sensorimotor paralysis
 - A. Symmetrical polyneuropathies
 - 1. Deficiency states: alcoholism (beriberi), pellagra, vitamin B₁₂ deficiency, chronic gastrointestinal disease (see Chap. 41)
 - 2. Poisoning with heavy metals and solvents: arsenic, lead, mercury, thallium, methyl *n*-butyl ketone, *n*-hexane, methyl bromide, ethylene oxide, organophosphates (TOCP etc.), acrylamide (see Chap. 43)
 - 3. Drug toxicity: isoniazid, ethionamide, hydralazine, nitrofurantoin and related nitrofurazones, disulfiram, carbon disulfide, vincristine, cisplatin, paclitaxel, chloramphenicol, phenytoin, pyridoxine, amitriptyline, dapsone, stilbamidine, trichlorethylene, thalidomide, clioquinol, amiodarone, adulterated agents such as L-tryptophan
 - 4. Uremic polyneuropathy (see Chap. 40)
 - 5. Subacute inflammatory polyneuropathy
 - B. Asymmetrical neuropathies (mononeuropathy multiplex)
 - 1. Diabetes
 - 2. Polyarteritis nodosa and other inflammatory angiopathic neuropathies (Churg-Strauss, hypereosinophilic, rheumatoid, lupus, Wegener granulomatosis, isolated peripheral nervous system vasculitis); see also Table 46-3
 - 3. Mixed cryoglobulinemia
 - 4. Sjögren-sicca syndrome
 - 5. Sarcoidosis
 - 6. Ischemic neuropathy with peripheral vascular disease
 - 7. Lyme disease
 - C. Unusual sensory neuropathies
 - 1. Wartenberg migrant sensory neuropathy
 - 2. Sensory perineuritis
 - D. Meningeal based nerve root disease (polyradiculopathy)
 - 1. Neoplastic infiltration
 - 2. Granulomatous and infectious infiltration: Lyme, sarcoid
 - 3. Spinal diseases: osteoarthritic spondylitis
 - 4. Idiopathic polyradiculopathy
- III. Syndrome of chronic sensorimotor polyneuropathy
 - A. Less chronic acquired forms
 - 1. Paraneoplastic: carcinoma, lymphoma, myeloma, and other malignancies
 - 2. Chronic inflammatory demyelinating polyneuropathy (CIDP)
 - 3. Paraproteinemias
 - 4. Uremia (occasionally subacute)
 - 5. Beriberi (usually subacute)
 - 6. Diabetes
 - 7. Connective tissue diseases
 - 8. Amyloidosis
 - 9. Leprosy
 - 10. Hypothyroidism
 - 11. Benign sensory form in the elderly
 - B. Syndrome of more chronic polyneuropathy, genetically determined forms (see Table 46-6)
 - 1. Inherited polyneuropathies of predominantly sensory type
 - a. Dominant mutilating sensory neuropathy in adults
 - b. Recessive mutilating sensory neuropathy of childhood
 - c. Congenital insensitivity to pain
 - d. Other inherited sensory neuropathies, including those associated with spinocerebellar degenerations, Riley-Day syndrome, and the universal anesthesia syndrome

Table 46-2 (Continued)**The principal neuropathic syndromes and their causes**

- C. Inherited polyneuropathies of mixed sensorimotor types
 - 1. Idiopathic group
 - a. Peroneal muscular atrophy [Charcot-Marie-Tooth; CMT types I (demyelinating) and II (axonal) and CMTX]
 - b. Hypertrophic polyneuropathy of Dejerine-Sottas, adult and childhood forms (CMT3)
 - c. Roussy-Lévy polyneuropathy (CMT3)
 - d. Polyneuropathy with optic atrophy, spastic paraparesis, spinocerebellar degeneration, mental retardation, and dementia
 - e. Hereditary liability to pressure palsy (HNPP)
 - 2. Inherited polyneuropathies with a recognized metabolic disorder (see also Chap. 37)
 - a. Refsum disease
 - b. Metachromatic leukodystrophy
 - c. Globoid-body leukodystrophy (Krabbe disease)
 - d. Adrenoleukodystrophy
 - e. Amyloid polyneuropathy
 - f. Porphyric polyneuropathy
 - g. Anderson-Fabry disease
 - h. Abetalipoproteinemia and Tangier disease
- IV. Neuropathy associated with mitochondrial diseases (see Chap. 37)
- V. Syndrome of recurrent or relapsing polyneuropathy
 - A. Guillain-Barré syndrome
 - B. Porphyria
 - C. Chronic inflammatory demyelinating polyneuropathy
 - D. Certain forms of mononeuritis multiplex
 - E. Beriberi or intoxications
 - F. Refsum disease, Tangier disease
- VI. Syndrome of mononeuropathy or plexopathy
 - A. Brachial plexus neuropathies
 - B. Brachial mononeuropathies
 - C. Causalgia
 - D. Lumbosacral plexopathies
 - E. Crural mononeuropathies
 - F. Migrant sensory neuropathy
 - G. Entrapment neuropathies

immunization has at one time or another been reported to precede GBS (some perhaps coincidentally). In recent years, it has come to be appreciated from serologic studies that the enteric organism *Campylobacter jejuni* is the most frequent identifiable antecedent infection but it accounts for only a relatively small proportion of cases. Other antecedent events or associated illnesses include viral exanthems and other viral illnesses [cytomegalovirus (CMV), Epstein-Barr virus (EBV), HIV], bacterial infections other than *Campylobacter* (*Mycoplasma pneumoniae*, Lyme disease), exposure to thrombolytic agents, and lymphoma (particularly Hodgkin disease). The administration of outmoded antirabies vaccines and the A/New Jersey (swine) influenza vaccine, given in late 1976, was associated with a slight increase in the incidence of GBS and at least one subsequent influenza vaccination program has been associated with a marginal increase in cases. Trauma and surgical operations may precede the neuropathy, but a causal association to them remains uncertain.

Historical Background The earliest description of an afebrile generalized paralysis is probably that of Wardrop and Ollivier, in 1834. Other important landmarks are Landry's report (1859) of an acute, ascending, predominantly motor paralysis with respiratory failure, leading to death; Osler's (1892) description of "febrile polyneuritis"; the account by Guillain, Barré, and Strohl (1916) of

a benign polyneuritis with albuminocytologic dissociation in the CSF (increase in protein without cells); and the elaboration of the clinical picture by many British and American physicians. The first comprehensive account of the pathology of GBS was that of Haymaker and Kernohan (1949), who stressed that edema of the nerve roots was an important change in the early stages of the disease. Subsequently, Asbury, Arnason, and Adams (1969) established that the essential lesion, from the beginning of the disease, is a perivascular mononuclear inflammatory infiltration of the roots and nerves. More recently it has been found that complement deposition on the myelin surface may be the earliest immunologic event. For details of the historical and other aspects of this disease, see the monographs by Ropper and colleagues and by Hughes.

Incidence The reported incidence rate has varied from 0.4 to 1.7 cases per 100,000 persons per year; the latter figure is probably the more accurate. It is generally nonseasonal and nonepidemic but isolated seasonal outbreaks have been recorded in rural China following exposure of children to *C. jejuni* through chicken feces deposited in rice paddies. Year after year, between 15 and 25 patients are admitted to each of our institutions. Females are slightly more susceptible. The age range of our consecutive patients has been 8 months to 81 years, with attack rates highest in persons 50 to 74 years of age. Cases are known in infants and in the very aged.

Symptomatology The typical case of GBS is readily identified. Paresthesias and slight numbness in the toes and fingers are the earliest symptoms; only infrequently are they absent throughout the illness. The major clinical manifestation is weakness that evolves more or less symmetrically over a period of several days to a week or two, or somewhat longer. The proximal as well as distal muscles of the limbs are involved, usually the lower extremities before the upper (thus the older term *Landry's ascending paralysis*); the trunk, intercostal, neck, and cranial muscles may be affected later. The weakness progresses in about 5 percent of patients to total motor paralysis with respiratory failure within a few days. In severe cases the ocular motor nerves are paralyzed and even the pupils may be unreactive.

More than half of the patients complain of pain and an aching discomfort in the muscles, mainly those of the hips, thighs, and back; these symptoms are frequently mistaken for lumbar disc disease, back strain, and various orthopedic diseases. A few describe burning in the fingers and toes and if this appears as an early symptom, it may become a persistent management problem. Sensory loss occurs to a variable degree during the first days and may be barely detectable. By the end of a week, vibration and joint position sense in the toes and fingers are usually reduced; when such loss is present, deep sensibility (touch-pressure-vibration) tends to be more affected than superficial (pain-temperature).

Reduced and then absent tendon reflexes are consistent findings. Rarely, only the ankle reflexes are lost during the first week of illness. At an early stage, the arm muscles may be less weak than the leg muscles, and in a few cases, they are spared almost entirely. Facial diplegia occurs in more than half of cases, sometimes bilaterally at the same time, or sequentially over days. Other cranial nerve palsies, if they occur, usually come later, after the arms and face are affected; infrequently they are the initial signs in a variant pattern of disease as described below.

Disturbances of autonomic function (sinus tachycardia and less often bradycardia, facial flushing, fluctuating hypertension and hypotension, loss of sweating, or episodic profuse diaphoresis) are common in minor form, and only infrequently do these abnormalities become pronounced or persist for more than a week. Urinary retention occurs in about 15 percent of patients soon after the onset of weakness, but catheterization is seldom required for more than a few days. There are in addition numerous medical complications secondary to immobilization and respiratory failure, as discussed further on, under "Treatment." At the onset of illness, the temperature is normal, and lymphadenopathy and splenomegaly, if they occur, are related to a preceding viral infection.

Variants of the Guillain-Barré Syndrome (See Table 46-3) Portions of the clinical picture frequently appear in isolated or abortive form and cause diagnostic confusion. Whereas in most patients the paralysis ascends from legs to trunk, arms, and cranial muscles and reaches a peak of severity within 10 to 14 days, occasionally the *pharyngeal-cervical-brachial* muscles are affected first or constitute the entire illness, creating difficulty in swallowing as well as neck and proximal arm weakness (Ropper, 1986). Ptosis, sometimes with ophthalmoplegia, may be added. This pattern may persist without the development of limb weakness. The differential diagnosis then includes myasthenia gravis, diphtheria, and botulism and a lesion affecting the central portion of the cervical spinal cord and lower brainstem.

A syndrome comprising virtual or *complete ophthalmoplegia with ataxia* and areflexia that probably represents a variant of GBS was described by Fisher (and is called *Fisher syndrome*.) A purely

Table 46-3
Variants of Guillain-Barré syndrome

Regional

Fisher syndrome of ophthalmoplegia, ataxia, and areflexia
Cervico-brachial-pharyngeal, often with ptosis
Oculopharyngeal weakness
Predominant paraparesis
Bilateral facial or abducens weakness with distal paresthesias
Ophthalmoplegia with GQ₁b autoantibodies

Functional

Generalized ataxia without dysarthria or nystagmus
Pure sensory
Pure motor
Pandysautonomia
Axonal

ophthalmoplegic form also exists; it may be coupled with the pharyngeal-cervical-brachial pattern mentioned earlier. The ophthalmoplegia, whether occurring alone or with weakness or ataxia of other parts, is almost uniformly associated with a specific antineuronal antibody, anti-GQ₁b. The ophthalmoplegic pattern raises the possibility of myasthenia gravis, botulism, diphtheria, tick paralysis, and basilar artery occlusion. Bilateral but asymmetrical *facial and abducens weakness*, coupled with distal paresthesias or with proximal leg weakness, are other fairly common variants in our experience (Ropper, 1994). The tendon reflexes may be absent initially only at the ankles or at the knees. Lyme disease and sarcoidosis are then considerations in diagnosis.

Paraparetic, ataxic, and purely motor or purely sensory forms of the illness have also been observed. Less difficulty attends these diagnoses if paresthesias in the acral extremities, progressive reduction or loss of reflexes, and relative symmetry of weakness appear after several days of signs. The laboratory tests that affirm the diagnosis of typical GBS give similar but generally milder abnormalities if they are carefully sought in all these variant forms.

There has been a recent tendency to separate a group of cases with presumed diffuse axonal damage on the basis of an abrupt and explosive onset, severe paralysis, minor sensory features, and the electrophysiologic finding of inexcitability of nerves. This *axonal type of GBS* represents 5 percent (or fewer) of cases but its identification has some value in that a poor response to treatment and very protracted recovery are to be expected in most cases. This variant is described later.

In a few patients the weakness continues to evolve for 3 to 4 weeks or even longer. From this group a chronic form of demyelinative neuropathy (chronic inflammatory demyelinating polyneuropathy, or CIDP) often emerges and an intermediate group that progress for 4 to 8 weeks and then improve can be identified (see further on).

Acute Axonal Form of Guillain-Barré Syndrome This subject has been alluded to earlier. Feasby and colleagues drew attention to an acute areflexic polyneuropathy clinically similar to GBS but characterized pathologically by widespread and severe axonal degeneration. In their initial report they described five patients, all with a rapid evolution of polyneuropathy and very slow and poor recovery. Unlike the common form of GBS, muscle atrophy in these patients became apparent relatively early in the disease (within weeks). The defining EMG features were the presence of

numerous electrically inexcitable motor nerves and signs of extensive denervation. Others, however, have questioned the specificity of this finding since the inability to excite motor nerves may also signify a distal demyelinating block, from which complete recovery is possible (Triggs et al). Nevertheless, most cases of very abrupt and severe denervating paralysis, particularly if postinfectious, are due to this form of GBS (Ropper 1986).

Postmortem examinations in these cases have disclosed severe axonal degeneration in nerves and roots, with minimal inflammatory changes and little demyelination, even early in the disease. Based on prominent deposits of complement and the presence of macrophages in the periaxonal space, a humoral antibody directed against some component of the axolemma has been postulated by Griffin and associates. Visser and colleagues reported similar findings in a series of acute motor polyneuropathies from Holland. The outbreaks of motor neuropathy that occur seasonally in rural China have many of the same characteristics. These cases appear to be triggered largely by *C. jejuni* infections. Some but not all sporadic instances of acute axonal GBS have been preceded by the same infection. It is noteworthy, however, that infection with the same bacteria can induce a typical demyelinating form of GBS. A proportion of cases, perhaps one quarter, are associated with circulating antibodies to the GM₁ ganglioside of peripheral nerve, and some of these in turn reflect recently preceding infection with *C. jejuni*. The acronyms AMAN (acute motor) and AMSAN (acute motor-sensory axonal neuropathy) are equivalents to axonal GBS.

Another variant of this illness of which we have seen several instances has been an acute multifocal neuropathy with electrophysiologic motor conduction block that leaves the reflexes unaltered and is related to anti-GM₁ antibody (Capasso et al). A chronic form of this illness, termed *multifocal motor neuropathy*, is more common and better understood (see further on).

Most experience with the generalized axonal form of GBS indicates that recovery is prolonged and complete resolution of weakness is uncommon. Intravenous administration of immune globulin (IVIG) and plasma exchange, the usual treatments for GBS as discussed later, have had slight beneficial effect but their use is not associated with the degree of improvement seen in demyelinating cases.

Whether this acute axonal polyneuropathy is a distinct entity or a variant of GBS cannot be answered with certainty. This may prove to be a semantic issue, depending on one's definition of the clinical, immunologic, and pathologic boundaries of GBS. Certainly, there is a degree of axonal damage in all severe cases of GBS, even when the predominant process is demyelinating. Currently we prefer to distinguish these cases from typical GBS if only to lower expectations for the response to immune treatments and for the ultimate clinical recovery. It should be reemphasized that the presence of electrically inexcitable nerves alone may be due to conduction block and give a misleading impression of axonal damage; the prognosis for cases with conduction block may be quite good. The differential diagnosis includes critical illness polyneuropathy and the rarer entities of porphyric neuropathy and tick paralysis.

Laboratory Findings The most important laboratory aids are the electrodiagnostic studies and the CSF examination. The CSF is under normal pressure and is acellular or contains only a few lymphocytes in all but 10 percent of patients; in the latter group, 10 to 50 cells (rarely more) per cubic millimeter, predominantly lymphocytes, may be found. The number of cells then decreases rapidly in a matter of 2 to 3 days; persistent pleocytosis suggests an alter-

native or additional diagnosis such as neoplastic meningitis, HIV, or Lyme infection. We have been unable to relate pleocytosis in the spinal fluid with any of the clinical features of GBS or to the severity of illness. Usually, the protein content is normal during the first few days of symptoms, but then it begins to rise, reaching a peak in 4 to 6 weeks and persisting at a variably elevated level for many weeks. The increase in CSF protein is probably a reflection of the widespread inflammatory disease of the nerve roots, but high values have had no clinical or prognostic significance in our material, perhaps apart from a few exceptional cases of pseudotumor cerebri (Ropper and Marmarou). In a few patients (fewer than 10 percent) the CSF protein values remain normal throughout the illness. It is worth stating that from our experience, among patients with Fisher syndrome and other restricted or axonal forms of GBS, there is a higher proportion with normal or only slightly elevated protein values.

Abnormalities of nerve conduction are early and dependable diagnostic indicators of GBS. In cases with a typical clinical and EMG presentation one can probably dispense with the CSF analysis as a confirmatory test. The most frequent early electrodiagnostic findings are a reduction in the amplitude of muscle action potentials, slowed conduction velocity, and conduction block in motor nerves singly or in combination (see Chap. 45). Prolonged distal latencies (reflecting distal conduction block) and prolonged or absent F-responses (indicating involvement of proximal parts of nerves and roots) are other important diagnostic findings, all reflecting focal demyelination. The H-reflex is almost always very delayed, or more often absent, but this does little more than confirm the loss of ankle reflexes. Although a limited electrodiagnostic examination may be normal early in the illness, a more thorough study, which includes measurement of late responses, almost invariably shows disordered conduction in an affected limb within days of the first symptom. Early on, features that indicate widespread axonal damage (the "axonal GBS" discussed earlier) portend a poor and protracted recovery in both young and old patients.

The clinical, CSF, and electrodiagnostic criteria for GBS have been reassessed by Asbury and Cornblath and are discussed in detail in the monograph by Ropper et al.

Most patients with acute GBS have shown gadolinium enhancement of the cauda equina roots on magnetic resonance imaging (MRI; 21 of 24 patients in our study), and this may serve as a useful test in complicated cases (Gorson, Ropper, et al).

Abnormalities of liver function occur in fewer than 10 percent of patients, probably reflecting a recent or ongoing viral hepatitis, usually due to CMV or EBV infections (rarely one of the hepatitis viruses). T-wave and other electrocardiographic changes of minor degree are reported frequently but are evanescent. The sedimentation rate is normal unless there is an additional process of infectious, neoplastic, or autoimmune nature, any of which can occasionally coexist with GBS. Hyponatremia occurs in a proportion of cases after the first week, especially in ventilated patients. This is usually attributable to the syndrome of inappropriate antidiuretic hormone secretion (SIADH), but a natriuretic type also occurs, from an excess of atrial natriuretic factor. Transient diabetes insipidus is a rare and unexplained complication. We are unable to comment on a high rate of proteinuria and glomerulonephritis reported by several groups in cases of GBS, but have found it only infrequently.

Pathologic Findings These have had a relatively consistent pattern and form. Even when the disease is fatal within a few days,

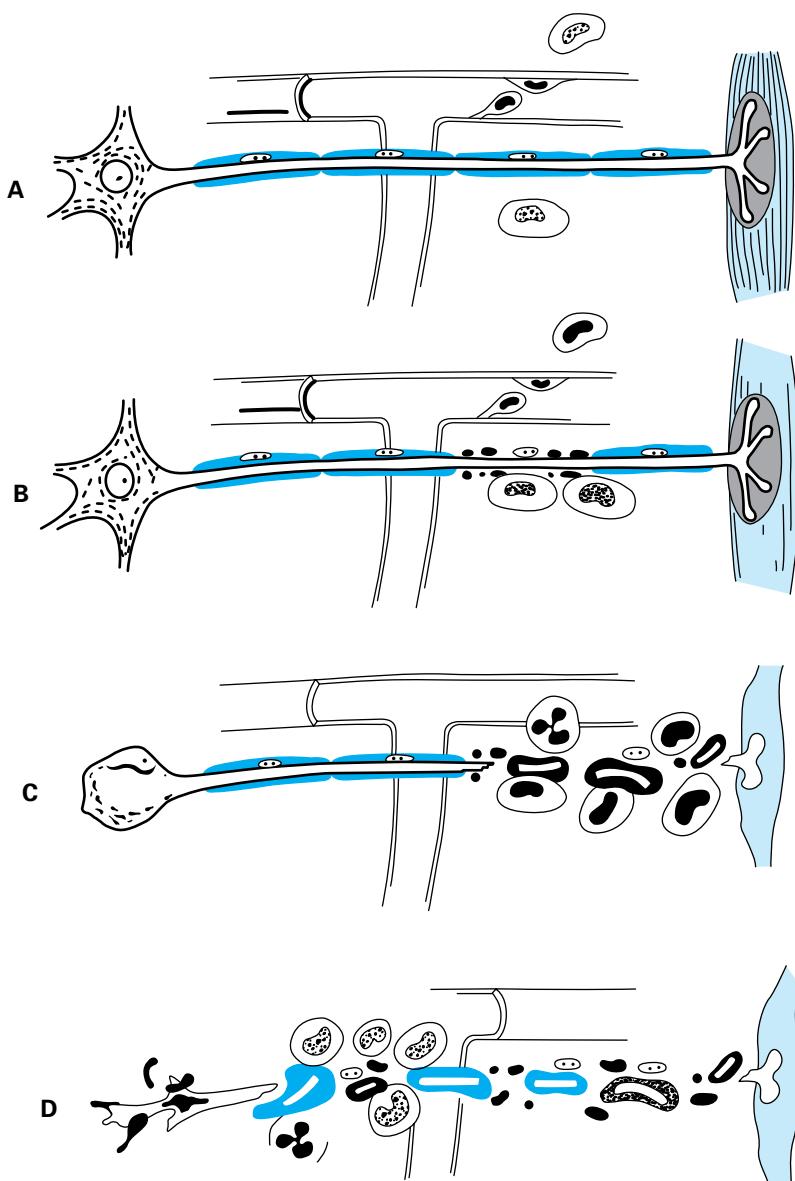

Figure 46-3. Diagram of probable cellular events in acute inflammatory polyneuropathy (Guillain-Barré syndrome). *A*, Lymphocytes attach to the walls of endoneurial vessels and migrate through the vessel wall, enlarging and transforming as they do so. At this stage no nerve damage has occurred. *B*, More lymphocytes have migrated into the surrounding tissue. The first effect on the nerve is breakdown of myelin, the axon being spared (segmental demyelination). This change appears to be mediated by the mononuclear exudate, but the mechanism is uncertain. *C*, The lesion is more intense, polymorphonuclear leukocytes being present as well as lymphocytes. There is interruption of the axon in addition to myelin sheath damage; as a result, the muscle undergoes denervation atrophy and the nerve cell body shows central chromatolysis. If the axonal damage is distal, the nerve cell body will survive, and regeneration and clinical recovery is likely. If, as in *D*, axonal interruption has occurred proximally because of a particularly intense root or proximal nerve lesion, the nerve cell body may die and undergo dissolution. In this situation, there is no regeneration, only the possibility of collateral reinnervation of muscle from surviving motor fibers. (From Asbury et al, 1969, by permission.)

virtually all cases show perivascular (mainly perivenous) lymphocytic infiltrates. Later, the characteristic inflammatory cell infiltrates and perivenous demyelination are combined with segmental demyelination and a variable degree of Wallerian degeneration. The cellular infiltrates are scattered throughout the cranial nerves, ven-

tral and dorsal roots, and dorsal root ganglia and along the entire length of the peripheral nerves. Sparse focal infiltrates of inflammatory cells (lymphocytes and other mononuclear cells) may also be found in lymph nodes, liver, spleen, heart, and other organs. Swelling of nerve roots at the site of their dural exit has been emphasized by some authors and theorized to cause root damage.

Variations of this pattern of peripheral nerve damage have been observed, each perhaps representing a different immunopathology. Rarely, in a clinically typical case, there may be widespread demyelinative changes and only a paucity of perivascular lymphocytes. In patients whose electrophysiologic tests display severe axonal damage early in the illness as discussed later, the pathologic findings corroborate the predominantly axonal nature of the disease with secondary myelin damage and little inflammatory response. An occasional case has shown an inflammatory process with primary axonal damage rather than demyelination (Honavar et al).

Pathogenesis and Etiology Most of the evidence supports a cell-mediated immunologic reaction directed at peripheral nerve. Waksman and Adams demonstrated that experimentally induced peripheral nerve disease (experimental allergic neuritis, or EAN), clinically and pathologically indistinguishable from GBS, develops in animals 2 weeks after immunization with peripheral nerve homogenates. Brostoff and colleagues suggested that the antigen in this reaction is a basic protein, designated P₂, found only in peripheral nerve myelin. Subsequent investigations by these authors indicated that the neuritogenic factor might be a specific peptide in the P₂ protein. However, it has become evident that there is no dominant antigen-antibody reaction in GBS and that any number of myelin and axonal elements may be involved in inciting the immune reaction. The pathologic steps in this proposed reaction are diagrammatically illustrated in Fig. 46-3. Hartung and colleagues have found high levels of soluble interleukin (IL)-2 receptors, that is shed from activated T cells, and IL-2 itself in the serum of patients with acute GBS, reflecting activation of these cells. As noted below, complement also seems to be a necessary factor in the initial attack on myelin.

Although the transmission of EAN by T cells sensitized to myelin is strong evidence of their role in GBS, antimyelin antibodies are probably involved in the initial part in the disease. The serum from patients with GBS causes damage to myelin in tissue cultures and induces a characteristic ("vesicular") form of myelin destruction. Subepineurial injection of serum from GBS patients into the sciatic nerve of rats leads to local demyelination and electrical conduction block. The studies by Koski and associates of complement-dependent myelin damage by IgM antimyelin antibodies in GBS provided evidence that antimyelin antibodies are able to initiate myelin destruction even though T cells and that macrophages are the ultimate

effectors of the damage. Indeed, the very earliest change that could be detected by Hafer-Macko and colleagues was the deposition of complement on the inner layer of myelin.

A number of autoantibodies directed at components of nerve ganglioside are detected inconsistently in patients with GBS, the most important being anti-GQ_{1b}, which is found in almost all patients with ophthalmoplegia. Approximately one-third of patients have anti-GM₁ antibodies early in their course, corresponding in most instances to a predominantly motor presentation and to axonal damage, the highest titers usually being associated with cases that follow *Campylobacter* infections. Antibodies directed against GD_{1a} or GT_{1b} have been associated in some cases with the pharyngeal-brachial-cervical variant. It would therefore seem that casting GBS exclusively as a humoral or as a cellular immune process is an oversimplification.

An unanswered question is how the immune reaction is initiated in humans. All attempts to isolate a virus or microbial agent from nerves or to demonstrate one by electron microscopy have failed, and it is more likely that a variety of agents—viral, bacterial (particularly *C. jejuni*), certain vaccines, and perhaps neural injury itself—are all capable, in susceptible individuals, of precipitating an immune response against components of autologous peripheral myelin. The occurrence of GBS in patients with acquired immune deficiency syndrome (AIDS) or with EBV or CMV infections simply indicates that these agents, too, induce such an autoimmune response without implicating a direct viral infection of nerve. The observation that only one of many individuals who are infected with a particular pathogen go on to develop GBS suggests that host factors are significant (there is, however, little consistency among HLA types in GBS patients). Whether the aforementioned antibodies against various gangliosides of peripheral nerve are pathogenically active is also uncertain.

Several animal diseases—namely coonhound paralysis of dogs, Marek's disease of chickens (a viral neuritis), and cauda equina neuritis of horses—all resemble GBS superficially but do not share its main clinical or pathologic features.

Differential Diagnosis GBS is not only the most frequent type of acute generalized polyneuropathy seen in a general hospital but also the most rapidly evolving and potentially fatal form. Any polyneuropathy that brings the patient to the brink of death or to respiratory failure within a few days will usually be of this variety. However, several other neurologic conditions must be considered. The immediate problem is to differentiate GBS from acute spinal cord disease marked by sensorimotor paralysis below a defined level and a marked sphincteric disturbance. There may be particular difficulty in the case of an acute lesion of the cord in which tendon reflexes are initially lost (spinal shock), or with necrotizing myelopathy, where a permanent loss of tendon reflexes follows extensive destruction of spinal gray matter (pages 781 and 1064). Also confusing is early and transient urinary retention in a proportion of patients with GBS. Several rules of thumb are useful in distinguishing the disease from a cervical myopathy: in GBS, the facial and respiratory muscles are usually involved if there is generalized paralysis; the fingertips should be paresthetic once sensory symptoms have ascended to the level of the midcalves; marked sensory loss proximal to the hands or feet or only of the trunk is unusual early in the illness; and tendon reflexes are almost invariably lost in limbs that are too weak to resist gravity.

A predominantly motor paralysis is the major characteristic of GBS, for which reason the differential diagnosis also includes po-

liomyelitis, now also caused by the West Nile virus and by enteroviruses other than the polio agent. In all these infectious cases the illness is marked by fever, meningoencephalitic symptoms, early pleocytosis in the spinal fluid, and purely motor and usually asymmetrical areflexic paralysis.

We have been several times misled by cases of carcinomatous meningitis that caused a subacute and fairly symmetric but mainly distal weakness and appeared similar to GBS. An irregular distribution of weakness between proximal and distal parts, the absence of facial weakness and the appearance of symptoms in one limb after another are always suggestive of this type of neoplastic infiltration of nerve roots. Sciatica may occur with either process but radicular pain in the arms is unusual in GBS. Examination of the spinal fluid usually settles the matter.

Another distinctive problem arises in distinguishing generalized GBS with ophthalmoparesis or the Fisher variant from basilar artery thrombosis. The presence of reactive pupils, areflexia, and F-wave abnormalities in GBS, and of lively reflexes and Babinski signs in the case of brainstem infarction, dependably separates the disorders. Ptosis and oculomotor weakness, features of GBS in some severe generalized cases and in Fisher syndrome, may cause confusion with acute myasthenia gravis, but in the latter disease there are no sensory symptoms and the tendon reflexes are unimpaired. The mandibular muscles remain relatively strong in GBS, whereas the exercised jaw hangs open in myasthenia. Botulism may also simulate GBS, but pupillary reflexes are lost early in botulism (pupillary paralysis occurs mainly in advanced cases of GBS), and there is usually a bradycardia, which is unusual for GBS. Tick paralysis, a disease of children in the United States but affecting both children and adults in Australia, may be nearly impossible to distinguish from GBS unless one finds the tick (page 1034). In addition to an ascending paralysis, both also sometimes cause ataxia and may paralyze eye movements, but sensory loss is not usually a feature of tick paralysis and the CSF protein remains normal. Ingestion of shellfish or reef fish contaminated with saxitoxin, ciguatoxin, or tetrodotoxin (ciguatera, neurotoxic shellfish poisoning) is another cause of acute facial-brachial paresthesias, weakness, tachypnea, and iridoplegia lasting a few days—symptoms that resemble the cranial nerve variants of GBS.

A number of neuromuscular disorders in critically ill patients with systemic medical conditions may be difficult to distinguish from GBS. These include a polyneuropathy of critical illness (see further on); an accelerated neuropathy of renal failure that is seen mainly in diabetic patients receiving peritoneal dialysis (both discussed further on); acute hypophosphatemia induced by hyperalimentation; polymyopathy produced by the administration of high-dose corticosteroids (page 1237); and the prolonged effects of neuromuscular blocking drugs, resulting in the accumulation of their metabolites in patients under conditions of renal failure and acidosis. Episodes of painful paralytic porphyria bear a superficial resemblance to GBS.

Treatment

General medical aspects In severe cases, respiratory assistance and careful nursing are paramount, since the disease remits naturally and the outlook for recovery is favorable in the majority. About one quarter of our patients in the recent era of treatment have required mechanical ventilation. Since a patient's condition may deteriorate unpredictably and rapidly in the first days of illness, virtually all but the mildest cases should be admitted to the

hospital for observation of respiratory, autonomic, and motor function. The comments that follow are applicable to most other forms of acute and subacute neuromuscular respiratory failure such as myasthenia gravis.

Measurement of maximal inspiratory force and expiratory vital capacity suffices for the bedside estimation of the adequacy of diaphragmatic strength and respiratory function. The trend of these measurements are a guide to the likelihood of respiratory failure. As in poliomyelitis, the strength of the neck muscles and trapezii, which share the same segmental innervation as the diaphragm, tends to parallel diaphragmatic strength. A rough estimate of breathing capacity may be obtained by having the patient count quickly on one deep breath. The ability to reach 20 generally corresponds to a vital capacity of greater than 1.5 L. If a downward trend in these measurements is recognized and the vital capacity diminishes to below about 10 mL/kg, endotracheal intubation and mechanical ventilation are considered. It should be noted that a fairly severe degree of impaired ventilation may occur before the first sign of dyspnea appears and even before there is any elevation of arterial carbon dioxide content. Incipient respiratory failure generally coincides with tachypnea and a slight decrease in arterial oxygen tension (PO_2 less than 85 mmHg) reflecting pulmonary atelectasis. If respiratory failure arises gradually, over days or longer, there is slight tachycardia, diaphoresis, restlessness, and tachypnea. Attempts to forestall the use of a positive-pressure ventilator by negative-pressure cuirass-type devices have been unsatisfactory in our experience. Patients with oropharyngeal weakness require intubation even earlier in order to prevent aspiration, but mechanical ventilation is not always necessary at the same time. These treatments are so demanding that the patient should be admitted to an intensive care unit staffed by personnel skilled in maintaining ventilation and airway patency.

The other major aspects of the treatment in severely affected patients involve the management of *cardiovascular autonomic instability* and the prevention of the many *general medical problems* that attend any immobilizing critical illness. Hypotension from *dysautonomia*, which occurs in about 10 percent of severely affected patients, is treated by intravenous volume infusion and by the use of vasopressor agents for brief periods. Extremes of hypertension are managed by short-acting and titratable antihypertensive medications, such as intravenous labetalol. The choice and dosing of an antihypertensive drug is important, since these episodes may be rapidly succeeded by precipitous declines in pressure. It is not clear if severe autonomic changes can be anticipated but various provocative maneuvers such as ocular pressure to elicit heart block are used in some units; we generally omit them.

Prevention of electrolyte imbalance, gastrointestinal hemorrhage, and particularly pulmonary embolism in patients who are bedbound (by the use of subcutaneous heparin or pneumatic compression boots), all require careful attention. Adynamic ileus is a problem in some cases, manifest first by abdominal pain coincident with nasogastric tube feeding and by bloating; it may lead to bowel perforation even if feeding is discontinued. As mentioned, a number of patients become hyponatremic, usually from SIADH but occasionally from a natriuresis, and the drop in sodium may be produced or exaggerated by positive-pressure mechanical ventilation. The distinction between the two conditions that cause hyponatremia determines the course of treatment: fluid restriction in the case of SIADH or salt replacement in the case of sodium loss.

Many patients have bizarre waking dreams or hallucinations

after weeks of immobilization. A mode of communication should be worked out by the nursing staff, preferably before the patient is intubated.

Failure to effectively clear the tracheobronchial airways and the need for prolonged mechanical ventilation are the usual indications for tracheostomy. In most cases this procedure can be postponed until the end of the third week of intubation. However, patients who become rapidly quadriplegic and ventilator-dependent may require tracheostomy earlier. Once tracheostomy is performed, careful tracheal toilet and treatment of pulmonary and urinary tract infections by the use of appropriate antibiotics are required. Prophylactic antibiotic treatment is not recommended. With tracheostomy and intensive care, the mortality from the disease can be reduced to about 3 percent (Ropper and Kehne) (see further on under "Prognosis").

The decisions to wean and then discontinue respiratory aid and to remove the endotracheal or tracheostomy tube are based on the degree and timing of recovery of respiratory function. The weaning process generally begins when the vital capacity reaches approximately 10 mL/kg and comfortable breathing can be sustained for a few minutes. The relative merits of the numerous methods of delivering positive pressure volume-cycled ventilation and its gradual withdrawal are too complex to be covered here but the reader is referred to the monograph, *Neurological and Neurosurgical Intensive Care*, by Ropper and colleagues.

Physical therapy (passive movement and positioning of limbs to prevent pressure palsies and, later, mild resistance exercises) should begin once they can be comfortably undertaken.

Plasma Exchange and Immune Globulin Specific treatment of the presumed immune disorder that underlies GBS includes plasma exchange (PE) and intravenous immunoglobulin (IVIG). Our practice has been to closely observe patients who are still able to walk for several days. If the patient has become unable to walk unaided or if he shows a significant reduction in vital capacity or signs of severe oropharyngeal weakness, plasma exchange or IVIG (not both) is instituted promptly. This typically occurs at the fifth to tenth day after the appearance of the first symptoms but may be as early as one day or as late as 3 weeks.

Three large randomized trials comprising more than 500 patients have established the usefulness of *plasma exchange* administered during the evolving phase of GBS. In patients who are treated within 2 weeks of onset, there is an approximate halving in the period of hospitalization, in the duration of mechanical ventilation, and in the time required to achieve independent ambulation. However, in the largest trial, if the first plasma exchange was delayed for 2 weeks or longer after the onset of the disease, the procedure was of little value. Nonetheless, if a patient continues to progress in the third or fourth week of illness, it is probably still appropriate to institute the exchanges. The most important predictors of responsiveness to plasma exchange treatment are the patient's age (responders are younger) and the preservation of motor compound muscle action potential amplitudes prior to instituting treatment (McKhann et al). One study has found that the overall condition of patients was better at 6 and 12 months after treatment as compared to untreated patients; other studies have been equivocal on this point.

The advised regimen of plasma exchange removes a total of 200 to 250 mL/kg of plasma in four to six treatments on alternate days, or over a shorter period if there is no coagulopathy. The replacement fluid is saline combined with 5% albumin. The need

for large-bore venous access usually requires the insertion of a double-lumen subclavian or internal jugular catheters and this may be the main source of complications (pneumothorax, infection, hemorrhage). In some patients, treatment can be instituted, and sometimes the entire course completed, through the antecubital veins. During and after the procedure, hypotension, hypoprothrombinemia with bleeding (e.g., epistaxis), and cardiac arrhythmias may occur. Some units prefer to measure the level of fibrinogen, which is greatly reduced by exchanges before the next exchange so as a gauge to the risk of potential hemorrhage. Reactions to the citrate that is used to prevent blood from clotting in the plasma exchange machine are common but can be obviated by the cautious addition of calcium to the intravenous return line. Hepatitis and AIDS are not risks if plasma is replaced with albumin and saline rather than with pooled plasma.

As effective as plasma exchange is, IVIG (0.4 g/kg per day for 5 consecutive days) is both easier to administer and probably safer because there is no need for large intravenous access. The results of the original trial conducted by van der Meché and colleagues have been corroborated in an international study led by Hughes, in which we participated. The latter study compared plasma exchange to IVIG and also evaluated their serial use. There was a tenuous trend toward a better outcome in patients who received plasma exchange, and results were perhaps slightly better in a group who were treated with plasma exchange followed immediately by 5 days of immune globulin infusions; in both instances, however, the differences failed to attain statistical significance and the three modes of treatment were said to be equivalent. Renal failure, proteinuria, and aseptic meningitis manifested most often by severe headache are rare complications of IVIG. The only serious reactions we have encountered were in a very few patients who congenitally lacked IgA and in whom pooled gamma globulin caused anaphylaxis. We have also encountered a few cases of marked inflammatory local venous thrombosis in the region of the infusion site.

After the use of either plasma exchange or IVIG, 5 to 10 percent of patients who initially improve will have a relapse that becomes apparent several days or up to 3 weeks after completion of treatment. If there was a good response to the initial therapy, the same treatment may be repeated or the alternative treatment may be tried; either can be successful. A few such patients relapse repeatedly and have a course indicative of chronic inflammatory demyelinating polyneuropathy (see further on). In a few such patients under our care the disease stabilized after several months in response to the administration of corticosteroids, with very gradual tapering of the dose over several months, or in combination with repeated courses of IVIG or plasma exchanges.

It should be pointed out that the clinical improvement that follows the administration of IVIG or PE usually cannot be readily discerned in an individual patient, i.e., it is apparent only by comparing treated and untreated large groups. For this reason it is not possible to judge that a patient who fails to improve or who worsens through the period of treatment has indeed derived no benefit from therapy. The question nevertheless arises regarding further plasma exchanges or continued infusion of immune globulin in cases of continued worsening or lack of improvement. Further complicating the matter are the limited expectations for early improvement in cases of axonal GBS. Our advice has been to repeat either of the two treatments if a patient is clearly declining, particularly if there is evidence of mainly demyelinating disease on the EMG, and if

the illness is not much longer than 3 weeks in duration. Performing plasma exchanges after the use of IVIG does not make sense to us (but this notion has not been tested); therefore, we either follow exchanges with IVIG or, more often, repeat a course of IVIG as suggested by Farcas and colleagues.

The value of corticosteroids alone in the treatment of GBS has been disputed for decades. Many clinicians were persuaded of their benefit. However, two randomized controlled studies, one with conventional-dose prednisolone and the other with high-dose methylprednisolone, have failed to demonstrate any beneficial effect (Hughes et al). Although corticosteroids can no longer be recommended as routine treatment for acute GBS, we have observed a few instances in which the administration of intravenous high-dose corticosteroids seemingly halted the progress of the acute disease.

Prognosis As already indicated, approximately 3 to 5 percent of patients do not survive the illness, even in the best-equipped hospitals. In the early stages, death is most often due to cardiac arrest, perhaps related to dysautonomia, adult respiratory distress syndrome, pneumo- or hemothorax, or some type of accidental machine failure. Later in the illness, pulmonary embolism and other medical complications (usually bacterial) of prolonged immobilization and respiratory failure are the main causes.

The majority of patients recover nearly completely (with mild motor deficits or sensory complaints in the feet or legs). In about 10 percent, however, the residual disability is pronounced; this occurs in those with the most severe and rapidly evolving form of the disease, when there has been evidence of widespread axonal damage (see later), and in those requiring early and prolonged mechanical ventilatory assistance. A consistent predictor of residual weakness is the EMG finding of severely reduced amplitudes of muscle action potentials and widespread denervation, both indicative of axonal damage. In patients with respiratory failure, the average period of machine-assisted respiration has been 22 days and the period of hospitalization approximately 50 days (these were twice as long prior to the introduction of PE and IVIG). As a rule, older adults recover more slowly than younger ones and children and have more residual weakness.

The most common residual difficulties are weakness of the lower leg muscles, numbness of the feet and toes, and mild bifacial weakness. A few patients are left with a sensory ataxia; when this occurs, it tends to be severe and quite disabling. Distal neuropathic pain and persistent autonomic problems occur but are infrequent. All manner of other late symptoms are attributed with little evidence to the illness and should be addressed on their own merits—fatigue and asthenia, muscle cramps, dizziness, pain, and breathlessness. Depression has not been frequent.

The speed of recovery varies but its pace is steady. Often it occurs within a few weeks or months; however, if axons have degenerated, their regeneration may require 6 to 18 months or longer. In our experience, little improvement can be expected in disabilities that have lasted 3 or more years.

Some 5 to 10 percent of patients suffer one or more recurrences of the acute polyneuropathy as mentioned. An illness that in the beginning appeared to be an acute inflammatory polyradiculoneuropathy may fail to stabilize and continue to progress steadily, or there may be an incomplete remission followed by a chronic, fluctuating, slowly progressive neuropathy. These chronic forms of inflammatory neuropathy are described in a later section of this chapter.

Critical Illness Polyneuropathy

An acute or subacute symmetrical polyneuropathy is a frequent development in critically ill and septic patients, particularly in those with failure of multiple organs (Zochodne et al). This type of neuropathy causes difficulty in weaning a patient from the ventilator, even as the underlying critical illness comes under control. The neuropathic process, predominantly of motor type, varies in severity from an electrophysiologic abnormality without obvious clinical signs to a pronounced quadripareisis with respiratory failure. Sensory symptoms and signs are variable but tend to be mild. Usually the cranial nerves are spared and there are no overt dysautonomic manifestations. In general, the disease appears after several days or more of profound sepsis (now called *systemic inflammatory response syndrome—SIRS*) and multiple organ failure and is preceded in most instances by a confusional state or a depressed state of consciousness (“septic encephalopathy”). The EMG findings of a primary axonal process with early denervation and a normal CSF distinguish this entity from the typical demyelinating form of GBS. Autopsy material has usually disclosed no inflammatory changes in the peripheral nerves. As mentioned, differentiating critical illness polyneuropathy from the axonal form of GBS is difficult and depends on the context in which the illness occurs. The toxic effects of drugs and antibiotics and nutritional deficiency must be considered in causation, but rarely can they be established. Perhaps some of the many systemic mediators of sepsis are toxic to the peripheral nervous system; tumor necrosis factor has been proposed as one such endogenous toxin.

This form of polyneuropathy must also be distinguished from a poorly understood *acute quadriplegic myopathy* that sometimes complicates critical illness (page 1237). High doses of corticosteroids, particularly in combination with neuromuscular blocking agents, have been implicated. The acute myopathy, which affects both distal and proximal muscles, is usually heralded by an elevation in the serum creatine kinase (CK) concentration (at times up to several thousand units) and myopathic potentials in the EMG, and there is a unique degeneration of myofilaments in all the muscles. This illness is described in more detail in Chap. 51.

Acute Uremic Polyneuropathy

In addition to the well-known chronic sensory neuropathy associated with chronic renal failure that is discussed later in the chapter, there is a more rapid (“accelerated”) process that has not been widely appreciated as a cause of acute and subacute weakness. Most patients in our series were diabetics with stable end-stage renal failure who had been treated by peritoneal dialysis for their long-standing kidney disease (Ropper, 1993). In contrast to the better characterized and less severe chronic uremic neuropathy (page 1149), generalized weakness and distal paresthesias progress in over one or more weeks until a bedbound state is reached. In some ways the illness simulates GBS. More aggressive dialysis or a change to hemodialysis has little immediate effect, although kidney transplantation is curative. Electrophysiologic studies show some demyelinating features but usually not a conduction block. There is raised CSF protein concentration (not unexpectedly, for there is usually an element of diabetic neuropathy). A few reported cases have been clinically almost indistinguishable from inflammatory demyelinating polyneuropathy, including, in some, a response to plasma exchange or gamma globulin. As with the more

common chronic uremic neuropathy, the cause of the acute form is not understood.

Acute Sensory Neuronopathy (Sensory Ganglionopathy)

Attention was drawn to this entity by Sterman and colleagues in a report of three adult patients with rapidly evolving sensory ataxia, areflexia, numbness, and pain, beginning in the face and spreading to involve the entire body. In each instance, the symptoms began within 4 to 12 days following the institution of penicillin therapy for a febrile illness (antibiotics were subsequently shown not to be the cause). Proprioception was profoundly reduced, but there was no weakness or muscle atrophy, despite generalized areflexia. The sensory deficit attained its maximum severity within a week, after which it stabilized and improved very little. Electrophysiologic studies showed absent or slowed sensory conduction but there were no abnormalities of motor nerve conduction or signs of denervation. In two of these patients, the CSF protein content was elevated to 126 and 175 mg/dL. Follow-up observations (for up to 5 years) disclosed no neoplastic or immunologic disorder, the usual causes of such a sensory neuronopathy. Lacking pathology, it was assumed, from the permanence of the condition, that sensory neurons were destroyed (*sensory neuronopathy*). In all likelihood, these cases were postinfectious and immune mediated.

A subsequent series of 42 patients reported by Windebank and colleagues emphasized an asymmetrical and brachial pattern of symptoms in some patients and an initial affection of the face in others. In contrast to Sterman’s cases, the CSF was usually normal and most patients had some improvement or a spontaneous resolution of symptoms. These authors viewed the process as a sensory neuropathy. In this and subsequent reports, as mentioned, antibiotics were not implicated.

At present, this clinical pattern should be viewed as a syndrome rather than as a disease. Probably, some instances are immune-postinfectious in nature. The same pattern of sensory loss evolving in a subacute or chronic manner is well known to occur as a paraneoplastic illness, described further on in this chapter, or in association with the Sjögren syndrome, scleroderma, lupus erythematosus, paraproteinemia, and HTLV-I infection. Certain drugs and other agents, especially cisplatin and excessive intake of pyridoxine, are also causes of a sensory neuronopathy. Also to be distinguished from sensory neuronopathy is a rare form of GBS that involves solely the large sensory fibers and produces ataxia. In the latter, there is usually some degree of proximal weakness, and the sensory changes do not normally extend to the face and trunk.

Diphtheritic Polyneuropathy

(See page 1031)

Some of the neurotoxic effects of *Corynebacterium diphtheriae* and the mode of action of the exotoxin elaborated by the bacillus are described in Chap. 43. Local action of the exotoxin may paralyze pharyngeal and laryngeal muscles (dysphagia, nasal voice) within 1 or 2 weeks after the onset of the infection and shortly thereafter may cause blurring of vision due to paralysis of accommodation, but these and other cranial nerve symptoms may be overlooked. At this stage, the cranial neuropathy must be distinguished from that of GBS, botulism, and most of all, from myasthenia gravis.

A polyneuropathy, coming 5 to 8 weeks later, takes the form

of an acute or subacute limb weakness with paresthesias and distal loss of vibratory and position sense. The weakness characteristically involves all extremities at the same time or may descend from arms to legs. After a few days to a week or more, the patient may be unable to stand or walk and occasionally the paralysis is so extensive as to impair respiration. The CSF protein is usually elevated (50 to 200 mg/dL). Diphtheritic deaths that occur after the pharyngeal infection has subsided are due to cardiomyopathy or, less often, to severe polyneuropathy with respiratory paralysis. This type of polyneuropathy, now quite rare, should be suspected in the midst of an outbreak of diphtheritic infection, as occurred recently in Russia (Logina and Donaghy).

The important pathologic change is one of segmental demyelination without inflammatory reaction of spinal roots, sensory ganglia, and adjacent spinal nerves. Anterior horn cells, axons, peripheral nerves distally, and muscle fibers remain normal (Fisher and Adams).

Treatment Diphtheria antitoxin, given within 48 h of the onset of the infection reduces the incidence and severity of neuropathic complications. Antitoxin is probably of little value once the polyneuropathy begins. Thereafter, treatment is purely symptomatic, along the lines indicated for GBS. The prognosis for full recovery is excellent once respiratory paralysis is circumvented.

Porphyric Polyneuropathy

A severe, rapidly advancing, more or less symmetrical and mainly motor polyneuropathy—often with abdominal pain, psychosis (delirium or confusion), and convulsions—may be a manifestation of *acute intermittent porphyria*. This type of porphyria is inherited as an autosomal dominant trait and is not associated with cutaneous sensitivity to sunlight. The metabolic defect is in the liver and is marked by increased production and urinary excretion of porphobilinogen and of the porphyrin precursor δ-amino-levulinic acid. The peripheral and central nervous systems may also be affected in another hepatic type of porphyria (the variegate type). In the latter, the skin is markedly sensitive to light and trauma, and porphyrins are at all times found in the stools. Both of these *hepatic* forms of porphyria are to be distinguished from the rarer *erythropoietic (congenital photosensitive)* porphyria, in which the nervous system is not affected.

The classic study of acute intermittent porphyria was made by Waldenstrom in 1937. The initial and often the most prominent symptom is moderate to severe colicky abdominal pain. It may be generalized or localized and is unattended by rigidity of the abdominal wall or tenderness. Constipation is frequent and radiographs show intestinal distention (ileus). Attacks last for days to weeks and repeated vomiting may lead to inanition. In latent forms, the patient may be asymptomatic or complain only of slight dyspepsia.

The disease can be identified after some time by its characteristic recurrent attacks, often precipitated by drugs such as sulphonamides, griseofulvin, estrogens, barbiturates, phenytoin, and the succinimide anticonvulsants. The possibility of sensitivity to these drugs must always be kept in mind when convulsions are being treated in the porphyric patient. The first attack rarely occurs before puberty, and the disease is most likely to threaten life during adolescence and early adulthood. In contrast, acute polyneuropathy that appears for the first time in mid- or late adult life is not likely to be porphyric.

The neurologic manifestations are usually those of an acute polyneuropathy involving the motor nerves more severely than the

sensory ones; less often both sensory and motor nerves are affected more or less equally and sometimes autonomic nerves as well. The symptoms may begin in the feet and legs and ascend, or they may begin in the hands and arms (sometimes asymmetrically) and spread in a few days to the trunk and legs. Often, the weakness predominates in the proximal muscles of the limbs and limb girdle muscles, in which case there is loss of knee jerks with preservation of reflexes at the ankles. Sensory loss, often extending on to the trunk, is present in half the cases. Facial paralysis, dysphagia, and ocular palsies are features of only the most severe cases. The CSF protein content is normal or slightly elevated.

The course of the polyneuropathy is variable. In mild cases the symptoms regress in a few weeks. Severe cases may progress to a fatal respiratory or cardiac paralysis in a few days, or the symptoms may advance in a saltatory fashion over several weeks, resulting in a severe sensorimotor paralysis that improves only after many months.

A disturbance of cerebral function (confusion, delirium, visual field defects, and convulsions) is likely to precede the severe but not always the mild forms of polyneuropathy, or there may be none of these central features. Cerebral manifestations subside in a few days or weeks, though one of our patients was left with a lasting homonymous hemianopia. Tachycardia and hypertension are frequent in the acute phase of the disease, and fever and leukocytosis may also occur in severe cases. In general, the prognosis for ultimate recovery is excellent, though relapse of the porphyria may result in cumulative involvement of the peripheral nervous system (see discussion of *relapsing polyneuropathy* further on).

In summary, the most characteristic features are the relapsing nature, acute onset, abdominal pain, psychotic symptoms, predominant motor neuropathy, often, an early bibrachial distribution of weakness, truncal sensory loss, and tachycardia. Rarely the neuropathy develops without other symptoms.

The pathologic findings in the peripheral nervous system vary according to the stage of the illness at which death occurs. In the first few days, the myelinated fibers may appear entirely normal, despite an almost complete paralysis. If symptoms had been present for weeks, degeneration of both axons and myelin sheaths are found in most of the peripheral nerves. The relation between the abnormality of porphyrin biosynthesis in the liver and nervous dysfunction has never been explained satisfactorily.

The diagnosis is confirmed by the demonstration of large amounts of porphobilinogen and δ-aminolevulinic acid in the urine. The urine turns dark when standing due to the formation of porphobilin, an oxidation product of porphobilinogen.

Treatment The use of intravenous glucose and intravenous hematin (4 mg/kg daily for 3 to 14 days) is recommended as the most direct and effective therapy (Windebank and Bonkovsky). Other aspects of treatment include respiratory support, use of beta-blocking agents (labetalol) if tachycardia and hypertension are severe, intravenous glucose to suppress the heme biosynthetic pathway, and pyridoxine (100 mg twice a day) on the supposition that vitamin B₆ depletion has occurred.

Prevention is of the utmost importance, since attacks can be precipitated by the aforementioned drugs, as well as numerous others that are porphyrinogenic.

Acute Toxic Polyneuropathies

As indicated in Chap. 43, the peripheral nerves may be affected by a wide variety of toxins, including metals, drugs, organophos-

phates, and industrial solvents. As a rule, the neuropathies induced by these agents fall into the chronic category (to be discussed further on). Certain drugs, however—notably triorthocresylphosphate (TOCP) and other organophosphates (see page 1037), thallium, and rarely arsenic—produce a polyneuropathy that may be fatal in a matter of days. It should be stressed that organophosphate neuropathy can be identified in almost all instances by the severe anticholinergic effects that are apparent immediately after exposure. Severe and permanent motor paralysis is caused by TOCP; this ultimately proves to be due to involvement of both upper and lower motor neurons.

Thallium salts, when taken in sufficient amount, may produce a clinical picture resembling that of GBS or an acute sensory polyneuropathy. If the salts are taken orally, there is first abdominal pain, vomiting, and diarrhea, followed within a few days by pain and tingling in the toes and fingertips and then rapid weakening of muscles of the limbs, initially the distal ones. As the weakness progresses, the tendon reflexes diminish. Pain sensation is reduced more than tactile, vibratory, and position sense. Persistent acral pain with allodynia has been a major feature in three of the five patients we have examined; in two of our patients there was no weakness, only sensory loss and ataxia. All cranial nerves except the first and eighth may be affected; facial palsies, ophthalmoplegia, nystagmus, optic neuritis with visual impairment, and vocal cord palsies are additional abnormalities, but only in the most severely affected patients. The CSF protein rises to more than 100 mg. Death may occur in the first 10 days, due to cardiac arrest. The early onset of painful paresthesias, sensory loss, and pain localized to joints, back, and chest as well as *rapid loss of hair* (after a week or two) all serve to differentiate this neuropathy from GBS, porphyria, and other acute polyneuropathies. Relative preservation of reflexes is noteworthy, and rapidly evolving, complete alopecia is a striking feature. Patients with lesser degrees of intoxication may recover completely within weeks or months. Thallium salts act like potassium, and a high intake of potassium chloride hastens the excretion of thallium. Chelating agents are of unproven value but are usually included in treatment.

Some cases of *arsenical* and possibly *mercurial* polyneuropathy may also develop acutely. More often these conditions evolve subacutely, for which reason they are discussed further on. As alluded to earlier and in Chap. 43, certain other toxic neuropathies, such as those related to organophosphate or diethylene chloride (Sterno) poisoning, may have an acute onset and progress over days.

In regard to this category of polyneuropathy, it must be pointed out that many instances are imputed with little substantiation to a toxic cause by both patients and unskeptical physicians. Before making such an attribution, it is useful to ask whether the clinical features are compatible with the known neurotoxicity of an environmental agent or drug; whether the severity of symptoms is consistent with degree of presumed exposure (real or imagined); whether the associated systemic signs of an intoxication were present; if other individuals similarly exposed had been affected; and whether symptoms stabilized or improved once the patient had been removed from the presumed source of exposure. Failure to satisfy these precepts generally signifies some other disorder.

Other Acute Polyneuropathies

On occasion, a vasculitic polyneuropathy associated with lupus erythematosus, polyarteritis nodosa, and related disorders may de-

velop as rapidly as GBS, and careful clinical and electrophysiologic testing may be needed to distinguish these disorders. Three of our patients with polyarteritis and one with Churg-Strauss disease became completely paralyzed within a week, and one died of intestinal perforation. However, most cases of neuropathy due to vasculitis evolve more slowly, and the syndrome then assumes an asymmetrical and multifocal distribution, for which reason it is described in the next section. There is no doubt that paraneoplastic neuropathies, discussed further in the subacute category, can evolve more rapidly than is typical for this process and thereby simulate GBS.

We have observed a few patients with alcoholism, occult carcinoma, Hodgkin disease, or renal transplantation who developed an acute polyneuropathy, as rapid in its evolution as GBS, and acute episodes of this type have also been described in patients with Refsum disease.

Acute Autonomic Polyneuropathy (“Pure Pandysantonoma”)

Since the first description of such a case by Young, Adams, and colleagues, a number of others have been recorded as summarized by Low et al. The condition, probably a type of postinfectious polyneuropathy within the category of GBS, is described in detail in Chap. 26. Some success has been achieved by treatment with IVIG.

A subacute and more chronic form, also immune in nature, is described further on under “Idiopathic Autonomic Neuropathy.”

SYNDROME OF SUBACUTE SENSORIMOTOR PARALYSIS

Placed in this category are neuropathies that evolve over several weeks to months and, after reaching their peak of severity, tend to persist for a variable period. Admittedly, the dividing line between such cases and those that evolve over somewhat shorter or longer periods is indistinct; there are diseases of nerve that overlap both the acute and the early chronic categories. In contrast to the acute polyneuropathies, however, most of those that are subacute have prominent sensory features and are of axonal type. The exception is a subacute inflammatory-demyelinative type, essentially a slow form of GBS, evolving over 4 to 8 weeks as described by Hughes and coworkers. Similarly, some instances of diphtheritic neuropathy evolve subacutely. Despite these qualifications, in the end, a symmetrical polyneuropathy syndrome of *subacute type* most often proves to be due to alcoholism and nutritional deficiency, to a remote effect of cancer (paraneoplastic, as described later), or to poisoning with arsenic, lead, or to the toxic effects of any number of drugs used for therapeutic purposes (cisplatin, nitrofurantoin, isoniazid, etc.). Occasionally other drugs, metals, and industrial solvents are incriminated; these are discussed in Chap. 43.

Nutritional Deficiency Neuropathy

(See Chap. 41)

In the western world, nutritional polyneuropathy is usually associated with chronic alcoholism. As indicated in page 989, all data point to the identity or at least close relationship between alcoholic neuropathy and neuropathic beriberi. A nutritional factor is responsible for both, though in any given case it often remains unclear whether the deficiency is one of thiamine, nicotinic acid, pyridoxine, pantothenic acid, folic acid, or a combination of these B

vitamins. We have not been persuaded of the existence of a form of polyneuropathy that is attributable solely to the direct toxic effect of alcohol, though claims of such an entity have been made. Nutritional neuropathy and other forms of deficiency neuropathy (Strachan syndrome, pellagra, vitamin B₁₂ deficiency, and malabsorption syndromes) are described fully in Chap. 41.

Paraneoplastic Polyneuropathy and Sensory Ganglionopathy

(See also page 586)

Although capable of producing diverse clinical presentations, most often the remote effect of cancer takes the form of a predominantly distal, symmetrical sensory, or sensorimotor polyneuropathy occurring as a remote effect of carcinoma or lymphoma. Weakness and atrophy, ataxia, and sensory loss of the limbs may advance over several weeks or months to the point where the patient is confined to a wheelchair or bed; usually the CSF protein concentration is mildly elevated. All these symptoms may occur months or even a year or longer before a malignant tumor is found, although usually the tumor is apparent and is most often lung cancer.

In most series, a mixed sensorimotor polyneuropathy is four to five times more frequent than a purely sensory one. The latter is the more distinctive syndrome (described originally by Denny-Brown); it is characterized by a loss of all modalities of sensation spreading from the distal to the proximal segments of the limbs and eventually to the trunk and face. There is severe ataxia and loss of tendon reflexes, but motor power is retained. More recently, it has been appreciated that the sensory loss in the beginning may have a multifocal distribution. The illness reaches its peak in a few weeks or months, and in a very few instances as mentioned the development has been as rapid as that of GBS. The pathologic changes are those of an inflammatory and destructive *sensory neuronopathy* (ganglionitis) and are sometimes part of a more widespread disorder of the nervous system related to the anti-Hu antibody (also termed *antinuclear neuronal antibody*); see page 585. This has proven to be most typical of small-cell cancer of the lung. In a large series of 71 patients with sensory neuronopathy reported by Dalmau and colleagues, more than half were associated with symptomatic inflammatory lesions in the temporal lobes (limbic encephalitis, page 586), the brainstem, and rarely the anterior horn neurons of the spinal cord. Other distinctive paraneoplastic syndromes such as cerebellar degeneration and Lambert-Eaton myasthenic syndrome were combined with polyneuropathy in isolated cases, and there were signs of dysautonomia in 28 percent. Our experience has been otherwise, with most cases of the myasthenic syndrome occurring in isolation.

The CSF protein is moderately elevated but acellular and shows high titers of the anti-Hu antibody. Sensory potentials are usually absent in all nerves after a few weeks but may be spared early on. The localization of anti-Hu antibody to the several affected regions of the nervous system and to the tumor itself has led to speculation that the lung tumors are typically small or invident because the antibody suppresses tumor growth. Almost all cases of paraneoplastic sensory neuropathy and a proportion of the more nondescript sensory predominant or sensorimotor paraneoplastic polyneuropathies also demonstrate anti-Hu antibodies, making, serum anti-Hu testing useful in distinguishing paraneoplastic varieties of sensory neuropathy and neuronopathy from those due to postinfectious or immune disorders such as Sjögren syndrome and HIV infection. The finding of high antibody titers should lead to

detailed radiologic and, in appropriate cases, bronchoscopic or PET examinations to detect an underlying cancer. A rare vasculitic mononeuritis multiplex that occurs with cancer is discussed further on.

An unusual assortment of polyneuropathies have been associated with non-Hodgkin lymphomas of both T- and B-cell types and with several related conditions such as Castleman disease (angiofollicular lymphoid hyperplasia), intravascular T-cell lymphoma (and the related lymphomatoid granulomatosis, page 565), hypersensitivity lymph node hyperplasia (angioimmunoblastic or immunoblastic lymphadenopathy), and Kimura disease (lymphoid hyperplasia with eosinophilia mainly involving skin). In most of these neuropathies, particularly the one associated with Castleman disease, there is a paraproteinemia, often polyclonal, thereby relating this group to the paraproteinemic neuropathies and to osteosclerotic myeloma, discussed later. In several of our cases, the neuropathic manifestations have appeared simultaneously with lymph node enlargement in the groin, axilla, or thorax. Clinically, the illness takes the form of GBS, chronic demyelinating polyneuropathy, subacute motor polyneuropathy or anterior horn cell disease, lumbar and brachial plexopathy, or a polyradiculopathy—each occurring as a paralytic condition clearly separable from cases of meningeal and neural infiltration by tumor. Corticosteroids have been helpful in some of our patients with the lymphoid diseases; in others, the neuropathy resolves spontaneously or with radiation of the lymph nodes but otherwise progresses for months. Vallat and colleagues have summarized their experience with the more conventional types of neuropathy accompanying non-Hodgkin lymphoma. Intravascular lymphoma, a widespread neoplastic and vascular disease described on page 565, may involve the peripheral nerves in a multiple mononeuropathy pattern.

The various forms of paraneoplastic polyneuropathy are manifest clinically in 2 to 5 percent of patients with malignant disease. The figures are higher if one includes the neuropathies accounted for by malnutrition and pressure palsies that occur in the later stages of cancer, and those identified by EMG in asymptomatic patients (Henson and Urich). As alluded to earlier, carcinoma of the lung accounts for about 50 percent of the cases of paraneoplastic sensorimotor polyneuropathy and for 75 percent of those with pure sensory neuropathy (Croft and Wilkinson); nevertheless, these neuropathies may be associated with neoplasms of all types.

Although anti-Hu binds to the peripheral nerve, the *pathology* of the paraneoplastic polyneuropathies has not been completely defined. In the purely sensory type, there is not only a loss of nerve cells in the dorsal root ganglia but also an inflammatory reaction (Horwitz et al)—much the same changes as occur with the sensory neuronopathy of Sjögren syndrome. In the mixed sensorimotor polyneuropathy, the degeneration is greater in the distal than it is in the proximal segments of the peripheral nerves, but it extends into the roots in advanced cases. Dorsal root ganglion cells may be reduced in number. If the histologic examination is performed early in the course of the neuropathy, sparse infiltrates of lymphocytes are observed, distributed in foci around blood vessels. Their relation to both segmental demyelination and axonal degeneration of myelinated fibers is unclear. No tumor cells are seen in the nerves or spinal ganglia, unlike the rare instances of carcinomatous and lymphomatous mononeuropathy multiplex, in which tumor cells actually infiltrate nerves. Degeneration of the dorsal columns and chromatolysis of anterior horn cells are secondary to changes in the peripheral nerves and roots.

The overall *prognosis* of the paraneoplastic neuropathies is poor. Even though the polyneuropathy may stabilize and not pro-

gress, or even remit to some extent on its own or with therapy, most of the patients succumb to the underlying tumor within a year. **Treatment** If the tumor can be treated effectively, the neuropathy may improve, the exception being the pure sensory neuronopathy. Treatment with plasma exchange, gamma globulin, or immunosuppression has had only a minimal effect, but there are anecdotal reports of success with very early immune treatment. In the report by Uchuya and colleagues, only 1 of 18 patients with a subacute sensory neuropathy improved and another became dependent for sustained improvement on immune globulin; most of the others stabilized or worsened, and the authors concluded that treatment was of doubtful value. Corticosteroids have not been tested in a systematic way but there is little clinical evidence to support their use.

Subacute Toxic Neuropathies

Arsenical Polyneuropathy Of the neuropathies caused by metallic poisoning, that due to arsenic is particularly well known. In cases of chronic poisoning, the neuropathic symptoms develop rather slowly, over a period of several weeks or months, and have the same sensory and motor distribution as the nutritional polyneuropathies. Gastrointestinal symptoms, the result of ingestion of arsenic compounds, may precede the polyneuropathy, which is nearly always associated with anemia, jaundice, brownish cutaneous pigmentation, hyperkeratosis of palms and soles, and later with white transverse banding of the nails (Mees lines). The disease is accompanied by an excess of arsenic in the urine and hair. Pathologically, this form of arsenical neuropathy is generally categorized as of the dying-back (axonal degeneration) type.

In patients who survive the ingestion of a single massive dose of arsenic, a more rapidly evolving polyneuropathy may appear after a period of 8 to 21 days as discussed earlier. The neuropathy may be preceded by severe gastrointestinal symptoms, renal and hepatic failure, and mental disturbances, convulsions, confusion, and coma—i.e., arsenical encephalopathy—the pathologic basis of which is a brain purpura, or pericapillary hemorrhages. Initially, the neuropathy that develops in this setting may resemble GBS, both clinically and electromyographically (partial conduction block, prolonged F responses).

Diagnosis and treatment of arsenical poisoning are discussed further in Chap. 43.

Lead Neuropathy (Plumbism) Lead neuropathy is an uncommon disorder. In adults, as a rule, it occurs following chronic exposure to lead paint or fumes (from smelting industries or burning batteries) or from ingestion of liquor distilled in lead pipes. Its most characteristic presentation is a predominantly motor mononeuropathy in the distribution of the radial nerves (wrist and finger drop). In a few personally observed patients, this was the main abnormality but there was also a slight sensory loss in the radial territory of the hand. Less commonly there is foot drop occurring alone or in combination with weakness of the proximal arm and shoulder girdle muscles. As pointed out in Chap. 43, lead neuropathy seldom occurs in children, in whom lead poisoning usually results in a devastating encephalopathy. Although the neuropathy has been known since ancient times, details of the pathology are still obscure. Axonal degeneration with secondary myelin change and swelling and chromatolysis of anterior horn cells has been described. Lead accumulates in the nerve and may be toxic to Schwann cells or to endothelial capillary cells, causing edema.

The diagnosis is established by the history of lead exposure, the predominant and restricted motor involvement, the associated medical findings (anemia, basophilic stippling of red blood cell precursors in the bone marrow, a “lead line” along the gingival margins, colicky abdominal pain, and constipation), and the urinary excretion of lead and coproporphyrins. Blood lead levels of more than 70 mg/dL are always abnormal. In patients with lower levels, doubling of the 24-h urinary lead excretion following an infusion of the chelating agent CaNa₂ EDTA indicates a significant degree of lead intoxication. Coproporphyrin in the urine is abnormal in any amount, but it may also be found in porphyria, alcoholism, iron deficiency, and other disorders as well as in lead intoxication.

Treatment consists of terminating the exposure to lead and eliminating lead from the bloodstream and the bones as discussed in Chap. 43. For this purpose, penicillamine, which is generally safe and can be administered orally, is preferable to dimercaprol [British antilewisite (BAL)] or EDTA.

Other Metals and Industrial Agents Chronic poisoning with *thallium* and sometimes with *lithium*, *gold*, *mercury*, and *platinum* (in the antineoplastic agent cisplatin as discussed further on) may produce a sensorimotor polyneuropathy similar to arsenical polyneuropathy; these intoxications are discussed in Chap. 43 and the acute form was addressed earlier in the chapter. A predominantly motor neuropathy is known to be induced by occupational exposure to metallic mercury and mercury vapor, but the connection to the mercury content in dental amalgam has little credibility. Exposure to manganese, bismuth, antimony, zinc, and copper may give rise to systemic signs of poisoning; some of them affect the central nervous system (CNS), but one cannot be certain that any of them specifically involves peripheral nerves. The devastating encephalopathy of organic mercury toxicity does not, to our knowledge, cause neuropathy.

As mentioned in Chap. 43, a predominantly motor polyneuropathy has been reported as a rare complication of *gold* therapy for rheumatoid arthritis. Most often the cumulative dose of gold had exceeded 1 g, but in a few instances the neuropathy occurred with 0.5 g. Painful distal burning is the initial complaint, and weakness and wasting follow. The onset of weakness, although usually insidious, can be abrupt enough to simulate GBS. There have been trigeminal, facial, and oculomotor palsies. One of the unusual features reported, not shared with most other toxic neuropathies, is a marked rise in CSF protein concentration.

A distal, symmetrical sensorimotor (predominantly sensory) axonopathy may follow exposure to certain hexacarbon industrial solvents. These include *n-hexane* (found in contact cements, thus affecting “glue sniffers” who inhale the vapors); *methyl n-butyl ketone* (used in the production of plastic-coated and color-printed fabrics); dimethylaminopropionitrile (DMAPN), used in the manufacture of polyurethane foam); the fumigant *methyl bromide*; and the gas sterilant *ethylene oxide*. Operating room nurses may be affected by the latter when the agent is absorbed through the skin, leaving a characteristic rash at exposed sites (usually the wrists, where a surgical gown ends). A mild peripheral neuropathy and CNS changes of memory loss and headaches have been reported by Brashear and colleagues. Nurses are also subject to a risk of *nitrous oxide* neurotoxicity; but at the present time the neuropathy has most often resulted from its repeated use as a euphoriant. The process is said to have the clinical and electrophysiologic features of a distal axonopathy but is more likely a myeloneuropathy related to impairment of vitamin B₁₂ metabolism. The associated macro-

cytic anemia is reversed by the administration of B_{12} , but the neurologic illness is less responsive (page 1092).

Triorthocresyl phosphate and *acrylamide* are potent peripheral nerve poisons. Both of these drugs cause a dying-back polyneuropathy with axonal degeneration and have been used experimentally to produce this effect. *Vacor*, a phenylnitrosurea rodenticide, has been taken as a suicidal agent. It gives rise to a profound sensory and autonomic neuropathy with abdominal pain and hyperglycemia due to acute pancreatitis.

Detailed accounts of the clinical and experimental neurotoxicology of these agents can be found in the monograph by Spencer et al.

Drug-Induced Neuropathies and Neuronopathies A large number of medications are sources of polyneuropathy of predominantly sensory type. Most are dose-dependent and are therefore more or less predictable after large cumulative doses of the drug have been given (e.g., in chemotherapy) or after prolonged administration for other reasons. Often, in the latter case, the patient and physician fail to connect the sensory symptoms to drug toxicity.

Antineoplastic Drugs Among chemotherapeutic agents in current use, *cisplatin* and *carboplatin* are known to consistently evoke a predominantly sensory polyneuropathy, which begins several weeks after completion of therapy in at least half of the patients (page 1039). Proprioception and vibratory sensation are most severely impaired. Some patients develop acrodynia and episodic color changes in the fingertips and toes, suggesting that autonomic nerves are also involved; in severe cases there is sensory ataxia and pseudoathetosis. The severity of histopathologic changes in the peripheral nervous system corresponds to the concentration of platinum in these tissues, the highest concentrations being found in dorsal root ganglia. There may be secondary degeneration in the posterior columns—the basis for a Lhermitte symptom reported by these patients.

The taxanes *paclitaxel* (Taxol) and the more potent *docetaxel* (Taxotere), both cited as inhibitors of the depolymerization of neurotubules, are used mainly in the treatment of ovarian cancer. They produce a sensory polyneuropathy similar to that of cisplatin. The nerve lesion regresses slowly with a reduction in dosage (see also page 1040). Pathologic studies have shown a distal axonopathy affecting mainly large fibers.

For decades it has been known that peripheral neuropathy commonly complicates the use of *vincristine*, an antineoplastic agent widely used in treatment of the lymphomas and leukemia (page 1039). Paresthesias are the most common early symptom, and loss of ankle jerks is an early manifestation. Some degree of weakness usually precedes objective sensory loss; the extensor muscles of the fingers and wrists are affected; later the dorsiflexors of the toes and feet causing foot drop, or, more often in our experience, foot drop may appear first. With the dose regimens currently used, the weakness is usually mild, but in the past some patients became quadriparetic and bedbound. Adults are more severely affected than are children, as are persons with preexisting polyneuropathies. The neuropathy is strictly dose-related, and reduction in dosage is followed by improvement of neuropathic symptoms although this may take several months. Many patients are then able to continue the use of vincristine in low dosage, such as 1 mg every 2 weeks, for many months.

Antimicrobial Drugs As mentioned in Chap. 43, *isoniazid* (INH)-induced polyneuropathy was a common occurrence in the early 1950s when this drug was first used for the treatment of tu-

erculosis. Symptoms of neuropathy appeared between 3 and 35 weeks after treatment was begun and affected about 10 percent of patients receiving therapeutic doses in the upper range (10 mg/kg daily). The initial symptoms are symmetrical numbness and tingling of the toes and feet, spreading, if the drug is continued, to the knees and occasionally to the hands. Aching and burning pain in these parts then becomes prominent. In addition to sensory loss, examination usually discloses a loss of tendon reflexes and weakness in the distal muscles of the legs. Severe degrees of weakness and loss of deep sensation are observed only rarely.

Isoniazid produces its effects on the peripheral nerves by interfering with pyridoxine metabolism, perhaps by inhibiting the phosphorylation of pyridoxine (the collective name for the B_6 group of vitamins) and decreasing the tissue levels of its active form, pyridoxal phosphate. The administration of 150 to 450 mg of pyridoxine daily, in conjunction with the isoniazid, completely prevents the neuropathy. The same mechanism is probably operative in the neuropathies that occasionally complicate the administration of the isoniazid-related substances such as *ethionamide*, used sometimes in the treatment of tuberculosis, and the now little-used antihypertensive agent *hydralazine*. Paradoxically, the taking of *extremely high doses of pyridoxine* over a prolonged period may, as alluded to earlier, actually cause a disabling, predominantly sensory ganglionopathy (Schaumburg et al).

A relatively mild sensory neuropathy (acral paresthesia) associated with optic neuropathy occasionally complicates *chloramphenicol* therapy. The chronic administration of *metronidazole* (used in the treatment of Crohn disease and anaerobic infections) may have the same effect. A predominantly motor neuropathy has been reported with the chronic administration of *dapsone*, a sulfone used to treat leprosy and certain dermatologic conditions. *Stilbamidine*, used in the treatment of kala azar, may also induce a purely sensory neuropathy with a propensity to affect the trigeminal nerves.

The introduction in 1952 of *nitrofurantoin* for the treatment of bladder infections was soon followed by reports of neurotoxicity attributable to the drug. The earliest symptoms are pain and tingling paresthesias of the toes and feet, followed shortly by similar sensations in the fingers. If the drug is not discontinued, the disorder progresses to a severe, symmetrical sensorimotor polyneuropathy. Patients with chronic renal failure and azotemia are particularly prone to neurotoxicity from nitrofurantoin because of diminished drug excretion resulting in high tissue levels. To make matters more complex, the uremic state itself may be responsible for a similar polyneuropathy, so that the distinction between uremic and nitrofurantoin neuropathy in the presence of chronic renal failure may be impossible. The neuropathologic studies of Lhermitte and colleagues disclosed an axonal degeneration in peripheral nerves and sensory roots.

Cardiac Drugs *Amiodarone*, a drug that is commonly used for treating recalcitrant ventricular tachyarrhythmias, induces a motor-sensory neuropathy in about 5 percent of patients after several months of treatment. *Perhexiline maleate*, another drug for the treatment of angina pectoris, may also cause a generalized, predominantly sensory polyneuropathy in a small proportion of patients. Affected persons show a striking neuronal lipidosis. Patients taking *niacin* to lower blood cholesterol levels may experience intense distal and truncal paresthesias, but no neuropathy has been identified.

Disulfiram (Antabuse) The development of a sensorimotor neuropathy similar to that produced by INH is sometimes associated

with the chronic use of disulfiram in the treatment of alcoholism. Its neurotoxic effects have been attributed to the action of *carbon disulfide*, which is produced during the metabolism of the drug, and is known to cause polyneuropathy and sometimes an optic neuropathy in workers in the viscose rayon industry. Pathologic data, though scant, tend to discredit this notion, insofar as disulfiram evokes a wallerian type of axonal degeneration, whereas carbon disulfide neuropathy is characterized by swollen (giant) axons that are filled with neurofilaments (Bouldin et al).

Other Pharmaceutical Agents Causing Polyneuropathy Some patients who have taken *phenytoin* for decades may show an absence of ankle and patellar reflexes, a mild distal symmetrical impairment of sensation, reduced conduction velocity in the peripheral nerves of the legs, and, rarely, weakness of the distal musculature. The mechanism and frequency of this complication are not clear. The cholesterol lowering "statin" drugs have been implicated in a painful, paresthetic distal axonal polyneuropathy, often, it has been stated, with retained reflexes (Geist et al). More often the problem with statins is one of a toxic myopathy. The frequency of polyneuropathy is very low but, if no other explanation is identified, it may be advisable to discontinue the drug. *Colchicine* has long been known to cause a myopathy, but a few cases of predominantly axonal sensory neuropathy have also been reported. *Thalidomide*, which can produce sensory polyneuropathy, had been withdrawn from the market but is now being used again experimentally for graft-versus-host disease and for drug-resistant erythema nodosum, leprous eruptions, and aphthous stomatitis, particularly in AIDS patients—also as an experimental antineoplastic agent for vascular tumors. The thalidomide polyneuropathy is dose-dependent and can be anticipated at certain levels of administration. Severe *botulinum* poisoning and the prolonged use of *neuromuscular blocking agents* is said to leave some patients with a distal axonopathy, but this must be rare. Residual effects of polyneuropathy were seen in patients with the toxic eosinophilia-myalgia syndrome; the problem was traced to the ingestion of *adulterated L-tryptophan* which had been used in nonprescription drugs for insomnia (page 1211). One patient under our care suffered permanent areflexic quadriplegia. There may be an eosinophilic infiltrate in nerves, but the neuropathy is probably the result of a direct toxic mechanism. A sensory neuropathy resulting from excessive *pyridoxine* ingestion, alluded to earlier, is still seen among individuals who take huge doses of vitamin supplements. *Amitriptyline* is capable of producing paresthesias, but the effect seems to be idiosyncratic and infrequent.

The anesthetic agent *trichloroethylene*, as with the aforementioned stilbamidine, has a predilection for cranial nerves, particularly the fifth. The neurotoxicity is apparently due to dichloroacetylene, formed as a decomposition product of trichloroethylene. The neuropathic potential of nitrous oxide has already been mentioned.

Diabetic Neuropathy

Diabetes mellitus is the cause of the most common polyneuropathy in general clinical practice for which reason it is accorded a separate section. Several limited forms of peripheral nerve disease are also the direct result of diabetes and for convenience of exposition they are included here; some of these are acute and focal and enter into the differential diagnosis of mononeuritis multiplex considered in the next section. In recent years attention has been directed to a possible association between a nondescript sensory polyneuropathy and impaired glucose tolerance, even without manifest diabetes,

persistent hyperglycemia, or elevation of the hemoglobin A-1c test. The survey by Sumner and colleagues makes a case for such an association but we remain uncertain about the relationship between glucose intolerance alone and polyneuropathy.

About 15 percent of patients with diabetes have both symptoms and signs of neuropathy, but nearly 50 percent have evidence of peripheral nerve damage as judged by nerve conduction abnormalities. The duration of diabetes is perhaps the most important factor in frequency of polyneuropathy. Somewhat fewer than 10 percent of patients have clinically evident neuropathy at the time of discovery of diabetes but this figure rises to 50 percent after 25 years. (The presence of diabetic retinopathy is also associated with a higher incidence of neuropathy.) It is not surprising, therefore, that neuropathy is most common in diabetic people older than 50 years of age; it is uncommon in those under 30 and rare in childhood. Dyck and colleagues (1993) studied 380 diabetics—27 percent with type 1 (insulin-dependent) forms and 73 percent with type 2 (noninsulin-dependent); symptomatic polyneuropathy was found in 15 percent of the first group and 13 percent of the second. The percentages were far higher when patients were selected electrophysiologically.

Several fairly distinct clinical syndromes have been delineated: (1) the most common, a distal, symmetrical, primarily sensory polyneuropathy affecting feet and legs more than hands in a chronic, slowly progressive manner; (2) acute diabetic ophthalmoplegia that affects the third, and less often, the sixth cranial nerve; (3) acute mononeuropathy of limbs or trunk including a painful thoracolumbar radiculopathy; (4) a rapidly evolving, painful, asymmetrical, predominantly motor multiple neuropathy affecting the upper lumbar roots and the proximal leg muscles (so-called diabetic amyotrophy); (5) a more symmetrical, proximal motor weakness and wasting, often without pain and with variable sensory loss pursuing a subacute or chronic course; (6) an autonomic neuropathy involving bowel, bladder, and circulatory reflexes; and (7) a painful thoracoabdominal radiculopathy. These forms of neuropathy often coexist or overlap, particularly the autonomic and distal symmetrical types and the subacute proximal neuropathies.

Most of the types of neuropathy listed above are thought to be due to ischemia or infarction of nerves or nerve fascicles, due to a diabetic microvasculopathy. All but the first are special types of *mononeuropathy multiplex*. The polyneuropathy is associated with small blood vessel disease (affecting the vaso nervorum) but possibly also with a poorly understood metabolic abnormality; however, other theories of causation abound. In recent years, an inflammatory process has been postulated as yet another mechanism of peripheral nerve damage. These aspects are discussed further on.

Distal Polyneuropathy The *distal, symmetrical, primarily sensory form* of polyneuropathy is the most common type. Although it is usually a chronic process, sometimes unnoticed by the patient, we include it here in order to provide a complete tabulation of the diabetic neuropathies. The main complaints are persistent and often distressing numbness and tingling, usually confined to the feet and lower legs, and worse at night. The ankle jerks are absent, and sometimes the patellar reflexes as well. As a rule, sensory loss is confined to the distal parts of the lower extremities, but in severe cases the hands are involved and the sensory loss may even spread to the anterior trunk, giving rise to confusion in diagnosis (Said et al). Trophic changes in the form of deep ulcerations and neuropathic degeneration of the joints (Charcot joints) are encountered

in the most severe and long-standing cases, presumably due to sensory analgesia, trophic changes, and repetitive injury. (Foot ulcerations are more common simply as a result of the microvascular disease of skin in diabetic patients.) Muscle weakness is usually mild, but in some patients a distal sensory neuropathy is combined with a proximal weakness and wasting of the types mentioned earlier. Treatment of the acral pain may be a major problem and is discussed further on.

In another group of patients with diabetic polyneuropathy the clinical picture may be dominated instead by loss of deep sensation, ataxia, and atony of the bladder, with only slight weakness of the limbs, in which case it resembles tabes dorsalis (hence the term *diabetic pseudotabes*). The similarity is even closer if lancinating pains in the legs, unreactive pupils, and neuropathic arthropathy are present.

Acute Diabetic Mononeuropathies Among these, *diabetic ophthalmoplegia* is a common occurrence, usually in a patient with well-established diabetes. It commonly presents as an isolated, painful third nerve palsy with sparing of pupillary function. In the first autopsied patient reported by Dreyfus, Adams, and colleagues, there was an ischemic lesion in the center of the retro-orbital portion of the third nerve. Subsequently, a similar case was described by Asbury and colleagues. Less often, the sixth nerve is involved. The disorder was described earlier in the chapter on page 233.

Isolated involvement of practically all the major peripheral nerves has been described in diabetes, but the ones most frequently involved are the *femoral*, *sciatic*, and *peroneal nerves* in about that order. Rarely is a nerve in the upper extremity affected. As mentioned, the acute mononeuropathies, both cranial and peripheral, are presumably due to infarction of the nerve but it is in studies of the third nerve that this pathologic basis has been most convincingly established as noted above. Recovery is the rule but may take many months.

Diabetic Multiple Mononeuropathies and Radiculopathies This category overlaps with the mononeuropathies. A syndrome of painful unilateral or asymmetrical multiple neuropathy tends to occur in older patients with relatively mild or even unrecognized diabetes. These affections of several single nerves occur in a random distribution and cause a mononeuritis multiplex. They often emerge during periods of transition in the diabetic illness, for example, when severe hyper- or hypoglycemia arises, when insulin treatment is being initiated or adjusted, or when there has been rapid weight loss. In the most characteristic type, which affects the lumbar roots, pain, which can be severe, begins in the low back or hip and spreads to the thigh and knee on one side. The discomfort has a deep, aching character with superimposed lancinating jabs, and there is a propensity for pain to be most severe at night. Weakness and later atrophy are evident in the pelvic girdle and thigh muscles, although the distal muscles of the leg may also be affected. The patellar reflex is lost on the affected side. Curiously, we have found the opposite patellar reflex to be absent in some patients. Deep and superficial sensation may be intact or mildly impaired, conforming to either a multiple nerve or multiple adjacent root distribution (i.e., L2 and L3) or both. Recovery is the rule although months and even years may elapse before it is complete. There is a tendency for the same syndrome to recur after an interval of months or years in the opposite leg. The EMG shows denervation in the L2–L3 and sometimes adjacent myotomes. As with the diabetic mononeuropathies, the upper extremities are only rarely affected by this process.

This form of neuropathy is often referred to as *diabetic amyotrophy*, a term that draws attention to one facet of the syndrome but is otherwise uninformative. Garland's name has also been attached to this diabetic lumbar radiculoplexopathy based on his early and thorough report (but he mistakenly attributed the condition to a spinal cord lesion). A potentially vasculitic mechanism demonstrated by Raff and colleagues has been supported by PJB Dyck and others. A vasculopathy involving vaso nervorum, the traditional explanation, seems more likely to us.

Clinical experience has shown that an identical painful lumbofemoral neuropathy may develop in nondiabetics; possibly this form is also vasculopathic or vasculitic. While lumbar disc herniation, retroperitoneal hematoma compressing upper lumbar roots, carcinomatous meningeal seeding, and neoplastic and sarcoid infiltration of the proximal lumbar plexus enter into the differential diagnosis, the diabetic type is usually so distinctive as to permit an early recognition on clinical grounds.

Also observed in diabetic patients is a syndrome of proximal symmetrical leg weakness, wasting, and reflex loss of more insidious onset and gradual evolution as discussed by Pascoe and colleagues. The iliopsoas, quadriceps, and hamstrings are involved in varying degrees. The muscles of the scapulae and upper limbs, usually the deltoid and triceps, are affected less frequently. Pain is not a consistent feature, as it is in the acute asymmetrical type, and sensory changes, if present, are distal, symmetrical, and usually mild.

In this attempt to delineate two types of proximal diabetic neuropathy, it must be emphasized that there is an overlap between them and that distal parts of a limb may be involved to a lesser degree in both conditions and that the timing of evolution of symptoms varies. Nor can the proximal and distal type be distinguished on pathologic or electrophysiologic grounds alone. Whether they should even be considered as separate entities is not clear.

Well known to diabetologists is a syndrome of *thoracolumbar radiculopathy* characterized by severe pain and dysesthesia. Almost always the diabetes has been of long-standing (Kikta et al). The pain is distributed over one or several adjacent segments of the chest or abdomen; it may be unilateral or less often bilateral and tends to follow recent weight loss. Superficial sensory loss can be detected over the involved area in most patients. The pathology of this state is not known but it is also presumed to be an ischemic radiculopathy. The EMG changes consist of fibrillations of the paraspinal and abdominal muscles in one or more adjacent myotomes, corresponding to the painful area. With better control of the diabetes, or perhaps spontaneously, recovery eventually occurs but it may be protracted. The differential diagnosis includes pre-eruptive herpes zoster, sarcoid infiltration of nerve roots, and the rare entity of thoracic disc rupture.

In all forms of diabetic polyneuropathy, the CSF protein may be elevated from 50 to 150 mg/dL and sometimes even higher. The protein concentration is usually normal in cases of diabetic mononeuropathy. (Whether a slight elevation of CSF protein, discovered incidentally, can be attributed to diabetes in the absence of a polyneuropathy is uncertain.)

In this type and the ones described further on, both type 1 and type 2 diabetic patients are susceptible, the duration of diabetes being a major factor.

Autonomic Neuropathy Symptoms of *autonomic involvement* include any combination of pupillary and lacrimal dysfunction, impairment of sweating and vascular reflexes, nocturnal diarrhea, at-

onicity of the gastrointestinal tract (gastroparesis) and bladder dilation, sexual impotence, and postural hypotension. The most striking examples in our experience have included severe abdominal and limb pain, reminiscent of tabetic crises.

The basis of this type of involvement is not well understood. Duchen and associates, who studied the sympathetic ganglia in diabetic patients with autonomic symptoms, described vacuoles and granular deposits in sympathetic neurons and little if any neuronal degeneration; there was also a loss of myelinated nerve fibers in the vagus and splanchnic nerves and the rami communicantes, as well as changes in neurons of the intermediolateral columns of the spinal cord.

Pathology and Pathophysiology In the mundane symmetrical distal diabetic polyneuropathy, a loss of myelinated nerve fibers is the most prominent finding according to Thomas and Tomlinson. In addition, segmental demyelination and remyelination of remaining axons are apparent in teased nerve fiber preparations. The latter findings are probably too severe and widespread to be simply a reflection of axonal degeneration. Occasionally, repeated demyelination and remyelination leads to onion-bulb formations of Schwann cells and fibroblasts, as it does in the relapsing inflammatory neuropathies. Unmyelinated fibers are also reduced in number in most specimens. Similar lesions are found in the posterior roots and posterior columns of the spinal cord and in the rami communicantes and sympathetic ganglia. Under the electron microscope, the basement membranes of intraneuronal capillaries are seen to be thickened and duplicated. There are changes in the microvasculature of the nerves as well, similar to what is seen in other organs and in the skin as noted later.

However, substantial uncertainties persist about the pathogenesis of the diabetic neuropathies. Both the cranial (diabetic ophthalmoplegia) and peripheral mononeuropathies as well as the painful, asymmetrical, predominantly proximal neuropathy of sudden onset have been considered by most neuropathologists to be ischemic in origin, secondary to a vasculopathy of the vasa nervorum that is a property of the diabetic state. Obliterative microvascular lesions were well illustrated by Raff and coworkers, and corresponding multiple small infarcts were found in the nerve trunks. The observations of Dyck and of Johnson and their associates have suggested that all forms of diabetic neuropathy could have the same microvascular basis. These authors described multiple foci of fiber loss throughout the length of the peripheral nerves, beginning in the proximal segments and becoming more frequent and severe in the distal segments. This pattern of change differs from that observed in diffuse metabolic disease of Schwann cells and in the dying-back type of neuropathy; i.e., the findings suggest an ischemic etiology. Fagerberg had earlier noted that the fascicular capillaries and epineurial arterioles have thickened and hyalinized basement membranes, similar to the microvascular changes seen in the retina, kidney, and other organs. But occlusion of vessels and frank infarction of nerve has not been observed in most cases of polyneuropathy for which reason a vascular pathogenesis remains unsettled in the minds of some pathologists.

In the past several years an alternative view has been offered, based largely on the work of PJB Dyck and colleagues and of Said and coworkers. They have found areas of perivascular inflammation and a suggestion of adjacent damage to nerve fascicles in the proximal asymmetric radicular plexus lesions. In Said's report, this necrotizing vasculitis was observed in 6 of 22 patients and a degree of perivascular inflammation in 21, changes not seen in the typical

distal sensory-motor polyneuropathy of diabetics. These findings, if valid, have implications for treatment, particularly since corticosteroids have been suggested with potential for worsening hyperglycemia. Inflammatory-vascular changes in diabetic nerves have not been as impressive in our material.

The several biochemical findings implicated in diabetic polyneuropathy and their interpretations have been reviewed by Thomas and Tomlinson and by Brown and Greene. The latter authors advance the idea that persistent hyperglycemia inhibits sodium-dependent myoinositol transport. Low levels of intraneuronal myoinositol reduce phosphoinositide metabolism and sodium-potassium ATPase activity. Others have emphasized a deficiency of aldose reductase and an elevation of polyols (particularly sorbitol) as being causally important. In reviewing these articles, one can only conclude that a convincing biochemical pathogenesis has yet to be formulated.

Another group of novel findings holds that there is a reduction in various trophic factors within diabetic nerves (NGF, VEGF, erythropoietin, etc.) and in diabetic animals, partial reversal of the polyneuropathy can be obtained by replacement of these factors through gene therapy. The work is provocative but its clinical meaning is not yet clear. Trials addressing this mode of treatment are noted later.

Treatment The only preventive treatment is the maintenance of the blood glucose concentration at a close to normal range, since the prevailing view, derived from prolonged human studies, is that there is some relationship between peripheral nerve damage and inadequate regulation of the diabetes. This notion is supported by the findings of the National Diabetic Complications Trial, in which 715 patients with type 1 diabetes were followed for 6 to 10 years. There was a clear relation between strict glucose control, by means of an intravenous insulin infusion system, and a reduction or delay in the occurrence of painful neuropathic symptoms, retinopathy, and nephropathy. However, this came at the price of a threefold increase in hypoglycemic reactions (see also Samanta and Burden). Whether similar protective effects apply to type 2 diabetes is not known, but for most patients this degree of control is not practical. A number of small trials have been conducted with aldose reductase inhibitors based on theoretical considerations of the above-mentioned metabolic changes (see Thomas and Tomlinson). Some recent interest has also been directed at the therapeutic use of gangliosides, which are normal components of neuronal membranes and can be administered exogenously. The authors have had no experience with either of these agents and neither one has entered routine practice.

The approach to treatment using gene therapy has been pursued in our laboratories founded by the late Dr. Jeffrey Isner. In experimental models of diabetic neuropathy the intramuscular administration of vascular endothelial growth factor (VEGF) has had a beneficial effect on several measures of nerve conduction and on the histologic changes of diabetic nerve damage in the treated limb. Whether this is mediated by a trophic influence on nerves and Schwann cells, or is the result of angiogenesis, is not known. Two trials of nerve growth factor (NGF) injections in almost 500 patients conducted by Apfel and colleagues gave equivocal results, the first being positive and the follow-up study not showing improvement. We are conducting a trial of VEGF in humans.

In the long term, the distressing paresthesias of the distal extremities are best managed with amitriptyline or one of the newer generation of antidepressants, such as sertraline or fluoxetine,

which are better tolerated. Shooting, stabbing pain also responds to some degree to carbamazepine or phenytoin, but in general the results are unimpressive. Neurontin may give somewhat better results, perhaps in part because high doses are well tolerated (Gorsor et al). Nerve blocks and epidural injections have been helpful in only a few patients. In the proximal asymmetrical, truncal, or ophthalmoplegic neuropathies, the severe pain usually lasts for only a short period and requires the judicious use of analgesics, as outlined in Chap. 8. *Prognosis* in patients with the distal, symmetrical sensory neuropathy is generally for slow progression; but in the other types improvement and eventual recovery may be expected over a period of months or years.

ASYMMETRICAL AND MULTIFOCAL POLYNEUROPATHIES (MONONEUROPATHY, OR MONONEURITIS MULTIPLEX)

(See Table 46-4)

Several systemic conditions may be accompanied by acute or subacute involvement of *multiple individual nerves* serially or almost simultaneously. This gives rise to a distinctive clinical picture that has been called mononeuritis multiplex. The most notable examples of this syndrome are associated with polyarteritis nodosa and other vasculitides, and another not uncommon form of idiopathic vasculitis that is confined to the peripheral nervous system. The distinctive features are the acute or subacute evolution of complete or almost complete sensorimotor paralysis of single peripheral nerves, in an asymmetric distribution and not respecting proximal or distal sites and pain. Less frequently, sarcoidosis, forms of HIV-related neuropathy, and Lyme disease present in this fashion. Leprosy, a special member of this group, is discussed further on and the diabetic mononeuropathies were addressed in the preceding section.

Table 46-4
Causes of mononeuritis multiplex

Common

- Polyarteritis nodosa^a
- Isolated vasculitis of peripheral nerves^a
- Wegener granulomatosis^a
- Diabetes
- Hereditary liability to preserve palsies
- Cryoglobulinemia^a
- Sarcoidosis
- Lyme disease
- HIV^a

Rare

- Sarcoidosis
- Paraneoplastic
- Amyloidosis
- Leprosy
- Systemic lupus^a
- Rheumatoid arthritis^a
- Leukemia-lymphoma infiltration
- Intravascular lymphoma
- Sjögren syndrome

^a Possible vasculitic mechanism.

Arteritic Angiopathic Neuropathies Approximately half of all cases of mononeuropathy multiplex can be traced to a *systemic vasculitis of the vasa nervorum*. These are the classic causes of mononeuritis multiplex. Included in this category are polyarteritis nodosa, the Churg-Strauss syndrome (allergic bronchial asthma and eosinophilia), rheumatoid arthritis, lupus erythematosus, scleroderma, cryoglobulinemia, Wegener granulomatosis, and the aforementioned idiopathic variety of vasculitis that is confined to the cranial peripheral nerves and has no systemic manifestations. A small-vessel arteritis is also the putative mechanism in the multiple mononeuropathies that complicate Lyme disease and AIDS. In Said's series of 200 cases of vasculitis affecting the peripheral nerves, 36 percent were due to polyarteritis nodosa, 21 percent to rheumatoid arthritis, and 4 percent to other connective tissue diseases; in 35 percent there were no signs of vasculitis beyond the peripheral nerves. Elevation of the sedimentation rate and other serologic abnormalities are typical features of this entire group. This subject has been reviewed by Chalk et al; Dyck and Said; and by Kissell.

Polyarteritis Nodosa Perhaps 75 percent of cases of polyarteritis nodosa show involvement of the small nutrient arteries of peripheral nerves (autopsy figures), but a symptomatic form of neuropathy develops in only about half this number. Involvement of the peripheral nerves may be the principal or first clue to the diagnosis of the underlying disease when, up to that time, the main components of the clinical picture—abdominal pain, hematuria, fever, eosinophilia, hypertension, vague limb pains, and asthma—had not fully declared themselves or had been misinterpreted.

Although characteristically a disease of multiple discrete mononeuropathies, the syndrome associated with polyarteritis nodosa may appear to be diffuse and more or less symmetrical as a result of the cumulation of many small nerve infarctions, i.e., it can simulate a polyneuropathy. In these cases, careful clinical and electrophysiologic examinations disclose elements of mononeuritis that have been engrafted on an otherwise ostensibly generalized process. For example, an asymmetrical foot or wrist drop, or a disproportionate affection of one nerve in a limb, such as ulnar palsy with relative sparing of function of the adjacent median nerve, are clues. More often it takes form throughout its course of a *mononeuropathy multiplex*, i.e., a random infarction of two or more individual nerves. The onset is usually abrupt, with symptoms of pain or numbness at a focal site along a nerve or in the distal distribution of an affected nerve, followed in hours or days by motor or sensory loss in the distribution of that nerve, and then by involvement in a saltatory fashion of other peripheral nerves. Both the spinal and cranial nerves may be affected but far less often than the nerves in the limbs. No two cases are identical.

The CSF is usually normal. Nerve biopsy, usually taken from the sural nerve, will usually show the necrotizing arteritis in medium sized vessels (fibrinoid necrosis of all three coats of the vessel walls), usually with numerous infiltrating eosinophils and with occlusion of vessels. Muscle biopsy may also show perivascular inflammation and necrosis but the diagnostic yield is less than for biopsy of an affected nerve. On the basis of the smaller size of affected vessels and the presence of perinuclear antinuclear cytoplasmic autoantibodies (p-ANCA), Lhote et al have differentiated a "microscopic" polyarteritis—an entity with which we have had little experience. Rapidly progressive glomerulonephritis and lung hemorrhage are the additional features of the latter disease, neuropathy occurring somewhat less frequently than in typical polyarteritis.

Treatment Mononeuropathy multiplex due to polyarteritis calls for treatment with corticosteroids and cyclophosphamide. We have used intravenous methylprednisolone, 1.5 mg/kg, for several days, followed by oral corticosteroid treatment, and cyclophosphamide, 1 g/m² intravenously once a month for several months, but other equivalent regimens have been suggested. Azathioprine is a reasonable alternative if cyclophosphamide is not tolerated. Treatment must be continued for at least several months. In intractable cases and in those with systemic involvement, treatment with methotrexate may be indicated. Spontaneous remission and therapeutic arrest are known, but many cases have a fatal outcome from kidney and systemic complications. The infarctive nerve palsies and sensory loss of the mononeuropathies generally persist to some degree even when the systemic disease is brought under control.

Churg-Strauss and Hypereosinophilic Syndrome These closely related systemic illnesses involve multiple individual peripheral nerves, much as in polyarteritis. The additional characteristic feature is an excess of circulating and tissue eosinophils (more so than in polyarteritis) and a tendency to involve the lungs and skin, in contrast to the typical renal and bowel infarctions of polyarteritis nodosa. There is, however, a considerable degree of pathologic and clinical overlap between polyarteritis and Churg-Strauss necrotizing vasculitis with asthma and vasculitic skin lesions and a more benign asthma-eosinophilia syndrome that is less aggressive and has a greater tendency for eosinophilic infiltration of other tissues. A medication (zaflurkast) that is used in Europe to treat asthma is said to have precipitated several cases of Churg-Strauss disease. Rarely, the illness has been preceded by treatment with a macrolide antibiotic (e.g., azithromycin), estrogen, and carbamazepine but these associations are uncertain and almost all cases are idiopathic.

As stated, the Churg-Strauss syndrome has many similarities to polyarteritis; indeed, the original article by Churg and Strauss in 1951 was meant in part to distinguish the two diseases on the basis of “allergic granulomas” and eosinophilic infiltrates that involved many organs. However, similar lesions within the skin and lungs have been reported from time to time in polyarteritis nodosa. Moreover, they are found in diseases such as Wegener granulomatosis, lupus erythematosus, rheumatoid disease, lymphoma, and endocarditis, but the eosinophilic infiltration is less pronounced than in Churg-Strauss syndrome. We have seen other types of cutaneous disease with vasculitic mononeuritis, the most impressive being a massive leukocytoclastic vasculitis of the skin (necrotic polymorphonuclear cells surrounding venules) resulting in large confluent hemorrhagic lesions.

In Churg-Strauss disease, rhinitis or asthma may be present for years and only later is there marked eosinophilia and organ infiltration, particularly an eosinophilic pneumonitis. The neuropathy, which then develops in approximately three-quarters of patients is usually preceded by fever and weight loss and takes the form of an acute, painful mononeuritis multiplex. The granular cytoplasmic pattern of antineutrophil cytoplasmic autoantibodies (c-ANCA) of the same type that occurs in Wegener granulomatosis is found in over half of cases (see later). An infarctive vasculitis involving the vasa nervorum can be detected in sural nerve biopsy, the special histologic feature possibly being a more intense eosinophilic infiltration than is usually seen in polyarteritis nodosa.

The *idiopathic eosinophilic syndrome* comprises a heterogeneous group of disorders, the common features of which are a persistent and extreme degree of eosinophilia and eosinophilic infiltration

of many organ systems. Neuropathy occurs in less than half of the cases, taking the form of a painful diffuse sensorimotor syndrome with axonal damage or of a mononeuritis multiplex (see Moore et al). The pathologic appearance is one of diffuse infiltration of the nerves by eosinophils rather than a vasculitis. The clinical effects are attributable to the infiltration itself or to a postulated tissue-damaging effect of the eosinophilic cell.

Treatment Both the Churg-Strauss and the idiopathic hypereosinophilic syndrome are treated with high doses of corticosteroids, after which the peripheral eosinophilia as well as tissue damage abate in several weeks or months. Further immunosuppressive treatment in the form of azathioprine, chlorambucil, or cyclophosphamide has been used in fulminant or refractory cases, which includes most of the ones that we have seen.

Wegener Granulomatosis (Necrotizing Granulomatous Vasculitis) This disorder gives rise to two neuropathic syndromes—one a symmetrical or asymmetrical multiple mononeuropathy indistinguishable from the other angiopathic neuropathies described earlier, the other involving the lower cranial nerves directly as they exit the skull and pass through the retropharyngeal tissues. The frequency of peripheral nerve involvement in Wegener disease is much lower than in the other classic vasculitides. Furthermore, the affected vessels are of a smaller caliber than in polyarteritis nodosa. Nonetheless, deGroot and colleagues have emphasized in a prospective analysis of 128 patients with Wegener disease that 25 had evidence of mononeuritis multiplex with the peroneal nerve most often involved and an even greater number, with a distal polyneuropathy. The proportion of their cases in which the neuropathy was the presenting or sole manifestation of disease was higher than in other similar series. The finding of circulating c-ANCA is relatively specific for Wegener granulomatosis and for Churg-Strauss disease, as mentioned earlier (Specks et al) and helps to differentiate it from polyarteritis (which displays p-ANCA) and from carcinoma, chordoma, sarcoidosis, and zoster. This vasculitis and its effects on the lower cranial nerves is discussed further on page 1189.

Essential Mixed Cryoglobulinemia This process may be associated with a vasculitic mononeuritis multiplex as well as a more generalized polyneuropathy. In many cases, glomerulonephritis, arthralgias, and purpura are conjoined, reflecting the systemic nature of the vasculopathy, but the mononeuritis may occur in isolation. The evolution in the cases under our care has been slower than in the typical vasculitic neuropathies, sometimes taking weeks or months between attacks of mononeuritis. The neurologic disorder may become quiescent for long periods, during which time considerable improvement may occur. There is no evident relationship between the mode of onset or severity of the neuropathy and the concentration of cryoprecipitable proteins in the serum. These proteins can be detected by cooling the serum and demonstrating a precipitation of IgG and IgM proteins that redissolve upon warming to 37°C (98.6°F). To demonstrate this phenomenon the blood sample must be carefully transported to the laboratory in a warm water bath. An association with hepatitis C is well known but most patients with cryoglobulinemia have manifested mononeuritis without this infection.

Treatment Garcia-Bragado and colleagues have suggested that the neuropathy can be stabilized by corticosteroids and cyclophosphamide. In our experience, plasma exchange has also been beneficial, but this therapeutic measure has not been systematically tested. Other aspects of the condition are discussed further on under

"Polyneuropathy Associated with Paraproteinemia" and under "Other Vasculitic Neuropathies."

Rheumatoid Arthritis Some 1 to 5 percent of patients with rheumatoid arthritis have vasculitic involvement of one or more nerves at some time in the course of their disease, apart from more mundane pressure neuropathies due to thickened tendons and destructive joint changes. The arteritis is of small-vessel fibrinoid type and immune globulins are demonstrable in the walls of vessels. Most of the affected patients have had severe rheumatic disease for many years and are strongly seropositive. In addition to the neuropathy, such patients often have rheumatoid nodules, skin vasculitis, weight loss, fever, a high titer of rheumatoid factor, and low serum complement.

There are also rarer forms of chronic progressive polyneuropathy that complicate rheumatoid arthritis; they are described further on.

Lupus Erythematosus Approximately 10 percent of patients with lupus will exhibit symptoms and signs of peripheral nerve involvement. Usually the neuropathy appears in the established and more advanced stages of the disease, but rarely it has been the initial presentation. In several of our cases the polyneuropathy has taken the form of a symmetrical, progressive sensorimotor paralysis, beginning in the feet and legs and extending to the arms, evolving over a period of several days or weeks and at times simulating GBS. In a few, weakness and areflexia were more prominent than the sensory loss; the latter involved mainly vibratory and position senses. A more common syndrome in our experience has been a progressive or relapsing disease that cannot be distinguished clinically from chronic inflammatory demyelinating polyneuropathy (discussed further on). Multiple mononeuropathies have also been reported, as has involvement of the autonomic nervous system. An elevation of CSF protein in some cases suggests nerve root involvement. Sural nerve biopsies may show vascular changes consisting of endothelial thickening and mononuclear inflammatory infiltrates in and around the small vessels for which reason the disease is included here with the other vasculitic neuropathies. Axonal degeneration is the most common change, but a chronic demyelinating pathology has also been described (Rechthand et al.). Vascular injury from deposition of immune complexes is the proposed mechanism of nerve damage.

Isolated (Nonsystemic) Vasculitic Neuropathy In contrast to the aforementioned disorders, which characteristically involve several tissues and organs in addition to the peripheral nerves, a necrotizing vasculitis may be limited to nerves. In our hospitals a case of this type appears about twice a year, i.e., about as often as all the other systemic vasculitic types put together. This restricted form usually presents as a subacute symmetrical or asymmetrical polyneuropathy with superimposed mononeuropathies or with multiple mononeuritis; circulating ANCA is found in some cases. It is notable that in the series reported by Collins and colleagues, the sedimentation rate was generally only mildly elevated, the mean being 38 mm/h, with only one quarter having values greater than 50 mm/h. The neuropathy tends to be indolent and less aggressive (and nonlethal) than the systemic forms of vasculitic neuropathy and has not always required treatment with cyclophosphamide (Dyck et al., 1987). Steroids in high doses have prevented progression of the disease. However, in the aforementioned series by Collins, the use of cyclophosphamide for 6 months with corticosteroids resulted in a

more rapid remission and fewer relapses. The main difficulty in diagnosis arises when the EMG performed early in the course of illness shows conduction block that simulates a demyelinating polyneuropathy. Nerve biopsy should then settle the issue.

Other Vasculitic Neuropathies In the past, administration of pooled serum for the treatment of infections often led to brachial neuritis (page 1163) and also to an immune mononeuritis multiplex, presumably from deposition of antibody-antigen complexes in the walls of the vasa nervorum. A similar "serum sickness" may occur after certain viral infections that have caused arthritis, rash, and fever. The neuropathy that arises with hepatitis C infection may also be of this type, perhaps mediated by a frequently associated cryoglobulinemia as mentioned earlier. Interferon, which has been effective in treating the hepatitis, may also ameliorate the neuropathy, but greater success has been achieved with cyclophosphamide. Pooled immunoglobulin for the treatment of diverse neuromuscular diseases has not, to our knowledge, led to a serum-sickness neuropathy, but one of our patients with Churg-Strauss disease developed a fulminating vasculitic skin eruption while being treated with IVIG.

In two cases of severe systemic vasculitis related to administration of hydralazine, we observed no neuropathic features; whether this applies to other drug-induced vasculitides is not known. The increasing appearance of vasculitic neuropathy with *HIV infection*, including a type that is probably independent of CMV infection, has already been mentioned; such cases have tended to improve spontaneously or with corticosteroid therapy. In about half of these cases of this type the CSF shows a predominance of polymorphonuclear cells. Also, from time to time a patient with a lymphoproliferative disorder such as Hodgkin disease will develop mononeuritis multiplex that is found by biopsy to be due to vasculitis. (A chronic demyelinating, nonvasculitic polyneuropathy is more common with lymphomas of any type as discussed earlier.)

A rare paraneoplastic variety of vasculitic neuropathy has been described. Oh reported two of his own cases and reviewed 13 previous ones. The most common underlying cancer was of the small oat cell lung type. The anti-Hu antibodies that are typical of paraneoplastic neurologic diseases from this cancer are generally not detected. Other solid tumors (renal, gastric, etc.) have been associated with a similar neuropathy but only in a few instances. Almost all have a slightly elevated protein concentration in the CSF, but few had a pleocytosis. At autopsy, the vasculitis was limited to nerve and muscle.

The role of small-vessel vasculitis in obscure axonal polyneuropathies of elderly patients is controversial. We have not found, as did by Chia and colleagues, an unexpected vasculitis in the nerve biopsies of such patients. The vaso-occlusive and infiltrative condition of intravascular lymphoma often includes a syndrome of multiple painless mononeuropathies.

Neuropathy Due to Critical Limb Ischemia A number of patients with severe atherosclerotic ischemic disease of the legs will be found to have localized sensory changes or impairment of reflexes. Usually the other effects of ischemia—claudication and pain at rest, absence of distal pulses, and trophic skin changes—are so prominent that the neurologic changes are overlooked. In experimental studies, combined occlusion of the aorta and many limb vessels are required to produce nerve ischemia because of the profusely ramifying neural vasculature. In our experience of

12 patients with a critically ischemic leg, there was a neuropathy with a pronounced distal predominance—sensory loss in the feet was worse than the symptoms might suggest and there was only mild weakness of the toes and depression or loss of the ankle reflex (Weinberg et al). Although paresthesias, numbness, and deep aching pain were characteristic, the patients were more limited by symptoms of their vascular claudication than the neuropathic ones. Restoration of circulation to the limb by surgical or other means resulted in some improvement of the regional neuropathy. Reviews of the literature on this subject are to be found in the writings of Chalk et al and Eames and Lange.

A poorly understood but presumably localized ischemic neuropathy occurs in the region of arteriovenous shunts that have been placed for the purpose of dialysis. Complaints of transient diffuse tingling of the hand are not uncommon soon after creation of the shunt, but only a few patients develop persistent forearm weakness and numbness and burning in the fingers, reflecting variable degrees of ulnar, radial, and median nerve and possibly also muscle ischemia. The possible role of an underlying uremic polyneuropathy in facilitating this neuropathy has not been studied.

A progressive, symmetrical polyneuropathy due to systemic cholesterol embolism has been described by Bendixen and colleagues. An inflammatory and necrotizing arteritis surrounds embolic cholesterol material within small vessels and appears to account for the progression of symptoms. This neuropathic process is probably more often discovered at autopsy than it is in the clinic, being eclipsed during life by the cerebral manifestations of cholesterol embolism. The entire illness simulates the generalized polyneuropathy of a small-vessel polyarteritis.

Sarcoidosis Sarcoidosis infrequently produces subacute or chronic polyneuropathy, polyradiculopathy, or mononeuropathies. A painful, small-fiber sensory neuropathy has also been described by Hoitsma and colleagues. Either type of neuropathy may be associated with granulomatous lesions in muscles (polymyositis) or with signs of CNS involvement, most often of the stalk of the pituitary with diabetes insipidus or a myelopathy.

Involvement of a single nerve with sarcoid most often implicates the facial nerve (facial palsy), but sometimes multiple cranial nerves are affected in succession (see page 1183). Or, there may be weakness and reflex and sensory loss in the distribution of one or more spinal nerves or roots. The occurrence of large, irregular zones of sensory loss over the trunk is said to distinguish the neuropathy of sarcoidosis from other forms of mononeuropathy multiplex. This type of sensory loss, particularly when accompanied by pain, resembles diabetic radiculopathy (see earlier).

Unlike the cases we have reported (Zuniga et al), in the series of 11 patients with sarcoid neuropathy studied by Said and colleagues, only 2 were known to have pulmonary sarcoidosis before the onset of neuropathic symptoms. Six had a focal or multifocal syndrome (including one with a clinical and electrophysiologic pattern that simulated multifocal conduction block). The remainder had a more nondescript symmetric polyneuropathy, one of acute onset. Facial diplegia was common, as is well known. The pathologic changes in nerve and muscle biopsy specimens consisted mainly of epineurial granulomas and endoneurial inflammatory infiltrates, but there were indications of necrotizing vasculitis in 7 cases. Among the cases we studied, 6 of 10 had a subacute or chronic sensorimotor polyneuropathy. It is notable that in only 2 of their patients were levels of angiotensin-converting enzyme elevated in the serum.

Lyme Disease (See also page 618) The neuropathy that develops in 10 to 15 percent of patients with this disease takes several forms. Cranial nerve involvement is well known, uni- or bilateral facial palsy being by far the most frequent manifestation (page 1182). Other cranial nerves are from time to time also affected and the disease may affect almost any of the somatic roots, most evident in the cervical or lumbar ones. Even phrenic nerve palsy has been attributed to Lyme disease in a few cases. An aseptic meningoradiculitis giving rise to a pleocytosis is particularly characteristic (although this may also occur in HIV and CMV and other forms of neuritis). Some of the CSF cells at times have immature features suggesting a lymphomatous infiltration. There may be radicular pain not unlike that of cervical or lumbar disc or plexus disease. The triad of cranial nerve palsies, radiculitis, and aseptic meningitis is characteristic of Lyme disease during its disseminated phase, i.e., from 1 to 3 weeks after the tick bite or the appearance of the typical rash. The disease tends to be seasonal in the period of maximal tick exposure. As to peripheral neuropathy with Lyme disease, the clinical situation is more complex. Several patterns of neuropathy have been recognized and they tend to appear some months after the Lyme infection and may last for years hence observing no seasonal pattern.

Besides the previously described cranial neuropathies, the following are the main neuropathic syndromes of Lyme disease: (1) multiple mononeuropathies (involvement of a single major nerve in the limbs, resulting in an isolated foot or wrist drop, is, however, distinctly rare); (2) a lumbar or brachial plexopathy (the latter being well described but rare); (3) a predominantly sensory polyneuropathy in which paresthesias and loss of superficial sensation in the feet and legs are coupled with loss of ankle jerks; (4) a generalized axonal polyneuropathy (Logigian et al), mainly sensory and sometimes accompanied by a mild encephalopathy; and (5) acute GBS (we have encountered only two such cases in over 400 patients with Guillain-Barré). Electrophysiologic testing indicates that the various peripheral nerve syndromes frequently overlap. All of the preceding processes excepting the one that resembles GBS usually occur as subacute or late complications of Lyme disease, several months or rarely years after the initial infection (in untreated cases). These later neuropathic syndromes respond less favorably to treatment than do the acute ones (see further on).

There are few adequate pathologic studies of the peripheral nerves in Lyme disease, since the disease is not fatal. No one has demonstrated the infective agent in the nerves, although this has been one of the suggested targets of disease.

Bannwarth Syndrome Special mention is made of an intensely painful lumbosacral polyradiculitis that has long been known in Europe under the term *Bannwarth syndrome* (in France it is known as Garin-Bujadoux syndrome). The pathogen is probably a spirochete slightly different from the one that causes Lyme disease in North America. In the Bannwarth syndrome, and in occasional cases of otherwise typical Lyme disease, there is an intense inflammatory reaction in the cauda equina giving rise to sciatic and buttock pain and bladder disorder. Less frequently a cervical polyradiculopathy occurs with shoulder and arm pain that we have been unable to distinguish on clinical grounds from brachial neuritis. The EMG, however, shows a preservation of sensory potentials, which marks the process as radicular rather than plexal (see further on). Headache and a brisk pleocytosis in the spinal fluid may accompany the pain and usually precedes radiculopathies by days. It should be commented that a similar syndrome of lumbar polyradiculitis may also be caused by the herpes and Epstein-Barr viruses

or more often by an opportunistic CMV infection in a patient with AIDS.

Diagnosis This is both aided and at times confused by serologic testing (see Chap. 32). The enzyme-linked immunosorbent assay (ELISA) is not altogether satisfactory because it frequently yields false-positive and, occasionally, false-negative results. Western blot testing is more specific. Knowledge that the patient has lived in or visited an endemic area is useful but far more important is evidence of a tick bite followed by the characteristic rash or a well-defined history of nonneurologic manifestations of Lyme disease (cardiac, arthritic). Indeed, one should be cautious in making this diagnosis unless a primary Lyme infectious syndrome had been present. Bifacial palsy in any of these clinical contexts also favors the diagnosis.

Treatment Treatment of the neuropathic disease is with intravenous antibiotics, preferably ceftriaxone 2 g daily for 1 month. Corticosteroids have an uncertain role in the painful radicular syndromes but we have used them in low doses and they apparently relieved the pain.

Sjögren-Sicca Syndrome This is a chronic, slowly progressive autoimmune disease characterized by lymphocytic infiltration of the exocrine glands, particularly the parotid and lacrimal glands resulting in keratoconjunctivitis sicca and xerostomia (dry eyes and mouth). The latter features may be combined with arthritis or with a wide range of other abnormalities, notably lymphoma, vasculitis, renal tubular defects, and quite often by a predominantly sensory polyneuropathy (see review by Kaplan et al). In the series collected by Grant and colleagues, the neuropathy was the presenting problem in 87 percent of 54 patients with the sicca complex. The sicca symptoms are usually mild and often reported only upon specific inquiry. A symmetrical sensory polyneuropathy or sensory ganglionopathy is the most common pattern. Sensorimotor polyneuropathy, polyradiculoneuropathy, autonomic neuropathy, or mononeuropathy (most often of the trigeminal nerve, as described by Kaltreider and Talal) are less common. We have observed yet another neuropathic syndrome taking the form of an asymmetrical sensory loss, mostly of position sense and involving the upper limbs predominantly, in association with tonic pupils and trigeminal anesthesia.

The sensory polyneuropathy of the Sjögren syndrome—more of an inflammatory ganglionitis or sensory neuronopathy (Griffin et al)—is of particular interest to neurologists, since most cases will first be seen by them. More than 90 percent of the patients are older women. The sensorimotor polyneuropathic syndrome begins with paresthesias of the feet and is usually mild in degree. The main clinical features are a subacute and widespread sensory loss that may include the trunk and a profoundly diminished kinesthetic sense, giving rise to sensory ataxia of the limb and of gait. Loss of pain and temperature sensation is variable; tendon reflexes are abolished. In time, many of these patients develop autonomic abnormalities such as bowel atony, urinary retention, loss of sweating, and pupillary changes. There is usually little or no pain but there have been exceptions.

Diagnosis Sjögren syndrome should be suspected in an older woman with sensory neuropathy or neuronopathy, particularly if sicca symptoms are present. The evaluation of suspected Sjögren disease is aided by the Schirmer or Rose Bengal tests (page 461), which can demonstrate a reduction of tearing. Even without this confirmatory test, we have found it advisable to perform a biopsy of the lip (at the epithelial-mucosal juncture) to detect inflammatory

changes in the small salivary glands. This is a minor office procedure in most instances. The diagnosis of Sjögren syndrome requires the detection of at least two collections of 50 or more lymphocytes in a 4 mm² specimen. Some patients have serologic abnormalities such as antinuclear antibodies (anti-Ro, also termed SS-A, and anti-La, or SS-B) or increased monoclonal immunoglobulins, particularly of the IgM subclass. The frequency of these specific Sjögren-specific antibodies varies greatly between series; they may be useful as screening tests, but the lip biopsy is a far more sensitive diagnostic procedure. In our series of 20 cases with salivary gland biopsies that demonstrated inflammatory changes diagnostic of the syndrome, only 6 had serologic evidence of the disease and two had positive serologic tests but a negative biopsy (Gorson and Ropper). The sedimentation rate in our patients was often slightly elevated, however, only 5 of our 20 had a value greater than 40 mm/min. The main differential diagnostic entity is a paraneoplastic sensory ganglionitis.

Mellgren and also Leger and their colleagues have stressed the point that a proportion of unexplained polyneuropathies in middle and late life are caused by Sjögren syndrome. The latter authors found typical Sjögren abnormalities in the lip biopsies of 7 of 32 patients with chronic axonal polyneuropathy that could not otherwise be classified. Several other studies have corroborated this finding of inflammatory disruption of the minor salivary glands in obscure neuropathies, particularly in older women and in some men. The diagnosis in our clinics, where lip biopsies are routinely performed in patients with nondescript sensory neuropathies, has not been nearly as frequent. Nonetheless, a search for Sjögren disease may be revealing in otherwise obscure sensory neuropathies.

Nerve biopsies in some cases have revealed a necrotizing vasculitis, inflammatory cell infiltrates, and focal nerve fiber destruction. Usually, the CSF protein is normal and there is no cellular reaction. The few times a dorsal root ganglion has been examined, there were infiltrates of mononuclear cells and lymphocytes and destruction of nerve cells.

Treatment Treatment of the sicca complex and the neuropathic manifestations is unfortunately largely symptomatic. Corticosteroids, cyclophosphamide, and chlorambucil have been used when the neuropathy is severe and are indicated when there is vasculitis involving renal and pulmonary structures. We have administered prednisone 60 mg daily, often in tandem with intermittent plasma exchange, with little evidence of response. In a few severe cases, monthly intravenous cyclophosphamide has been added. Others have recorded more encouraging results.

The review of the neurologic manifestations of Sjögren syndrome by Lafitte is recommended.

Idiopathic Sensory Ganglionopathies (Chronic Ataxic Neuropathy) In addition to the subacute palsensory syndrome described above and paraneoplastic, postinfectious, or toxic processes (page 1128), there is a more chronic idiopathic variety characterized by severe global sensory loss and ataxia. We have encountered several such patients with sensory loss and pronounced ataxia resembling the cases described by Dalakas. The numbness and sensory findings progressed over months and spread to proximal parts of the arms and legs and then to the trunk. The face and top of the scalp were finally involved. Despite severe ataxia and complete areflexia, muscular power remained normal. Pain was not a problem. There are reports of fasciculations in a few patients (but not in the ones we have seen). Within a year, most of these patients became completely disabled from the ataxia, unable to walk or even

feed themselves. Autonomic failure was another feature in a few, and one of ours became deaf. Extensive examinations for an *occult cancer*, *paraproteinemia*, *Sjögren disease*, *Refsum disease*, *autoimmune diseases*, and all potential causes of an ataxic neuropathy, proved to be frustratingly negative. Of course, it is possible that some patients had an as yet undiscovered tumor. Yet other instances have had all the features of a truncal-limb sensory neuropathy, with little or no ataxia and only muted reflexes; these have had a more benign course but still no cause was found (why most of our patients have been male physicians, as reported by Romero, is entirely unclear). Illa and colleagues, in a review of 17 patients with idiopathic sensory ataxic neuropathy found antibodies against the ganglioside GD₁ in only one case, and concluded that the majority were not due to an immunologic mechanism.

The motor nerve conduction studies have been normal or slightly impaired, while the sensory potentials were eventually lost (but they may at first be normal). A puzzling feature in two patients has been an unexpected preservation of many sensory nerve potentials even after a year of illness. In these cases the process presumably lay in the dorsal roots rather than in the ganglia. In a few instances the MRI has shown a change in the posterior columns of the spinal cord, presumably secondary to root disease. The spinal fluid has generally contained a slightly elevated protein concentration with few or no cells, up to 18 /mm³ in our cases.

Pathologic examination of the sensory ganglia in a few cases has exposed an inflammatory process identical to that of Sjögren disease. Our attempts at treatment using plasma exchanges, IVIG, corticosteroids, and immunosuppressive agents have been mostly unsuccessful.

Idiopathic Autonomic Neuropathy Under this term is collected a group of dysautonomias that on extensive evaluation cannot be attributed to diabetes or amyloidosis. A fair number, almost half in the series of Suarez and colleagues, are acute in onset and conform to the “pure pandysautonomia” condition described by Young and colleagues and discussed earlier as a variant of GBS. The others, however, pursue a subacute or chronic course and about one quarter of these has an associated serum antibody that is directed against the acetylcholine receptor of sensory ganglia (Klein et al). Orthostatic hypotension is the leading feature and in those with the previously mentioned antibody, pupillary changes and difficulty with accommodation, dry mouth and dry eyes, and gastrointestinal paresis were the most common findings according to Sandroni and colleagues. Perhaps another subgroup is in some way related to Sjögren syndrome since sicca symptoms are prominent but these later features could just as well be a component of the autonomic failure and the appropriate antibodies have been found only rarely.

There is not enough information to determine if all these cases are accounted for by one process or to judge the effects of various immune treatments.

Migrant Sensory Neuropathy (Wartenberg Syndrome) The defining feature of this syndrome is a searing and pulling sensation involving a small cutaneous area of a limb evoked by extending or stretching the limb, as happens when reaching for an object with the extended arm and hand, or when kneeling, or pointing with the foot. The pain is momentary but leaves in its wake a patch of numbness. Cutaneous sensory nerves must be involved in some way and are irritated during such a maneuver. Often the area involved is proximal to the most terminal sensory distribution of the nerve, encompassing, for example, a patch on the lateral side of

the hand and the proximal fifth finger or a larger region over the patella (the sites affected in three of our patients). Recovery of the patch of numbness takes several weeks but it may persist if the symptoms are induced repeatedly. Except for these patches of cutaneous analgesia, the clinical examination is normal. Selected sensory nerves may show abnormalities in conduction. Matthews and Esiri have listed the many areas that may be affected in a single patient and have described an increase in the endoneurial connective tissue in a biopsied sural nerve. The process may come in episodes over many years, without symptoms between attacks. A spurious diagnosis of multiple sclerosis is often made. The pathology is not known but some form of fibrosis or inflammation of cutaneous nerves has been suggested, perhaps in some way similar to the condition described below.

Sensory Perineuritis Under this title, Asbury and colleagues described a patchy, painful, partially remitting distal cutaneous sensory neuropathy. The pathologic picture was one of inflammatory scarring restricted to the perineurium, with compression of the contained nerve fibers. As with the Wartenberg syndrome earlier, the reflexes and motor function were unaffected. Digital nerves as well as the medial and lateral branches of the superficial peroneal nerve were the ones most often involved. Matthews and Squier have described a trigeminal and occipital distribution of painful sensory symptoms, and one of the patients of Asbury and coworkers also had symptoms on the scalp. A Tinel sign is characteristically elicited by tapping the skin overlying the involved cutaneous nerves and is indicative of partial nerve damage and regeneration. The differential diagnosis includes numerous other forms of painful sensory neuropathy but the patchy and painful and often burning quality of symptoms distinguishes this process. The diagnosis can only be established with certainty by biopsy of a distal cutaneous branch of a sensory nerve. Perhaps some of the large group of patients with “burning” feet may have a small-fiber neuropathy that affects intradermal nerve fibers in a similar way (see further on).

Since the original report, the fibrosing perineurial pathologic changes that characterize perineuritis have been described in a number of polyneuropathies, mainly in diabetic patients but also in those with cryoglobulinemia, nutritional diseases, and malignancies (Sorenson et al). However, these patients displayed a diversity of clinical patterns of neuropathy, mainly mononeuritis multiplex and demyelinating neuropathy. These findings indicate that the pathologic feature of perineuritis may be less specific than initially thought but the perineuritis clinical syndrome is still a useful concept. A proportion of the idiopathic cases respond to corticosteroids.

Celiac-Sprue Disease Among the multitude of odd neurologic manifestations attributed to this disease (see pages 977 and 1001) the best known are a cerebellar ataxia and myoclonus. In addition, Hadjivassiliou and colleagues have reported patients with a range of neuromuscular disorders in whom the neurologic symptoms antedated the diagnosis of the bowel disorder. A nondescript sensorimotor neuropathy was the most frequent complication, but one patient was said to have a mononeuritis multiplex. In a small prospective survey of treated celiac disease, Luostarinen and colleagues found 23 percent with evidence of a polyneuropathy by EMG testing but the clinical findings were scant. Antigliadin antibodies (simple antibodies directed against gluten), as well as more specific antitransglutaminase antibodies and histologic examination of a duodenal biopsy are confirmatory of the diagnosis. Luos-

tarinan et al have suggested that a search be made for these antibodies in patients with polyneuropathies of obscure origin. It is not clear how many of their cases could be attributed to nutritional deficiency. We have not encountered a definite case despite systematic attempts to detect the special antibodies in the evaluation of obscure neuropathies.

Numerous other systemic diseases have reportedly been conjoined with peripheral neuropathy, among them, temporal arteritis. In most of these anecdotal reports it is impossible to interpret etiologic relationships.

Syndrome of Polyradiculopathy with or without Meningeal Infiltration

These are among the most clinically complex diseases of the peripheral nerves. Involvement of multiple spinal nerve roots produces a distinctive but sometimes confusing constellation of findings, usually quite different from those of polyneuropathy and from multiple mononeuropathies. As described earlier, muscle weakness due to polyradiculopathy is characteristically asymmetrical and variably distributed in proximal and distal parts of the limbs, reflecting the fact that the involved muscles have a common root innervation (for example, the combination of hamstring and gastrocnemius, or of iliopsoas, quadriceps, and obturator). However, muscles with similar innervation are not necessarily affected to the same degree because of the disproportionate contribution of a given root to each muscle it supplies. Sensory loss tends also to be similarly patchy and to involve both the proximal and distal aspects of a dermatome. As a rule, pain is common (though not invariable) while the sensory findings tend to be less prominent than the motor ones. In keeping with nerve root pattern, certain tendon reflexes may be spared; a normal ankle jerk combined with an absent knee jerk, or the opposite, are particularly suggestive of a polyradiculopathy (or a lumbar plexopathy). Pain often takes the form of sharp jabs projected into the innervated zone of the involved root. As with mononeuritis multiplex, the cumulative effect of multiple root lesions can simulate a polyneuropathy in which case the tendency for polyradiculopathy to involve proximal muscles is the most helpful distinguishing feature.

A special pattern of polyradiculopathy may occur wherein all the sensory roots are involved diffusely. The clinical state is similar to that of a sensory ganglionopathy described earlier. Large- and small-fiber sensory loss is combined with ataxia while power is normal and there is no atrophy. A prominent feature is shooting and burning pain. We have also occasionally found sensory loss over the anterior abdomen and thorax, a finding more typical of chronic dying-back axonal polyneuropathy.

Some of the diseases that affect nerve roots solely or predominantly have already been discussed. They can be grouped into three broad categories: (1) diseases of the spinal column that compress adjacent roots; (2) infiltrative diseases of the meninges that secondarily involve the roots as they course through the subarachnoid space, including neoplastic granulomatous infiltration; and (3) intrinsic neuropathies, usually inflammatory, infectious, or diabetic, that have a predilection for the radicular portion of the nerves. An elevated CSF protein and a pleocytosis usually accompany neoplastic or inflammatory meningeal diseases; the others show variable formulas in the spinal fluid.

Often what appears to be a polyneuropathy on clinical grounds turns out to have an electrophysiologic pattern of root disease at multiple spinal levels. McGonagle and colleagues estimated that

polyradiculopathies accounted for 5 percent of all cases referred to their EMG laboratory and our experience approximates this. Careful EMG testing is therefore the most useful ancillary examination in cases of complex neuropathic syndromes since the pattern of muscle denervation can be ascertained and a common root pattern can then be logically derived. Of great confirmatory value is the preservation of sensory potentials in nerves that innervate regions of sensory loss and supply weak and denervated muscles. This proves that the lesion is located proximal to the dorsal root ganglion and spares the peripheral sensory axons. Loss of the F and H late responses is also typical of polyradiculopathies (see page 1100). The proximal location of the lesion can be further corroborated by early evidence of weakness and denervation in the paraspinal, gluteal, or rhomboid muscles, which are supplied by nerves that arise very proximally from the roots. In axonal neuropathy, these proximal muscles are the last to be involved.

Among the acute and subacute meningeal radiculopathies, neoplastic infiltration (carcinomatous and lymphomatous) is the most common. Others are Lyme disease, sarcoidosis, herpes genitalis, arachnoiditis, AIDS-related cauda equina neuritis of CMV infection, or independently by EBV. In the past, meningeal syphilis was a common cause. Diseases of the spine, exemplified by lumbar and cervical spondylosis, commonly impinge on nerve roots, as discussed in Chap. 11. Metastatic carcinoma of the vertebral bodies may compress one or several adjacent roots by encroaching on posterolateral recesses of the canal and proximal neural foramina. Among rarer causes of polyradiculopathy is a chronic lumbosacral syndrome associated with dural eventrations surrounding nerve roots which may complicate ankylosing spondylitis (see page 180).

Finally, it should be mentioned that one is confronted not infrequently by a subacute or chronic polyradiculopathy and abnormal CSF formula, for which extensive examination fails to identify any one of the diseases enumerated above. This idiopathic form of polyradiculopathy comes to our attention once or twice yearly. Some will turn out to have a lymphomatous infiltration at autopsy for which reason we have on occasion asked our neurosurgeons to remove a midlumbar motor rootlet for examination. Also particularly difficult diagnostically is a polyradiculopathy that involves the motor roots exclusively or predominantly that is distinguishable from motor neuron disease except for the complete absence of widespread denervation or of progressive upper motor neuron signs and, differing from the immune motor neuropathies discussed further on, by the absence of conduction block.

SYNDROME OF CHRONIC SENSORIMOTOR POLYNEUROPATHY

In these syndromes, impairment of sensation, weakness, muscular atrophy, and loss of tendon reflexes progress over a period of many months or years. Within this large category, two groups are distinguished. In the first and *less chronic* of the two groups the neuropathy develops over a period of months or a year or two. Comprising this group are mainly *acquired* processes such as certain metabolic and immune-mediated polyneuropathies. Paraneoplastic neuropathies may also fall into this category though they are more often subacute in onset, being almost fully developed in a matter of months or less. Leprous neuritis is the one infectious member of this group and also the one exception to the rule that all chronic neuropathies are more or less symmetrical in pattern. The polyneuropathies that make up the second group are *far more chronic* than

the first, evolving insidiously over many years or decades. Constituting this second group are mainly the *heredodegenerative* diseases of the peripheral nervous system.

Acquired Forms of Chronic Polyneuropathy

Polyneuropathy Associated with Paraproteinemia The occurrence of a chronic sensorimotor polyneuropathy in association with an abnormality of serum immunoglobulins is recognized with increasing frequency but its boundaries are still not well established as will be apparent in the following discussion. The excess blood protein, called a *paraprotein*, or an M-spike is usually in the form of a monoclonal immunoglobulin. It may be an isolated abnormality or a by-product of a plasma cell malignancy, specifically multiple myeloma, plasmacytoma, or Waldenstrom macroglobulinemia. Several lines of evidence suggest that a pathogenetically active antibody against components of myelin or axon is present in at least some of these diseases. Special forms of neuropathy are also associated with amyloidosis. Both the acquired and genetic forms of amyloidosis are discussed further on.

Monoclonal Gammopathy of Undetermined Significance (MGUS, Benign Monoclonal Gammopathy) The association of a nonneoplastic IgM monoclonal protein and a neuropathy was first described by Forssman and colleagues and was treated as coincidental until Kahn established a compelling statistical association between them. A more direct relationship was established by the finding of antiperipheral nerve antibodies in some patients who had such a protein in their blood. This important category of polyneuropathy is associated with a nonneoplastic monoclonal or polyclonal excess of immunoglobulin (IgG, IgM, or IgA, rarely others; see reviews of Kyle and Dyck and of Thomas and Willison). These cases are far more common than those with malignant plasma cell disorders. In our experience, monoclonal proteins underlie the largest group of otherwise unexplained neuropathies in adults.

The polyneuropathy associated with monoclonal gammopathy affects mainly, but not exclusively, males in the sixth and seventh decades of life. The onset is insidious over weeks or months with numbness and paresthesias of the feet and then of the hands, followed by a relatively symmetrical weakness and slight wasting of these muscles over a year or so. In some patients sensory signs predominate. The tendon reflexes, eventually lost or diminished, may be preserved in the early phases of the illness. The course is usually slowly progressive, sometimes static after a year or so and rarely remitting and relapsing. The CSF typically shows an elevation of the protein in the range of 50 to 100 mg/dL and this is not due to passive diffusion of the excess paraprotein into the CSF.

The majority of cases of polyneuropathy with monoclonal gammopathy have a demyelinating or mixed axonal-demyelinating pattern in the EMG, but once the illness is well established most will have predominantly axonal features. With the exception of somewhat less sensory loss and preserved or reduced tendon reflexes (the latter in some axonal cases) we have been unable to distinguish the axonal and demyelinating groups on clinical grounds or by their response to therapy (Gorson, Ropper, et al). Sural nerve biopsies show a loss of myelinated fibers of all sizes; unmyelinated fibers are mostly spared; hypertrophic changes, reflecting cycles of demyelination and remyelination with fibrosis are present in about half the cases according to Smith et al. They found the monoclonal IgM antibody bound to surviving myelin sheaths,

and Latov and coworkers have shown that the serum IgM fraction often displays antimyelin activity.

Typically, the monoclonal protein in the blood is present in a concentration less than 2 g/100 mL and there is no evidence of multiple myeloma or other malignant disease. It should be emphasized that routine serum protein electrophoresis (SPEP) fails to detect the majority of these paraproteins; immunolectrophoresis (IEP) or the more sophisticated immunofixation testing is required. The bone marrow aspirate shows a normal or only mildly increased proportion of plasma cells, which are the ostensible source of the paraprotein, and the plasma cells are not morphologically atypical, as they are in myeloma. Insofar as myeloma becomes manifest in fewer than one quarter of patients many years after the gammopathy has been recognized, the condition is now termed *monoclonal gammopathy of undetermined significance* (MGUS), although the older term, *benign monoclonal gammopathy*, is less cumbersome.

The importance of excess immunoglobulin can be appreciated by noting that some 6 percent of patients referred to the Mayo Clinic with chronic polyneuropathy of unknown cause and as many as 20 percent in our clinical material and in other series have proved to have a monoclonal paraproteinemia (of course, the majority of patients with a blood paraprotein do not develop neuropathy). Despite the fact that IgG is the most frequent paraprotein in adults, a polyneuropathy is associated somewhat more often with the IgM class. Combining three large series of patients with neuropathy and monoclonal paraproteinemias (62 patients of Yeung et al, 65 patients of Gosselin et al, and 34 of our patients reported by Simovic et al), there were 96 with IgM, 50 with IgG, and 15 with IgA subclass paraproteins. An identical but infrequent condition exists in which only the light chain component of an immunoglobulin is overproduced by the plasma cells and is found exclusively in the urine (similar to the Bence-Jones protein of multiple myeloma).

Most affected patients have had a *kappa* light chain component although *lambda* light chain has special significance as discussed further on in relation to plasmacytoma and the "POEMS" syndrome. In our experience and in that of others, the group with IgM paraprotein has more often displayed severe sensory findings and a demyelinative type of EMG abnormality when compared with the IgG group. However, with the exception of the special antimyelin-associated glycoprotein (MAG) syndrome (see later), we have not found the degrees of difference in clinical features and response to treatment between the immunoglobulin subclasses that has been reported by others (Simovic et al).

Although more than a dozen specific antibodies against myelin and other components of nerve have been identified among the paraproteins, the most important ones, present in 50 to 75 percent of patients with IgM-associated neuropathies, are the ones that react with a MAG, related glycolipids, or sulfatide components of myelin (referred to as SGPG and SPLPG). Deep sensory loss with gait imbalance, severe tremor, and a Romberg sign are typical findings in the group with anti-MAG activity, while weakness and atrophy tend to appear later in the illness. Other IgM antineuronal antibodies have a more tentative connection to polyneuropathy. Polyclonal IgM antibodies against the GM₁ antigen of myelin are linked with multifocal motor conduction block, described further on, but are sometimes found coincidentally in patients with anti-MAG protein. It is reasonable to assume that IgG monoclonal gammopathies are also capable of causing chronic neuropathies, but the evidence is less compelling and based mainly on the frequency of their coincidence. Indeed, it has been suggested that in many reported in-

stances this association is coincidental. Nonetheless, when such cases are treated similarly to the IgM group with polyneuropathy, they respond as well or better. Finally, it should be noted that in about 15 percent of our patients with anti-MAG antibody the illness has been mild and static for years at a time, even without treatment.

Only a small number of our patients have developed myeloma or Waldenstrom disease. A bone marrow examination is generally not necessary unless the concentration of the paraprotein exceeds 3 g/dL or climbs progressively over years, or if other hematologic changes such as unexplained anemia or thrombocytopenia develop.

Treatment In most cases of uncomplicated monoclonal gammopathy, particularly if not of long-standing, plasma exchange produces transient improvement for several weeks to months, somewhat more so in patients with IgG and IgA types of neuropathy than in those with the IgM type (Dyck et al, 1991). The treatment regimen is approximately the same as for GBS, a total volume of approximately 200 to 250 mL/kg exchanged in each of 4 to 6 treatments over about 10 days and the removed plasma replaced with a mixture of albumin and saline.

In patients who are found to have serum activity against specific components of myelin (particularly anti-MAG), plasma exchange alone has effected transient improvement in only 30 to 40 percent and sustained improvement in only 10 percent of our patients. This discouraging outcome was obtained in cases with slowly progressive ataxia and marked distal sensory loss. Sequential series of plasma exchanges every two to four months has sometimes resulted in repeated but transient responses. According to some reports the response to immunosuppression with intravenous cyclophosphamide or fludarabine, mycophenolate (Cellcept), or oral chlorambucil, when coupled with plasma exchanges has been somewhat better, at times allowing a reduction in the frequency of exchanges. We have observed this only with cyclophosphamide (Gorson et al). Rituximab, which has the appeal of having a preferential effect on the B-cell lymphocyte population, is being tested in these diseases with mixed results so far.

Improvement with high-dose infused immunoglobulin (IVIG) has been effective in half of our cases with typical paraproteinemia, and 20 percent of those with anti-MAG neuropathy have improved for at least a brief period. Other reports are not as positive. In almost all instances immunosuppression and the plasma exchanges or IVIG must be repeated indefinitely at intervals of one to several months as determined by the clinical course. An indwelling catheter is then usually required for venous access. This group of neuropathies responds poorly or not at all to corticosteroids.

Osteosclerotic Myeloma (POEMS Syndrome) and Multiple Myeloma A neuropathy associated with *multiple myeloma* has already been mentioned under "Paraneoplastic Neuropathy and Sensory Ganglionopathy." This polyneuropathy complicates 13 to 14 percent of cases of multiple myeloma and has a disproportionately high association with the osteosclerotic form of the disease. An abnormal monoclonal and excessive gamma globulin (mainly with the *kappa* light chain component in multiple myeloma but *lambda* in the osteosclerotic type) is found in the serum of over 80 percent of patients with myelomatous neuropathy.

In a special and small group of patients with single or other limited degrees of osteosclerotic myeloma, a sensorimotor polyneuropathy termed *POEMS* arises. [Polyneuropathy (P) of moderate severity is associated with organomegaly (O), endocrinopathy (E), elevated *M* protein, and skin changes S (mainly hypertrichosis and skin thickening), hence the acronym *POEMS*.] The same process has been referred to as the Crow-Fukase syndrome in Japan,

where the disease is prevalent. In many cases of *POEMS* there is lymphadenopathy attributable to the angiofollicular hyperplasia of Castleman disease. Another characteristic feature of the osteosclerotic-related polyneuropathy is a greatly elevated CSF protein. The presence of the disease can be suspected from the presence of an immunoglobulin spike in the blood, often polyclonal or biclonal rather than monoclonal, and possessing a lambda light chain component. The diagnosis requires the demonstration of the osteosclerotic lesion by a radiographic survey of the long bones, pelvis, spine, and skull (a bone scan is often insensitive) and a bone marrow examination, which shows a moderate increase in the number of well-differentiated plasma cells. In most of our patients there have been several discrete bone lesions concentrated in the ribs and spine; the skull and long bones may harbor such lesions as well, or the lesions may be in the form of a single nodule, often in the spinal column.

Treatment The neuropathy that complicates a solitary plasmacytoma may improve markedly following irradiation of the bone lesion. Multiple lesions, including those in the *POEMS* syndrome, when treated with chemotherapy (melphalan and prednisone) or focused radiation, demonstrate some improvement or stabilization in the neuropathy. Treatment with plasma exchange has yielded uncertain but somewhat positive results in our patients.

Waldenstrom Macroglobulinemia *Macroglobulinemia* was the term applied by Waldenstrom to a systemic condition occurring mainly in elderly persons and characterized by fatigue, weakness, and a bleeding diathesis. Immunoelectrophoretic examination of the blood disclosed a marked and mostly monoclonal increase in the IgM plasma fraction. About half of patients with Waldenstrom disease and polyneuropathy will have anti-MAG antibodies, similar to the proportion in patients with nonmalignant IgM paraproteins. A significant proportion of patients with this hyperproteinemia have a hyperviscosity state manifest by diffuse slowing of retinal and cerebral circulation—giving rise to episodic confusion, coma, impairment of vision, and sometimes strokes—(*Bing-Neel syndrome*). The neuropathy, when present, evolves over months or longer and may be asymmetrical, particularly at the onset, but becomes symmetrical and distal. The pattern in our patients has been of the latter type, very slowly progressive, and limited to the feet and legs with mild sensory ataxia and loss of knee and ankle jerks. The CSF protein is usually elevated and the globulin fraction increased. In a case recorded by Rowland and colleagues, the polyneuropathy was purely motor and simulated motor neuron disease; other cases of this type, albeit rare, have been brought to our attention in clinical exercises and medical writings. Treatment is discussed below.

Cryoglobulinemia As mentioned previously in the section on vasculitic neuropathies, *cryoglobulin*, a serum protein that precipitates on cooling, is usually of the IgG or IgM type and most often polyclonal. While cryoglobulinemia may occur without any apparent associated condition (essential cryoglobulinemia), it also accompanies a wide variety of disorders such as multiple myeloma, lymphoma, connective tissue disease, chronic infection, and, particularly, hepatitis C. Peripheral neuropathy occurs in a small proportion both of the essential and symptomatic cases. Occasionally the neuropathy evolves over a period of a few days and remits rapidly. More often it takes the form of a distal symmetrical sensorimotor loss, which develops insidiously in association with the Raynaud phenomenon and purpuric eruptions of the skin. Initially, the neuropathic symptoms consist only of pain and paresthesias that may be precipitated by exposure to cold (as often, there is no

cold sensitivity). Later, weakness and wasting develop, more in the legs than in the arms, and more or less in the distribution as the vascular changes. In some cases there may be a mononeuropathy multiplex with severe denervation in the territory of the involved nerves (Garcia-Bragado et al). In a few cases, the two neuropathic syndromes have been combined.

As remarked earlier, detection of cryoglobulin requires special handling of the blood sample. The specimen should be carried to the laboratory in a bath of warm water to prevent precipitation of the protein.

Any of the paraproteinemic states may be associated with amyloid polyneuropathy. This subject is accorded a separate section later.

The pathology of the cryoglobulinemic and macroglobulinemic neuropathies has been incompletely studied and the mechanisms by which these disorders cause neuropathy are uncertain. One presumes that some component of the paraprotein acts as an antineuronal antibody or that deposition of the protein is in some way toxic. In our most thoroughly autopsied case, there was widespread distal axonal degeneration of nondescript type without amyloid deposition or inflammatory cells; yet in other reported cases, amyloid has been found in the nerve and the neuropathy has been attributed directly to it. Immune deposits of IgM had impregnated the inner layers of the perineurium in the case reported by Ongreboer de Visser and colleagues. Dalakas and Engel have made similar observations. In yet other instances, the neuropathy of cryoglobulinemia is due to the intravascular deposition of cryoglobulins, causing a more acute vasculitic mononeuritis multiplex as discussed earlier (Chad et al).

Treatment In the macroglobulinemic neuropathies, the use of prednisone, the alkylating agent chlorambucil, cyclophosphamide, and repeated plasma exchange has at times led to improvement both in the systemic and neuropathic symptoms, although recovery has been incomplete. The optimal treatment of cryoglobulinemic neuropathy has not been settled. We have used plasma exchange and added immunosuppression in the vasculitic variety of this disease.

Primary (Nonfamilial, AL) Amyloid Neuropathy A heredofamilial type of amyloidosis is well known. There are in addition more numerous sporadic instances of a peripheral neuropathy caused by amyloid deposition. As in the familial variety, the heart, kidneys, and gastrointestinal tract may be involved. This acquired type of amyloid disease has also been called *primary systemic amyloidosis* to distinguish it from the variety associated with chronic diseases. In most cases, the amyloid is derived from a paraproteinemia for which reason it is included in this section, but the proportion of "benign" and malignant plasma cell sources of the protein varies from one report to another. For example, in the large series of Kyle and Bayrd, only 26 percent of patients with primary amyloidosis had a malignant plasma cell dyscrasia. This agrees with our own experience, but other series have found rates of myeloma as high as 75 percent. In either case, 90 percent of cases of primary amyloidosis are the result of a monoclonal protein in the blood (rarely polyclonal). Macrophage enzymes cleave the larger immunoglobulin molecules as light chains that aggregate to form amyloid deposits in tissue, or the plasma cells may produce light chains directly ("light chain disease"). Lambda light chain predominates in the idiopathic variety of amyloidosis, and kappa light chain is more common in myeloma. In a few cases the light chain is found only in the urine (as Bence Jones protein).

In primary amyloidosis there is no evidence of preceding or

coexisting disease (except the association with paraproteinemia or multiple myeloma). *Secondary amyloidosis*, an infrequent occurrence nowadays, is the result of chronic infection or other chronic disease outside the nervous system and, as a rule is not associated with neuropathy. In contrast, *familial amyloidosis*, a third variety, is almost invariably associated with neuropathy but is associated with a paraprotein in a small proportion of cases and the amount of immunoglobulin is small (see page 1160).

Primary amyloidosis is mainly a disease of older men, the median age at the time of diagnosis being 65 years. In our clinical material, the majority of the patients have had peripheral neuropathy but this may reflect a referral bias since in other series less than one-third were so affected (Kyle and Dyck). The neuropathic symptoms and signs are similar to those of hereditary amyloid polyneuropathy discussed further on, but the progress of the disease is considerably more rapid.

The initial symptoms are sensory—numbness, paresthesias, and often acral pain—and the signs are characteristic of involvement of small-diameter sensory fibers (loss of pain and thermal sensation). It is the painful aspect and the autonomic features discussed later that distinguish this disease from the other paraproteinemic neuropathies and indeed, from most other polyneuropathies. Weakness follows, initially limited to the feet but becoming more extensive as the disease progresses and eventually spreads to the hands and arms. There is only later a loss of mainly large fibers that mediate sensations of touch, pressure, and proprioception. Twenty-five percent of patients have carpal tunnel syndrome from infiltration of the flexor retinaculum. Exceptionally, patterns other than the painful and sensory predominant polyneuropathy have been associated with amyloidosis. Preferential involvement of motor nerves, lumbar roots, plexopathy, and amyloidomas involving single nerves (sciatic, facial, trigeminal) have been reported. Unusual cases of mononeuritis multiplex have been difficult to explain, including a reported case by Gorson and Skinner.

Autonomic involvement can be severe and may become evident early in the course of the illness; several of our patients presented with disturbances of gastrointestinal motility, especially episodic diarrhea and orthostatic symptoms or impotence and bladder disturbances. The pupils may show a slow reaction to light, or there may be a reduction in sweating. An infiltrative *amyloid myopathy* also occurs as a rare complication of the disease; it presents as an enlargement and induration of many muscles, particularly those of the tongue (macroglossia), pharynx, and larynx.

Progression of the illness is relatively rapid, the mean survival being 12 to 24 months. An indolent neuropathy that evolves over years is not likely to be due to amyloidosis, though we have seen such a case. Death is usually due to the renal, cardiac, or gastrointestinal effects of amyloid deposits, the manifestations of which are already evident in over half of the patients who present with neuropathy. A nephrotic syndrome is characteristic.

Analysis of the serum and urine, searching for an abnormal paraprotein is the most useful screening test. Next in value is a microscopic examination of abdominal fat pad, gingival, or rectal biopsy for deposition of amyloid in tissue or blood vessels. If a sensory neuropathy or evidence of organ infiltration is evident, biopsy of the sural nerve or of the involved viscera has a high diagnostic yield. Muscle tissue gives variable results. The liver biopsy is positive in virtually all cases and the kidney shows amyloid infiltration in 85 percent. In several of our patients with a clinical syndrome typical of amyloid neuropathy, but in whom amyloid was absent in the sural nerve, the diagnosis was established only after

sequential biopsy of numerous sites (fat pad, kidney, liver). Also, if the sural nerve is severely depopulated of nerve fibers, the amount of congophilic staining and the characteristic birefringence may be meager and yield a spuriously negative result. It is also critical to assure the accuracy of congophilic staining by comparison with positive and negative control tissue from the same laboratory. The CSF has a normal or mildly elevated protein concentration but this does not distinguish the neuropathic process from many others.

Lachmann and colleagues have emphasized that 10 percent of patients who appear by all the usual criteria to have primary amyloidosis will turn out in the end to have a genetic type. However, only a small proportion of the latter group has a monoclonal gammopathy and it tends to be of low concentration (estimated to occur in one quarter of familial cases but we have not encountered it). This difference and the rapid progression of the primary acquired form assist in distinguishing it from the genetic type.

In addition to the more slowly evolving familial types, the differential diagnosis of acquired amyloid neuropathy includes the myelomatous varieties, toxic and nutritional small-fiber neuropathies, paraneoplastic polyneuropathy, Sjögren disease, and an idiopathic small-fiber sensory neuropathy, all of which can cause pain and which we have encountered more frequently than amyloidosis.

The hereditary amyloid polyneuropathies are discussed further on (page 1160).

Treatment The prognosis is dismal and attempts at immunomodulation, immunosuppression (which may help the renal disease), or removal of amyloid by plasma exchange have been marginally effective. The most recent approach has been bone marrow suppression with high doses of melphalan followed by stem-cell replacement (harvested from the patient). Several such patients have survived for years with marked improvement in the neuropathy.

Pain is a serious problem that may be treated with transcutaneous fentanyl patches or with oral narcotic medications. Orthostatic hypotension responds to the use of leg stockings and mineralocorticoids as well as sleeping with the bed elevated at the head so that the patient's entire body is angled down toward the feet.

Chronic Inflammatory Demyelinating Polyradiculoneuropathy This form of polyneuropathy was separated from acute inflammatory polyradiculopathy, or GBS, by Austin in 1958 on the basis of a prolonged and relapsing course, enlargement of nerves, and responsiveness to corticosteroids. Excluding the duration of evolution, there are numerous clinical similarities between the acute and chronic forms. Both are widespread polyradiculoneuropathies, usually with cytoalbuminologic dissociation of the CSF (raised protein concentration with fewer or no cells); both exhibit nerve conduction abnormalities characteristic of a demyelinating neuropathy (reduced conduction velocity and partial conduction block in motor nerves), and pathologically, both show similar multifocal perivenous inflammatory infiltrates. But there are also important differences, the most evident of which are the mode of evolution and prognosis. As a rule, CIDP begins insidiously and evolves slowly, either in a steadily progressive or stepwise manner, attaining its maximum severity after several months or longer. From the beginning it may be asymmetrical or involve the arms predominantly. However, in a small proportion of patients (16 percent in the series of McCombe et al, and a smaller proportion in our own series) the disease at first emerges from a mild or moderate case of GBS. In

these latter cases the illness thereafter becomes relapsing or it simply worsens slowly and progressively.

An antecedent infection is identified far less regularly in patients with CIDP than in those with GBS and is probably not a necessary component of the disease. Furthermore, CIDP may be distinct immunologically from GBS, insofar as certain HLA antigens occur with greater frequency in patients with CIDP than they do in the normal population, whereas there are no clear HLA propensities in patients with GBS. Finally, in contrast to acute GBS, many cases of CIDP respond favorably to the administration of prednisone. An ambiguity is introduced here because, as mentioned earlier, Hughes has described a group of patients with polyneuritis in whom weakness progressed steadily for 4 to 12 weeks and who responded to corticosteroids, thus again blurring the distinction between GBS and CIDP.

The chronic symmetric sensorimotor loss coupled with EMG findings of demyelination largely define the illness. The typical EMG findings are of multifocal conduction block as described in Chap. 45, prolonged distal latencies (distal block), nerve conduction slowing to less than 80 percent of normal in several nerves, loss of late responses, and dispersion of the compound muscle action potentials, further reflecting demyelination in motor nerves. One or several of these changes have been present in more than three quarters of our patients (Gorson, Ropper, et al). In the early stages of the disease demyelinative features must be carefully sought by testing multiple nerves at several sites along this course. After several months there is often some degree of axonal change (30 percent of our series), but the fundamental process continues to be one of multiple foci of demyelination. Most dependable is the absence of denervation changes early on despite weakness and reduced amplitude of the motor action potential, indicative of a demyelinating block to conduction at a proximal site.

Several large series of CIDP cases are available for review. Dyck and colleagues (1975) studied 53 patients in whom the neuropathy progressed for more than 6 months. The clinical course was monophasic and slowly progressive in about one-third, stepwise and progressive in another third, and relapsing in the remaining third. The periods of worsening or improvement were measured in weeks or months. Infections and inoculations in the 3 months preceding the onset of CIDP were no more frequent than in the population at large. Weakness of the limbs, particularly of the proximal leg muscles, or numbness, paresthesias, and dysesthesias of the hands and feet were the initial symptoms. In 45 of the 53 patients, the signs were those of a mixed sensorimotor polyneuropathy with weakness of the shoulder, upper arm, and thigh muscles, in addition to motor and sensory loss in the distal parts of the limbs. In 5 patients the neuropathy was purely motor, and in 3, purely sensory. Cranial nerve abnormalities were distinctly unusual. Enlarged, firm nerves were found in 6 patients. Not emphasized in their series is the common occurrence of a cerebellar-like tremor in cases of long-standing. In the series reported by McCombe et al comprising 92 patients, two major subgroups were recognized—*relapsing* (corresponding to the relapsing and stepwise progressive cases of Dyck et al) and *nonrelapsing* ones. In our own series of more than 100 patients, we have been impressed with several additional unusual patterns of clinical presentation. In 10 percent, numbness and weakness of the hands preceded involvement of the feet, which is unusual in other polyneuropathies. A sensory ataxic form, a purely motor form, and mononeuropathies superimposed on a mild generalized polyneuropathy each accounted for approximately 5 percent of the cases. As mentioned earlier, a small pro-

portion began as acute GBS but continued to progress or relapsed in the following months (Gorson et al, 1997). Other comprehensive accounts have been given by Barohn, Cornblath, Dyck, and Hughes and their associates. All of these studies delimited the time course of CIDP to encompass progression for longer than 8 or 12 weeks. The term *subacute demyelinating neuropathy* has been used to describe a Guillain-Barré illness that progresses for only 4 to 8 weeks and is responsive to corticosteroids.

Also recognized is the frequency (up to one quarter of the patients in some series, less often in our experience) with which there was a systemic condition such as paraproteinemia, lymphoma, an undifferentiated reactive adenopathy, or lupus in association with an inflammatory demyelinating polyneuropathy. These associations create problems in nosology that can be reconciled by labeling a given instance as "CIDP with paraproteinemia," "CIDP with lupus," etc., thus separating such cases from the idiopathic variety. These symptomatic inflammatory polyneuropathies respond to corticosteroids, albeit unpredictably, and to treatment of the underlying disease.

The status of a predominantly axonal polyneuropathy that clinically simulates CIDP and responds to some extent to the same immunomodulating treatments has been described by Uncini et al and by Gorson and Ropper. The present authors have the impression that it is an immune-mediated neuropathy comparable to CIDP but obviously with preferential destruction of axons rather than of myelin. Its frequency as a cause of acquired polyneuropathy is not known but we see several new cases every year.

Laboratory Features The CSF protein is elevated in 80 percent of patients with CIDP, typically in the range of 75 to 200 mg/dL. In rare instances there is papilledema and a pseudotumor syndrome in relation to extremely high levels of CSF protein (usually >1000 mg/dL). Elevation of the CSF gamma globulin fraction and a mild lymphocytic pleocytosis are reportedly found in 10 percent of patients (more consistently in those that are HIV-seropositive), a considerably higher percentage than in our series.

In biopsy material (sural nerve), half of cases are found to have interstitial and perivascular infiltrates of inflammatory cells, although one expects that most nerves would show these changes if a sufficient number could be sampled. In other biopsy specimens there is only demyelination, or in cases of long-standing, severe depletion of all nerve fibers. As in GBS, the demyelination appears to be effected by T cells and macrophages within the endoneurium and perineurium. The loss of myelinated fibers is variable and many of the remaining fibers are seen to be undergoing Wallerian degeneration or show changes of segmental demyelination or demyelination-remyelination. So-called onion-bulb formations are conspicuous in the recurrent and relapsing cases. The few complete autopsy studies have shown only minimal or patchy inflammation and a considerable degree of axonal damage, probably reflecting the long duration of illness before examination. The presence of endoneurial and subperineurial edema has been emphasized by Prien and McLeod.

Treatment Several well-conducted trials have shown that there is short-term benefit from the intravenous infusion of high doses of gamma globulin (2 g/kg in divided infusions over 4 or 5 days). More than half of our patients have responded to this treatment, albeit for only several weeks or months, after which the infusions must be repeated. A desire to spare patients the side effects of indefinite prednisone administration (see later) make this mode of therapy a reasonable alternative. Some patients have been treated with repeated infusions for almost 10 years without ill effects. Pa-

tients who require treatment at such short intervals as to be impractical have benefited from the addition of small doses of prednisone or of an immunosuppressive drug as described below. The main drawbacks of IVIG are its expense and the several hours required for its infusion. Rare instances of nephrotic syndrome, aseptic meningitis, serum sickness, thrombotic arterial occlusion, including stroke and hypotension have been reported, particularly if the infusion is too rapid.

Half of patients with CIDP also respond well to plasma exchanges. In a prospective double-blind trial, Dyck and colleagues found that plasma exchange administered twice weekly for 3 weeks had a beneficial effect on both neurologic disability and nerve conduction. The response to plasma exchange in our patients has been comparable to that obtained with IVIG and with steroids, but it has become clear that some patients respond to one type of treatment and not the other. The beneficial effects in most patients begin to subside in 10 to 21 days, or even less. In some cases the response lasts longer, as found by Dyck and in the series by Hahn et al. For these reasons we prefer to try plasma exchange or immune globulin before committing a patient to long-term treatment with prednisone. The relative ease of administering IVIG favors its use first, followed by a series of plasma exchanges if there is no improvement. When there is a clear response, three or four brief series of plasma exchanges or repeated infusions of immune globulin often suffice to bring the patient to an improved level of function. These treatments can be supplemented by small doses of prednisone when frequent infusions or exchanges become impractical.

It has been our experience that in about one-third of cases, IVIG and plasma exchange may cease to have clinical benefit after repeated use for one or more years. Corticosteroids were formerly the mainstay of therapy, but most patients become dependent on the medication and correspondingly suffer side effects. The general approach has shifted to utilizing these medications as a third type of treatment after plasma exchange or IVIG, and as an adjunct to one of the previously mentioned treatments. The usual regimen begins with 60 to 80 mg of prednisone daily that is tapered over months to the lowest effective dose, typically 25 to 40 mg. A small number of patients will have no response to corticosteroids within the first 1 or 2 months but will do so if treatment is continued. The drug produces tremor or may exacerbate the tremor caused by the neuropathy. Should a sustained trial of prednisone therapy prove unsuccessful, a course of azathioprine (for at least 3 months), 3 mg/kg in a single daily dose, has been recommended (Dalakas and Engel), but as mentioned, a controlled trial has failed to show benefit from this combination and we have had little success with it.

When the preceding measures prove unsatisfactory, cyclophosphamide or mycophenolate can be added, or another similar immunosuppressive medication, but we have been unable to draw any firm conclusions as to the effectiveness of these combined regimens.

Some patients who have failed to benefit from the aforementioned treatments have improved in response to the administration of α -interferon (Gorson et al), and Vallat has shown in a small trial that β -interferon may be similarly successful in a small group of patients who failed other therapies. A larger trial is being conducted in order to determine if adjunctive treatment with β -interferon allows an increase in the interval between infusions of IVIG. High-dose cyclophosphamide has proven helpful in several cases under our care, although it has as often failed (see Brannagan et al). The usual regimen is 50 mg/kg IV daily for 4 days followed by granulocyte-stimulating factor beginning on the tenth day until the ab-

solute neutrophil count recovers. Individual reports of successful treatment by autologous stem-cell transplantation after high-dose chemotherapy have appeared (Vermuelen and van Oers). This may become an option in severe and treatment-resistant cases. We have no explanation for the remarkable improvement and continued good health of a few of our patients after a severe toxic bacterial infection (Ropper).

One of the problems most difficult to address is a lack of clear clinical measurements to guide retreatment with IVIG and plasma exchange and even the proper adjustment of the steroid dose. Often one may be influenced by the patient's fear of losing any ground and even slight changes in sensory or motor symptoms.

It has been stated that patients with discrete relapses have a better prognosis than those with a progressive course. In McCombe's series, 73 percent were said to have eventually recovered but the long-term outcome has generally been poor. In a small number of patients, less than 10 percent, has the disease finally burned out. Unexplained remission occurs occasionally.

Multifocal Motor Neuropathy and Multifocal Conduction Block

Several polyneuropathies that share many of the features of CIDP have been delineated on the basis of some unique clinical or electrophysiologic attribute. These include particularly *multifocal motor neuropathy* and *multifocal conduction block*. The latter seems to be a type of CIDP with the main feature being a block to sensory and motor conduction across focal sites in a limited number of nerves as described below. In multifocal motor neuropathy, there are multiple sites of block in motor nerves alone, without change in sensory conduction.

The distinction between these two entities has been somewhat blurred by the finding of mild but consistent demyelination in sensory nerve biopsies from patients with multifocal motor neuropathy (Corse et al). While these conditions may perhaps be considered for the moment as types of CIDP, there is a high concordance of multifocal motor neuropathy with a particular IgM antibody, anti-GM_i, directed against a ganglioside component of peripheral myelin (Pestronk et al). For this reason, some view this illness as belonging to the class of paraproteinemic neuropathies (see earlier and Simmons et al), and it is distinctive enough clinically to be categorized separately. Its importance as a clinical entity lies in the similarity of the clinical picture to a purely lower motor neuron type of amyotrophic lateral sclerosis and, unlike ALS, its responsiveness to treatment.

Multifocal motor neuropathy predominates in men. It usually begins with an acute to subacute motor mononeuropathy, manifest, for example, as weakness of the wrist or foot drop, and is often joined insidiously by another focal motor palsy. The process is painless, unlike vasculitic mononeuritis multiplex, involves the nerve incompletely, and, in its usual form, is unaccompanied by any sensory symptoms such as paresthesias or numbness. Despite the initially demyelinating character of the disorder, there is almost always atrophy of the weakened muscle within months, and there may be a few fasciculations, thus reminiscent of ALS. Nevertheless, the weakness tends to be out of proportion to atrophy. Usually, the tendon reflex is lost or muted in an affected region, but for unexplained reasons, some patients have one or more brisk reflexes. Our experience has been that this latter reflex change does not reach the point of appearing "pathologic" and that clonus and Babinski signs are categorically not part of the illness.

When there is an association with sensory symptoms or sensory loss and there is slowing of sensory conduction in regions of

motor conduction block, the acronym MADSAM (Multifocal Acquired Demyelinating Sensory and Motor Neuropathy) has been used, but the disorder while similar to multifocal conduction block, more resembles CIDP. This also conforms to what has been called Lewis-Sumner syndrome based on the original description by these authors and their colleagues of subacute, painless asymmetric, distal multiple mononeuropathies. The ulnar and median nerves were involved and there was motor conduction block and sensory slowing in affected nerves. Curiously, two of their five original patients had optic neuritis, a feature not reported by others. The disease is not connected to antibodies against GM1.

Treatment For multifocal motor conduction block, IVIG infusions have been highly effective, albeit temporarily, in over half of patients. Some authoritative clinicians favor the early addition of cyclophosphamide, 1 g/m² monthly for 6 months in treatment-resistant cases or when the frequency of infusions is unsustainable. Other immune-modulating drugs such as rituximab are being tried. There is no response to corticosteroids. The MADSAM illness responds similarly to CIDP in most instances.

Uremic Polyneuropathy Polyneuropathy is among the most common complications of chronic renal failure. Robson estimated that it complicates end-stage renal failure in two-thirds of patients who are about to begin dialysis therapy. Bolton's figures are much the same; 70 percent of his patients being dialyzed regularly had uremic polyneuropathy and in 30 percent it was moderate or severe in degree. As in the original description by Asbury, Victor, and Adams, the neuropathy takes the form of a painless, progressive, symmetrical sensorimotor paralysis of the legs and then of the arms. In some patients, the neuropathy begins with burning dysesthesias of the feet or with sensations of creeping, crawling, and itching of the legs and thighs, which tend to be worse at night and are relieved by movement ("restless legs" syndrome, page 339). Renal failure accompanied by diabetes may give rise to a particularly severe form.

The combination of muscle weakness and atrophy, areflexia, sensory loss, and the graduated distally predominant distribution of the neurologic deficit in the limbs leaves little doubt about the neuropathic nature of the disorder. Usually the neuropathy evolves slowly over many months, at times more subacutely. Infrequent instances of a more acute sensorimotor polyneuropathy that have been reported occur mainly in diabetic patients receiving peritoneal dialysis as discussed earlier on (see page 1128; Ropper; Asbury et al.). Also, a rare uremic polymyositis with hypophosphatemia has been described (Layzer). The neuropathy has been observed with all types of chronic kidney disease. More important to the development of chronic neuropathy than the nature of the renal lesion are the duration and severity of the renal failure and symptomatic uremia.

With long-term hemodialysis, the neuropathic symptoms and signs stabilize but improve in relatively few patients. In fact, rapid hemodialysis may occasionally worsen the polyneuropathy temporarily. Peritoneal dialysis appears to be more successful than hemodialysis in improving the neuropathy but this observation has not been firmly established. Complete recovery, occurring over a period of 6 to 12 months, usually follows successful renal transplantation for the reasons given later.

The pathologic findings are those of a nonspecific axonal degeneration. In rapidly progressive cases, there is a tendency for the large fibers to be affected; this is evident particularly on electrophysiologic testing which shows slowing of nerve conduction ve-

locities, but there is no conduction block as occurs in other acquired demyelinating polyneuropathies. The pathologic changes are most intense in the distal segments of the nerves, with the expected chromatolysis of their cell bodies.

The cause of uremic polyneuropathy is unknown. What has been called the “middle molecule” theory is plausible. The end stage of renal failure is associated with the accumulation of toxic substances in the range of 300 to 2000 molecular weight. Furthermore, the concentration of these substances, which include methylguanidine and myoinositol, has been shown to correlate with the degree of neurotoxicity (Funck-Brentano et al). These toxins (and the clinical signs of neuropathy) are not greatly reduced by chronic hemodialysis. In contrast, the transplanted kidney effectively eliminates substances of wide-ranging molecular weights, which would account for the almost invariable improvement of neuropathy after transplantation. As is the case with uremic encephalopathy, urea alone given to experimental animals and in controlled studies of humans, does not seem capable of inducing a metabolic neuropathy.

Alcoholic-Nutritional Polyneuropathy (See page 989 and Chap. 41) In all patients with alcoholic-nutritional polyneuropathy who for some reason remain untreated with vitamin and protein restoration, the weakness and atrophy of the legs, and to a lesser extent the arms, may reach an extreme degree. Thus this disease, though subacute in its evolution as described earlier in the chapter, becomes a frequent cause of chronic polyneuropathy. There are usually prominent sensory features and considerable acral pain and allodynia. Certain cases of diabetic neuropathy behave similarly.

Leprous Polyneuritis This is the classic example of an infectious neuritis, due to the direct invasion of nerves by the acid-fast *Mycobacterium leprae*. The disease is still frequent in India and Central Africa, but there are many lesser endemic foci including parts of South America and of Florida, Texas, and Louisiana that border on the Gulf of Mexico.

The initial lesion in leprosy is an innocuous-looking skin macule or papule, which is often hypopigmented and lacking in sensation and is caused by the invasion of cutaneous nerves by *M. leprae*. In patients with a degree of immunologic resistance to infection the disease may progress no further than this stage, which is spoken of as *indeterminate leprosy*, or it may evolve in several ways, depending mainly upon the resistance of the host. The bacilli may be locally invasive, producing a circumscribed epithelioid granuloma that involves cutaneous and subcutaneous nerves and results in a characteristic hypopigmented patch of superficial numbness and sensory loss (*tuberculoid leprosy*). The underlying subcutaneous sensory nerves may be palpably enlarged. If a large nerve in the vicinity of the granuloma is invaded (the ulnar, median, peroneal, posterior auricular, and facial nerves are most frequently affected), a sensorimotor deficit in the distribution of that nerve is added to the patch of cutaneous anesthesia.

In contrast to the limited tuberculoid variety of leprosy, lack of resistance to the organism permits the proliferation and hematogenous spread of bacilli and the diffuse infiltration of skin, ciliary bodies, testes, lymph nodes, and nerves (*lepromatous leprosy*). Widespread invasion of the cutaneous nerves produces a symmetrical pattern of pain and temperature loss involving the pinnae of the ears as well as the dorsal surfaces of hands, forearms, and feet and anterolateral aspects of the legs—a distribution that is determined by the relative coolness of these parts of the skin. This tem-

perature-dependent pattern is the most characteristic feature of the disease as pointed out by our colleague T. Sabin. The sensory maps he has drawn (Fig. 46-4) are typical of established cases. The nose, earlobes, and elbows may be affected early as a result of the coolness of the skin in those areas. The process evolves over years. Eventually the anesthesia spreads to involve most of the cutaneous surface. Extensive sensory loss is followed by impaired motor function owing to invasion of muscular nerves where they lie closest to the skin (the ulnar nerve is the most vulnerable). There is a loss

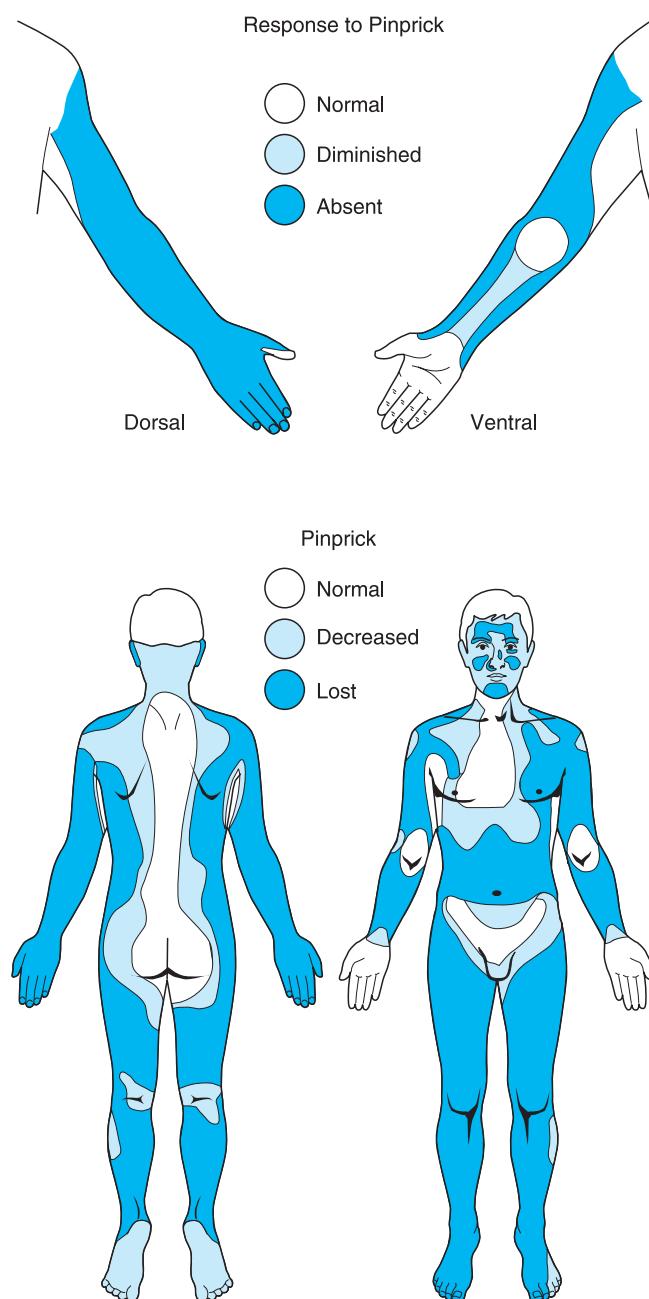

Figure 46-4. Patterns of sensory loss in leprosy. The localization of these areas to cooler portions of the body is unique to this disorder. Shown in the upper figure is the sparing of the palmar and antecubital surfaces and variation in the sensation within the distribution of a single sensory nerve. In the lower figure, almost universal analgesia is found but there is still sparing of warmer regions of skin. (From Sabin with permission.)

of sweating in areas of sensory loss, but otherwise the autonomic nervous system is unaffected. In distinction to other polyneuropathies, tendon reflexes are usually preserved in leprosy despite widespread sensory loss. Probably this is the result of sparing of most of the muscular and larger sensory nerves. Because of widespread anesthesia, injuries may pass unrecognized, with resultant infections, trophic changes, and loss of tissue. Variations in host immunity result in patterns of disease having both tuberculoid and lepromatous characteristics (dimorphous leprosy). Erythema nodosum occurs in a few cases. The diagnosis can be made from a skin scraping or biopsy but often, multiple samples are required.

Treatment All forms of leprosy require long-term treatment with sulfones (dapsone being the most commonly used), rifampin, and clofazimine. The skin lesions of lepromatous leprosy are responsive to thalidomide, which itself may cause a sensory neuropathy (page 1041; Barnhill and McDougall). Reactivation of disease, or a conversion from the tuberculoid to the lepromatous pattern, may occur during times of reduced immunity.

Polyneuropathy with Hypothyroidism Although characteristic disturbances of skeletal muscle are known to complicate hypothyroidism (see Chap. 51), the demonstration of a definite polyneuropathy has been infrequent. However, a number of elderly myxedematous patients complain of weakness and numbness of the feet, legs, and, to a lesser extent, hands, for which no other explanation can be found. Loss of reflexes, diminution in vibratory, joint-position, and touch-pressure sensations, and weakness in the distal parts of the limbs are the usual findings. The neuropathic manifestations are seldom severe. Nerve conduction velocities are slowed, and the protein content of the CSF is usually increased to more than 100 mg/dL. Possibly the latter finding is a reflection of the increased protein content of the serum in the hypothyroid state. The subjective improvement and complete or near-complete reversibility of neuropathic signs following treatment with thyroid hormones provides convincing evidence of a hypothyroid etiology. In biopsies of nerve, an edematous protein infiltration of the endoneurium and perineurium, a kind of metachromatic mucoid material, has been seen. Dyck and Lambert (who should be credited for drawing attention to this neuropathy) noted segmental demyelination in teased fiber preparations. In electron-microscopic sections, a slight increase in glycogen, acid mucopolysaccharides, and aggregates of glycogen and cytoplasmic laminar bodies in Schwann cells have been observed by others.

Polyneuropathy of sensorimotor type has also been observed in association with a syndrome of chronic lymphocytic thyroiditis and alopecia (Hart et al).

Chronic Mild Sensory Polyneuropathy of the Elderly (Burning Feet Syndrome) All neurologists have observed numerous cases of a relatively nonprogressive sensory polyneuropathy in elderly patients. Tingling paresthesias of feet and lower legs, sensory loss, and absent ankle reflexes are the usual findings. The hands may be mildly affected but leg weakness and imbalance are absent or trifling. A painful variety is also known (see later). Laboratory studies may be normal or reveal minimally altered sensory conduction, but the evaluation has often not been extensive, and therefore it is difficult to say if Sjögren syndrome, glucose intolerance, or another underlying disease is responsible. Usually this chronic condition progresses little.

The most common variant of this form of chronic sensory polyneuropathy is one that affects mainly elderly women, who

Table 46-5
Causes of painful sensory neuropathy (Adapted from Mendell and Sahenk)

Common
Idiopathic in the elderly
Diabetes
Vasculitis
Residue of Guillain-Barré syndrome
Renal failure
Connective tissue disease, especially Sjögren disease
Human immune deficiency virus
Less Common
Amyloidosis, familial and primary
Paraneoplastic
Sarcoidosis
Toxic neuropathy, esp. arsenic poisoning
Fabry disease
Perineuritis

complain of slowly progressive (over years) *painful burning and numbness of the feet*, ascending to the ankles or midcalves. There are few findings on examination; often only a mild or moderate loss of pinprick and thermal sensation, and ankle reflexes that may or may not be reduced. Again, there is little or no progression over the years. Most of these cases are idiopathic but there is a broad differential diagnosis including the diseases mentioned earlier, as outlined by Mendell and Sahenk (Table 46-5 is adapted from their discussion). Identifiable causes for painful sensory neuropathy in elderly include mainly diabetes, alcoholic-nutritional deficiency states, connective tissue disease, amyloidosis, and vasculitis.

Electrophysiologic tests are likewise normal or virtually so; a few show diminished sural nerve potentials and minor changes of motor amplitudes. When these changes cannot be ascribed to diabetes, malnutrition, medications, or the other causes listed in the table, a substantial group of patients is left and are in need of symptomatic relief. Some have been helped by gabapentin or by antidepressants (amitriptyline, desipramine, or sertraline) and analgesic cream applied nightly to the soles and toes. Surprisingly, a few of the more severe cases have apparently responded to gamma globulin infusions but these observations require corroboration (Gorson and Ropper, 1995). In a number of cases of burning feet, the intra-dermal sensory nerves in skin biopsy specimens are said to be depleted of fibers but the meaning of this finding is not certain (Periquet et al).

Multiple Symmetrical Lipomas with Sensorimotor Polyneuropathy Whereas the usual cutaneous lipomas have no neurologic accompaniments, this clinical curiosity, known as Lanois-Bensaude disease, consists of symmetrical lipomas of the neck and shoulders that are associated with polyneuropathy and sometimes deafness. A mitochondrial disorder is suspected. Details can be found in the review by Neumann.

GENETIC FORMS OF CHRONIC POLYNEUROPATHY

In this large category of chronic polyneuropathy, symptoms evolve gradually over a period of many years. A polyneuropathy that advances slowly over a period of five to ten years or more is almost

invariably genetic in origin. The neuropathic disease may be remarkably restricted, as in familial analgesia with foot ulcers, or extensive, as in familial peroneal muscular atrophy. The time of onset of these very chronic neuropathies is usually in early life but often cannot be dated with certainty by the patient or family. In infants, the condition may be mistaken for muscular dystrophy or infantile muscular atrophy until sensory testing becomes possible. In the developing child, whose musculature naturally increases in power and volume with age, it may be difficult to decide whether the disease is progressive. In some cases, ataxia of the limbs may be pronounced at a stage when sensory loss exceeds paresis.

Strongly indicative of one of these conditions of early onset are pes cavus, hammer toes, and, in extreme forms, talipes equinus. One of these deformities is commonly detected in most cases of generalized inherited polyneuropathy. In later stages, trophic changes of skin and bone in distal parts of the limbs indicate involvement of small (pain) fibers, and the presence of deformed and degenerated joints (Charcot joint) appear and are indicative of a loss of articular pain fibers. The mutilating effects are the result of repeated injury to analgesic parts and to a lack of autonomic vascular reflexes. The atrophy of muscle and trophic changes in the skin are generally more marked than in the acquired forms of polyneuropathy.

The CSF protein content may remain mildly or moderately elevated over a period of years. Charcot-Marie-Tooth disease (type 1) shows slowed nerve conduction as a consequence of a disorder of myelin. A distinctive feature of hereditary neuropathy is the uniformity of the electrophysiologic changes, e.g., the same degree of slowing of nerve conduction velocity in all the nerves of the lower limbs, or in all the motor nerves, a feature that distinguishes this group from all acquired neuropathies.

There has been much difficulty in classifying the chronic familial polyneuropathies. Recent genetic findings have greatly simplified the matter of classification and have permitted the creation of a nosology that more or less parallels the clinical one. The proposed classifications in Tables 46-2 and 46-6 represent an attempt to conciliate the clinical and genetic data.

Of this large and varied group, only the sensorimotor Charcot-Marie-Tooth type is likely to be seen with any regularity by neurologists and general physicians. This group has become quite large as more individual mutations are discovered. The commonly encountered varieties are indicated in italics in Table 46-6. As a rough guide to the frequency of various types detected in a large neuromuscular clinic, Boerkoel and colleagues found that of 153 unrelated patients, 79 had the mutation that corresponds to the common variety of Charcot-Marie-Tooth disease (CMT1A), but what is of equal interest, 50 patients with a clear history of heredofamilial neuropathy had none of the currently detectable mutations.

Table 46-6 summarizes the major forms of hereditary neuropathy. These are designated as subcategories of Charcot-Marie-Tooth (CMT) disease and grouped by patterns of inheritance. Thus, the dominantly inherited myelinopathies have been designated CMT1 and the dominant axonopathies CMT2. The myelinopathies with onset in infancy are subsumed under CMT3, while most recessively inherited neuropathies (both axonal and demyelinating) are called CMT4. The hereditary sensory neuropathies, sometimes also called hereditary sensory and autonomic neuropathies, are also listed (HSN and HSAN). An alternate nomenclature, which describes the CMT classes as hereditary motor and sensory neuropathies (HMSN), is used elsewhere and mentioned in some of the discussion that follows.

Inherited Polyneuropathies of Mixed Sensorimotor-Autonomic Types

Peroneal Muscular Atrophy [Charcot-Marie-Tooth Disease, or CMT Types 1 and 2; Hereditary Motor-Sensory Neuropathy, or HMSN Types I and II (Dyck); and Related Conditions (See Table 46-6)] The hallmarks of this class of polyneuropathies are genetic transmission, complete symmetry, slow progression, and loss of myelin out of proportion to axons. These are the most common forms of inherited peripheral neuropathy and indeed among the most common of all inherited neurologic diseases. The frequency of the disease cannot be stated with precision because of its clinical heterogeneity, but the usually quoted prevalence is 1 in 2500 of the population, the most frequent subtype occurring in 1 in 4000. More than 15 subtypes have been described but only a few occur with any regularity.

Because the disease was described in 1886 almost simultaneously by Tooth in England and by Charcot and Marie in France, all their names have been attached to it, even though similar cases had been recorded earlier by Eulenberg (1856), Friedreich (1873), Ormerod (1884), and Osler (1880). The secondary changes in the spinal cord and the occasional association of this disease with Friedreich ataxia led early observers to consider it as a hereditary myelopathy and not to class it with the neuropathies, but the evidence supporting the latter grouping is now unassailable. The two important advances in our understanding of this disease since the original descriptions have been the separation of the main subtypes on the basis of their electrophysiologic (EMG) features, and the discovery of gene mutations which cause many of these diseases. In most cases, these mutations can be related to alterations in components of peripheral nerve myelin or axons.

Genetic Transmission The pattern of inheritance of Charcot-Marie-Tooth disease is most often that of an autosomal dominant trait, with almost complete penetrance; less often it is autosomal recessive and rarely X-linked dominant or X-linked recessive (see Table 46-6). Some cases, probably a small number, arise as de novo mutations (Hoogendoijk et al.). The common types that are connected to chromosomes 1 or 17 cannot be easily distinguished from one another on clinical grounds but they have distinctive EMG features. Seventy percent of CMT type 1 cases result from duplication of the gene for a peripheral myelin protein (PMP22) on chromosome 17 p11 (type CMT1A). Other studies of the PMP22 and PO (another myelin protein) gene expression in CMT1 and CMT3 cases (Dejerine-Sottas disease) have yielded discordant results because mutations on different loci, including one on chromosome 1, lead to different presentations, as noted in Table 46-6. The disease termed *hereditary liability to pressure palsies* also displays an aberration on chromosome 17, but in the form of a deletion rather than a duplication of the gene for PMP22. This disease is discussed further on, under "Brachial Plexus Neuropathies." Yet an additional X-linked variant is the result of a mutation of the gene for connexin-32, another component of myelin, and is seen reasonably often.

Undoubtedly, further studies of genes and gene products will continue to advance our understanding of the inherited neuropathies, but for the present, clinicians are still best served by the descriptive clinical classification outlined in Table 46-2—acknowledging, of course, the clinical heterogeneity of this class of disorders.

Clinical and Electrophysiologic Features Dyck and Lambert and Harding and Thomas have subdivided CMT disease into two

Table 46-6
Classification of the inherited peripheral neuropathies

	PATHOLOGY	ONSET	GENE	CLINICAL AND THERAPEUTIC FEATURES
I. Charcot-Marie-Tooth (CMT) and related disorders				
1. CMT1 (dominantly inherited myelinopathy)				
CMT1A*	demyelinating	c	Duplication of gene for peripheral myelin protein (PMP22)	Early areflexia, distal weakness, sensory loss
CMT1B*	demyelinating	c, a	Myelin protein P0	Early areflexia, distal weakness, sensory loss
CMT1C	demyelinating	a	Lipopolysaccharide-induced TNF α	
CMT1D, CMT4E	demyelinating	c, a	Transcription factor EGR2	May be severe and congenital
CMT1F, CMT2E	demyelinating, axonal	c,a	Neurofilament light subunit	
Congenital hypomyelination	demyelinating	c	Rho guanine exchange factor	Mild or asymptomatic
2. CMT2 (dominantly inherited axonopathy)				
CMT 2A*	axonal	c, a	Kinesin KIF1B β motor protein	
CMT2A (alt)	axonal	c, a	Mitofusin (MFN2)	
CMT2B	axonal	a	GTP binding protein RAB7	Prominent vocal cord, diaphragm paralysis
CMT2C	axonal	c, a		
CMT2D	axonal	a	Glycyl t-RNA synthetase (GARS)	
CMT2F 1	axonal	c, a	Heat shock protein 27	Slow, motor predominant
CMT2F 2	axonal	c, a	Heat shock protein 22	Slow, motor predominant
3. AR - CMT2 - (recessively inherited axonopathy)				
AR-CMT2A	axonal		Nuclear membrane lamin A/C	
4. CMT3 (congenital myelinopathy)	demyelinating	inf	PMP22, P0, EGR2 (above)	
5. CMT4 (recessively inherited myelino-axonopathy)				
CMT4A	demyelinating	c	Ganglioside induc'd different'n protein	May be rapidly progressive
CMT4B	demyelinating	c	Myotubularin-related protein	Focally folded myelin
CMT4B 2	demyelinating	c, a	SET-binding factor (SBF2)	
CMT4C	demyelinating	c	Novel neural protein (KIAA1985)	Early scoliosis
CMT4D	demyelinating	c	Schwann cell protein Nm-ycDRG1	Neuropathy + hearing loss
CMT4F	demyelinating	c	Nuclear membrane protein (periaxin)	Early onset, severe
6. CMT X (XD)*	demyelinating	c, a	Connexin-32	
7. Neuralgic amyotrophy (AD)	axonal	c, a	Unknown	Focal, painful brachial plexitis
8. HNPP*	axonal	c	PMP22 gene deletion	Focal entrapments, chronic neuropathy
II. Hereditary Sensory and Autonomic Neuropathy (HSAN)				
1. HSAN1 (AD)	axonal	a	Serine palmitoyl transferase	Small fibersensory and distal motor deficits
2. HSAN2 (AR)	axonal	inf	Novel neuronal protein	
3. HSAN3 (Riley-Day, AR)	axonal	inf	Kinase associated protein (IKBKAP)	
4. HSAN4 (AR)	axonal	inf	TrkA / NGF receptor	Congenital SN with anhidrosis
5. HSAN6 (AR)	axonal	inf	Nerve growth factor - beta	Absent pain
III. Familial Amyloid Polyneuropathies (AD)				
1. Type 1 – Portuguese	axonal	a	Transthyretin	Liver transplant may be beneficial
2. Type 2 – Indiana / Swiss	axonal	a	Transthyretin	Liver transplant may be beneficial
3. Type 3 – Van Allen	axonal	a	Apolipoprotein A1	Lax skin and “blood hound” face; corticospinal, posterior column deficits
4. Type 4 – Finnish	axonal	a	Gelsolin	

Table 46-6 (Continued)

Classification of the inherited peripheral neuropathies

	PATHOLOGY	ONSET	GENE	CLINICAL AND THERAPEUTIC FEATURES
IV. Hereditary Disorders of Lipid Metabolism Causing Neuropathy (AR)				
1. Metachromatic leukodystrophy	demyelinating	inf-a	Arylsulfatase A and B	
2. Krabbe disease	demyelinating, axonal	inf-a	β -galactosidase	Early bone marrow transplant may be beneficial
3. Fabry disease	axonal	c	α -galactosidase	Heat-induced pain, macular rash
4. Adrenomyeloneuropathy (XR/XD)	demyelinating, axonal	inf-a	ABCD1 transporter	Early bone marrow transplant may be beneficial
5. Refsum disease	demyelinating	inf-a	Phytanoyl- α CoA-hydroxylase	Dietary restriction may ameliorate the disease.
6. Tangier disease	axonal	a	ABC1	Small fiber neuropathy, facial weakness, low HDL
V. Miscellaneous Inherited Neuropathies				
1. Giant axonal neuropathy (AR)	axonal	c	Gigaxonin	
2. Porphyria (AR)	axonal	c, a	Porphobilinogen deaminase	May respond to hematin, glucose
3. "Mitochondrial" neuropathies	axonal			
4. Severe PNS, CNS demyelination (AD)	demyelinating	inf, c	Myelin transcription factor SOX10	CNS, PNS hypomyelination

*The more common varieties of inherited neuropathy are italicized.

inf = infantile onset.

c = childhood onset.

a = adult onset.

broad types: hereditary motor sensory neuropathy (HMSN) I and II or CMT1 and 2. This subdivision is made on the basis of conduction velocity in the median or ulnar nerve—slow (mean conduction velocity less than 38 m/s) in type 1 and normal or near normal conduction in type 2. Electromyographers therefore refer to these respectively as the demyelinating and axonal types. In both, the compound muscle action potentials and sensory potentials are greatly reduced in amplitude, and in type 2 there are findings of denervation. However, in type 1 there is severe and widespread slowing of nerve conduction, but the type of electrical conduction block that characterizes the acquired demyelinating neuropathies is not found. To reiterate, in distinction to most acquired diseases of peripheral nerves, *the EMG findings, particularly the pronounced slowing of conduction in CMT1, are uniform throughout the peripheral nervous system*.

The classic form of CMT has its onset during late childhood or adolescence, although neurologists are increasingly aware that some cases, particularly type 2, may not attract attention until middle life. Type 1 cases have a peak appearance during the first decade. The peak onset of type 2 is in the second decade or even later; an onset in middle adult life is not unknown. Both motor and sensory signs are said to be more severe in the first type (Harding and Thomas). Difficulty running, frequent weakness and sprains of the ankles, or stumbling and slapping of the feet are noted by the parents of young children. Adult patients have difficulty dating the onset of symptoms. With milder forms, they may not even be aware of having a neuropathic illness. In some cases, the striking and widespread changes on EMG only come to light when this test is performed for the diagnosis of an unrelated problem or when a parent becomes aware of his neuropathy after a child proves to have the disease.

The chronic degeneration of peripheral nerves and roots results in distal muscle atrophy beginning in the feet and legs and later involving the hands. The extensor hallucis and digitorum longus, the perone, and the intrinsic muscles of the feet are affected early in life and this muscle imbalance produces the bony changes of pes cavus and *pied en griffe* (high arches and hammertoes). Later, all muscles of the legs and sometimes the lower third of the thigh become weak and atrophic. The thin legs have been likened to those of a stork or, if the lower thigh muscles are affected, to an “inverted champagne bottle.” Eventually the nerves to the calf muscles degenerate and the ability to plantar flex the feet is lost. After a period of years, atrophy of the hand and forearm muscles develops. The hands later become clawed. The wasting seldom extends above the elbows or above the middle third of the thighs. Paresthesias and cramps are present, but only to slight or moderate degree and there is always some impairment, usually slight, of deep and superficial sensation in the feet and hands, shading off proximally. Rarely, the sensory loss is severe, and perforating ulcers may appear as in the pure sensory varieties of inherited neuropathy. The tendon reflexes are absent in the involved limbs. The illness progresses very slowly over decades, giving the impression of stabilization for long periods.

Walking difficulty, which is ultimately the main disability, is due to a combination of sensory ataxia and weakness. Foot drop and instability of the ankles are additional handicaps. The feet and legs may ache after use and cramps may be troublesome, as mentioned, but otherwise pain is unusual; the feet may become cold, swollen, and blue, secondary to inactivity of the muscles of the feet and legs and their dependent position. There is usually no disturbance of autonomic function. Fixed pupils, optic atrophy, nystagmus and endocrinopathies, epilepsy, and spina bifida, which have been reported

occasionally in association with peroneal muscular atrophy, probably represent coincidental congenital disorders. The only distinguishing clinical feature between types 1 and 2, and this is present in only a minority of cases, is enlargement of the nerves in type 1, most easily appreciated by palpation of the greater auricular nerves. Aside from secondary changes in bone formation such as pes cavus, these patients do not display dysmorphic features.

The clinical heterogeneity of CMT disease has been alluded to in the previous discussion and is evident in the numerous mutations that give rise to similar chronic polyneuropathies. Restricted forms are known to affect only the peroneal and pectoral or scapular muscles (scapuloperoneal form of Dawidenkow). The “*familial claw foot with absent tendon jerks*” of Symonds and Shaw is another similar variant.

Laboratory data are of little help, except for reduced amplitudes of the compound muscle and sensory action potentials and the uniform and pronounced slowing of nerve conduction in CMT1 (often in the range of 20 m/s) or near normal velocities with evidence of denervation in type 2. The CSF is usually normal. Genetic tests for the most common type 1A (PMP duplication), type 2, and for the X-linked and 1B varieties are available, and it should now be possible to identify many more cases, including sporadic ones (see Table 46-6). It is seldom necessary to resort to nerve biopsy to establish the diagnosis but on some occasions we obtained a biopsy from a patient with negative genetic testing in whom we could not exclude chronic inflammatory demyelinating polyneuropathy.

Pathologic Findings Degenerative changes in the nerves result in depletion of the population of large sensory and motor fibers, leaving only the condensed endoneurial connective tissue. As far as one can tell, axons and myelin sheaths are both affected, the distal parts of the nerve more than the proximal. In type I, the nerves may be enlarged, with “onion-bulb” formations of Schwann cells and fibroblasts, as in Dejerine-Sottas disease (type III HMSN in the Dyck classification). This change can often be seen in sural nerve biopsies. Anterior horn cells are slightly diminished in number and some are chromatolyzed as a secondary change. Dorsal root ganglion cells suffer a similar fate. The disease involves sensory posterior root fibers with degeneration of the posterior columns of Goll more than of Burdach. The autonomic nervous system remains relatively intact. The muscles contain large fields of atrophic fibers (group atrophy). Some of the larger fibers have a target appearance and may show degenerative changes. All these muscle changes are typical of neurogenic denervation. Claims of a coincidental myelopathy and degeneration of spinocerebellar and corticospinal tracts probably indicate that the associated disease was really Friedreich ataxia or some other combination of chronic myelopathy and neuropathy.

Treatment No specific treatment is known. Stabilizing the ankles by arthrodeses is indicated if foot drop is severe and the disease has reached the point where it is not progressing. Pediatric orthopedic specialists have experience with several techniques to stabilize the joints of weakened limbs. Regular exercise, but avoiding excessive weight training, is usually prescribed. In mild and early cases, fitting the legs with light braces and the shoes with springs to overcome foot drop can be helpful.

The differential diagnosis involves the distal muscular dystrophies (page 1223), late forms of familial motor system disease, Friedreich ataxia (page 931), Roussy-Lévy syndrome (see later) and other familial polyneuropathies, and, in adult onset cases, CIDP and the paraproteinemic neuropathies, discussed earlier.

Heredity Neuropathy with Pressure Palsies (HNPP) This unusual but distinctive process of multiple recurrent local neuropathies first reported by Earl and colleagues is caused by a deletion of the PMP22 gene which is duplicated in the previously described CMT1A. In both CMT1A and HNPP, the PMP22 gene is functionally normal. These disorders arise because the total dose of the PMP22 protein is abnormal. In CMT1A, the gene is duplicated on one chromosome, and the total PMP22 protein is therefore predicted to be increased; by contrast, in HNPP, the gene is deleted from one chromosome, so that the PMP22 protein is predicted to be at half-normal levels. HNPP is transmitted as a dominant trait. In these individuals, the focal neuropathies and plexopathies are generally not painful (in contrast with hereditary neuralgic amyotrophy discussed further on, page 1166). Focal nerve lesions are often provoked by slight or even brief compression. In addition to recurrent focal nerve palsies, most individuals with HNPP have a chronic but slowly progressive demyelinating sensorimotor neuropathy that is mild on clinical examination (e.g., not all cases show areflexia). Electrophysiological studies are moderately abnormal with some slowing of conduction and distal motor and sensory nerve abnormalities. Nerve biopsies from these patients are most remarkable for the presence of localized nerve sheath thickening with duplication of the myelin lamellae (so-called tomaculae).

Hypertrophic Neuropathy of Infancy (Dejerine-Sottas Disease, CMT3, or HMSN III of Dyck) This relatively rare but striking neuropathy is inherited as an autosomal recessive trait. It begins in childhood or infancy, earlier than the classic form of peroneal muscular atrophy. Walking is delayed in onset and then progressively impaired. Pain and paresthesias in the feet are early symptoms, followed by the development of symmetrical weakness and wasting of the distal portions of the limbs. Talipes equinovarus postures with clawfeet and later clawhands are common. All modalities of sensation are impaired in a distal distribution, and the tendon reflexes are absent. Miotic, unreactive pupils, nystagmus, and kyphoscoliosis have been observed in some cases. The trunk and other cranial nerves are spared. The ulnar, median, radial, posterior neck, and peroneal nerves stand out like tendons and are easily followed with the gently roving finger. The enlarged nerves are not tender. Unlike other forms of CMT, the CSF protein is persistently elevated in Dejerine-Sottas disease in all likelihood because the spinal roots are enlarged. Nerve conduction velocities are markedly reduced, even when there is little or no functional impairment. Patients are usually much more disabled than those with peroneal muscular atrophy and are confined to wheelchairs at an early age. Treatment is purely symptomatic.

It is important to emphasize that the occurrence of hypertrophic neuropathy is not confined to this particular inherited disease. If one groups all patients in whom the nerves are diffusely enlarged (incorrectly called “hypertrophic,” since it is mainly a nonspecific reaction of the epineural and perineural connective tissue that contributes to the bulk of the nerves), several different diseases, both genetic and acquired, are included. The identifying histologic lesion in these cases is the “onion bulb,” which consists of a whorl of overlapping, intertwined, attenuated Schwann cell processes that encircle naked or finely myelinated axons and of endoneurial fibrofilaments. Enlarged nerves have been described in cases of recurrent demyelinating polyneuritis (CIDP), familial amyloidosis, Refsum disease (HMSN type IV of Dyck), peroneal muscular atrophy type I, and other diseases. As was first pointed out by Thomas, any pathologic process that causes recurrent seg-

mental demyelination and subsequent repair and remyelination may have this effect. In some patients with a history of early childhood hereditary polyneuropathy, the nerves are not yet palpably enlarged but the characteristic Schwann cell abnormalities are revealed in biopsy material from a cutaneous nerve.

As the molecular basis of the inherited polyneuropathies has been elucidated, it has become clear that diverse molecular defects can give rise to the same clinical phenotype. From a neurobiologic perspective, it was intriguing that both Dejerine-Sottas and Roux-Lévy syndromes were linked to a recessively inherited loss of the myelin protein P_O, and that the salient clinical features of this disorder are manifestations of defective nerve myelination. However, it has also become apparent that nearly identical clinical syndromes are associated with mutations in the genes for PMP22 and for the Schwann cell deoxyribonucleic acid (DNA)-binding protein EGR2. Moreover, it is also now evident that while some mutations in the P_O gene cause infantile onset neuropathies with the Dejerine-Sottas and Roux-Lévy phenotypes, other mutations in the same gene cause adult onset neuropathies. While the early onset cases show marked slowing of nerve conduction, the adult ones have conduction velocities that are typically above 35 m/s. The infancy-onset cases reveal major disruptions of folding of compact myelin, while in the adult-onset cases subtle alterations in the myelin protein P_O lead to a slow, predominantly axonal degeneration in adult life.

Inherited Polyneuropathies of Predominantly Sensory Type

Common to the several diseases comprising this group are insensitivity to pain, lancinating pains, and ulcers of the feet and hands, leading to osteomyelitis, osteolysis, stress fractures, and recurrent episodes of cellulitis. Since similar symptoms and signs occur in syringomyelia, leprosy, and tabes dorsalis, there is considerable uncertainty in older writings on this subject as to whether the reported cases were examples of one of these diseases or of hereditary neuropathy. According to Dyck, it was Leplat in 1846 who first described plantar ulcers (*mal perforant du pied*), followed by Nelaton in 1852. Morvan in 1883 reported his observations of adult patients who had developed suppuration of the pulps of insensitive fingers (whitlows). It is now generally agreed that Morvan's cases were examples of syringomyelia, whereas the family described by Nelaton was probably an example of the recessive form of childhood sensory polyneuropathy, since familial syringomyelia in children is practically unknown. We agree with Dyck that most such cases are examples of sensory polyneuropathy.

Mutilating Hereditary (Dominant) Sensory Polyneuropathy in Adults (Hereditary Sensory and Autonomic Neuropathy, HSAN1) The characteristic features of this group of polyneuropathies are an autosomal dominant mode of inheritance and onset of symptoms in the second decade or later. Characteristically this begins with subtle loss of sensation for painful stimuli in the feet (e.g., inability to feel the hot sand or hot water in a tub). As the disease evolves there is involvement of the feet with calluses of the soles and, later, episodes of blistering, ulceration, and lymphangitis followed by osteomyelitis and osteolysis, shooting pains, distal sensory loss with greater affection of pain and thermal sensation than of touch and pressure, loss of sweating, diminution or absence of tendon reflexes, and only slight loss of muscle power. Over time, loss of pain sensation in the fingers leads to fingertip ulcerations, osteomyelitis, and amputations.

The plantar ulcer overlying the head of a metatarsal bone is the most dreaded complication, since it may develop into osteomyelitis. Infection of the pulp of the fingers and paronychias are uncommon. Some patients have a mild pes cavus and weakness of the peroneal and pretibial muscles, with foot drop and steppage gait. Lancinating pains may occur in the legs, thighs, and shoulders, and, exceptionally, the pain may last for days or longer and be as disabling as that of tabes dorsalis; however, in the majority of patients there is no pain whatsoever. Neural deafness was present in one of Denny-Brown's patients. In the latter case, which was studied postmortem, there was a loss of small nerve cells in the lumbar-sacral dorsal root ganglia; the dorsal roots were thin, and the fibers in the posterior columns of the spinal cord and those in the peripheral nerves were diminished in number. Myelinated and unmyelinated fibers were both affected. Both axonal degeneration and segmental demyelination have been demonstrated in teased nerve preparations. Sensory nerve conduction may be absent or is uniformly slowed in every nerve tested.

It must be emphasized that despite its categorization as a "sensory and autonomic neuropathy," the most common, dominantly inherited form, termed *HSAN1*, also entails progressive, disabling, distal motor weakness, a consequence of ongoing axonopathy and denervation. As indicated in Table 46-6, the molecular pathogenesis of the hereditary sensory and autonomic neuropathies is beginning to be understood. It is clear, for example, that *HSAN1* is a consequence of a loss of function of the enzyme serine palmitoyl transferase, which is the rate-limiting step in the biosynthesis of sphingolipids.

Recessive Mutilating Sensory Polyneuropathy of Childhood Here the pattern of inheritance is autosomal recessive. Onset is in infancy and early childhood and walking is delayed; there is pes cavus deformity and the first movements are ataxic. Ulcerations of the tips of toes and fingers and repeated infections of these parts result in the formation of paronychias and whitlows. The tendon reflexes are absent, but muscular power is well preserved. All sensory modalities are impaired (touch-pressure somewhat more than pain-temperature), mainly in the distal parts of the limbs but also over the trunk. In addition, there are reports of several sibships in which multiple members had a sensory neuropathy manifest by a generalized insensitivity to pain of the type described later. The lesions and electrophysiologic findings are similar to those in the dominantly inherited sensory neuropathy.

In all types of hereditary sensory neuropathy, measures must be taken to prevent stress fractures, acral mutilation, and infection. This is more difficult in the small child who does not understand the problem.

It is now evident that some of the infantile hereditary sensory neuropathies are due to a disruption of molecular signaling pathways for neurotropic substances such as nerve growth factor that are critical to neural development.

Congenital Insensitivity to Pain In *congenital indifference to pain*, a syndrome in which the patient throughout life is unreactive to the pain of injury, there is no loss of the ability to distinguish pinprick and other noxious stimuli from nonnoxious ones. Furthermore, the nervous system of such individuals seems to be normal. There is, however, another variety characterized by universal analgesia (Swanson and colleagues). This latter type is inherited as an autosomal recessive trait and at least one form involves the gene for a nerve growth factor receptor located on chromosome 1q im-

mediately adjacent to the site of the mutation for Charcot-Marie-Tooth disease type 1B (Table 46-6). During childhood, one of the patients of Swanson et al had high fever when the environmental temperature was raised, and the other possibly had orthostatic hypotension. One of the patients died in his twelfth year and was found to have an absence of small neurons in the dorsal root ganglia, an absence of Lissauer's tracts, and a decrease in size of the descending spinal tracts of the trigeminal nerves. Sweat glands were present in the skin but were not innervated.

Other Forms of Inherited Sensory Neuropathy Included here are the neuropathy of Friedreich ataxia, which is discussed in Chap. 39; the Riley-Day syndrome, which is discussed further on in this chapter; neuropathy with cerebellar degeneration; and the neuropathies in which there are recognized metabolic abnormalities, including familial amyloidosis. We regularly see unclassifiable examples of an almost pure sensory or sensorimotor type. Some years ago a young man and woman with universal anesthesia affecting head, neck, trunk, and limbs came to our attention (Adams et al); all forms of sensation were absent. The patients were areflexic but retained nearly full motor power; their movements were ataxic. Autonomic functions were impaired but not abolished. In a sural nerve biopsy, nearly all fibers—large and small, myelinated and unmyelinated—had disappeared. Surprisingly, there were no trophic changes of any kind. Donaghy and others have described a unique variant of the recessively inherited form of sensory neuropathy in which there was an associated neurotrophic keratitis and a selective loss of small myelinated fibers in sural nerve biopsies. We continue to observe variant and unclassifiable cases such as these every year.

Hereditary Areflexic Dystasia (Roussy-Lévy Syndrome, CMT3) In 1926 Roussy and Lévy reported 7 cases of a dominantly inherited ataxic and neuropathic malady that had not previously been described. Its close relation to Friedreich ataxia and the amyotrophy of Charcot-Marie-Tooth disease was recognized. For many years thereafter the existence of this entity was disputed and, only recently, on the basis of molecular genetic testing, have these relationships been clarified.

The condition in question is a sensory ataxia (dystasia) with pes cavus and areflexia, affecting mainly the lower legs and progressing later to involve the hands. Some degree of sensory loss, mainly of vibratory and position sense, has been described in all cases. Atrophy of the muscles of the legs and postural tremor eventually become prominent. The patients do not have evidence of cerebellar disease (dysarthria, tremor, nystagmus, etc.). Kyphoscoliosis, a feature typical of Friedreich disease, has been described in several cases. Although the feet may be cold or slightly discolored, no autonomic defects are documented and the nerves are not palpably enlarged. Electrocardiographic abnormalities similar to those of Friedreich ataxia have been noted in one family but are not usual. The onset in many patients is during infancy, possibly dating from birth, and the course is relatively benign; all descendants of the original Roussy-Lévy family were still able to walk during their seventh decade of life.

On clinical and pathologic grounds, Dyck et al placed the Roussy-Lévy kinships within the category of the demyelinating type of Charcot-Marie-Tooth disease (CMT1). The mode of inheritance of the two syndromes, their benign course, pattern of neurologic signs, slow nerve conduction, and biopsy features (demyelination of nerve fibers with onion bulb formation) are much the

same. This view has been reinforced by the genetic findings reported by Planté-Bordeneuve et al. In affected members of the original Roussy-Lévy family, these investigators identified a point mutation in the domain of the myelin protein gene P_0 , the same gene that is implicated in Dejerine-Sottas disease. Based on limited pathologic study, there is no cerebellar degeneration; nevertheless, the shared clinical features with Friedreich ataxia are unmistakable.

Polyneuropathy with Cerebellar Degeneration (See page 934) Several such cases of adult onset have come to our attention over the years. Unlike Friedreich disease, the ataxia is mild, and there is no kyphoscoliosis but pes cavus or hammer-toe deformities are found, attesting to the early onset of the neuropathy. The lower legs become atrophic and findings characteristic of CMT such as absent ankle reflexes and mild to moderate loss of distal deep sensibility are present. There is no Romberg sign and no Babinski signs. The outstanding feature is a profound atrophy of the cerebellar hemispheres, and to some extent of the vermis, on MRI. Although the illness is slowly progressive, our patients, like those with Roussy-Lévy disease, have remained highly functional into late age, having difficulty mostly with maintaining balance when dancing or wearing high-heeled shoes. The EMG is consistent with CMT2. The electrocardiogram has been normal. Several, but not all, such patients have had a family history of a similar process but the available genetic testing has failed to reveal the site of a mutation.

Polyneuropathy with Spastic Paraparesis From time to time we have observed children and young adults with unmistakable progressive spastic paraparesis superimposed on a sensorimotor polyneuropathy of extremely chronic evolution. Sural nerve biopsy in two of our cases disclosed a typical "hypertrophic" polyneuropathy. In another case only loss of nerve fibers was found. Cavanaugh and colleagues and Harding and Thomas have reported similar patients. Our patients were severely disabled, being barely able to stand on their atrophic legs. The disease is slowly progressive. The patients described by Cavanaugh and coworkers had mainly sensory deficits and were not disabled. A more ambiguous form of disease has been described by Vucic and colleagues in which there is typical CMT but with brisk reflexes. There were Babinski signs in half the patients and spastic dysphonia in a few others. The mutation is not known.

While few in number, some cases of chronic polyneuropathy are combined with optic atrophy, with or without deafness or retinitis pigmentosa, and Dyck has classed these in a separate group. Jaradeh and Dyck have also described a hereditary motor-sensory polyneuropathy with the later development of a parkinsonian or a choreic-dystonic syndrome that responded to L-dopa. Most cases of this type have had an autosomal recessive inheritance.

Hereditary Recurrent Brachial Plexopathy (Hereditary Neuralgic Amyotrophy, HNA) This entity, mentioned earlier in relation to hereditary neuropathy with pressure palsies because of the implication of a similar genetic locus, is discussed in a later section of the chapter under "Brachial Neuritis."

Inherited Polyneuropathies with a Recognized Metabolic Disorder

Refsum Disease (Heredopathia Atactica Polyneuritiformis; HMSN IV) This rare disorder, named after Refsum who made the first clinical observations, is inherited as an autosomal recessive

trait and has its onset in late childhood, adolescence, or early adult life. Diagnosis is based on a combination of clinical manifestations—retinitis pigmentosa, cerebellar ataxia, and chronic polyneuropathy—coupled with the metabolic marker of the disease, an increase in blood phytanic acid. Phytanic acid accumulates because of a deficiency of the peroxisomal enzyme, phytanoyl-CoA hydroxylase. The deficiency is caused by mutations in one of two disparate genes. Cardiomyopathy and neurogenic deafness are present in most patients, and pupillary abnormalities, cataracts, and ichthyotic skin changes (particularly on the shins) are added features in some. Anosmia and night-blindness with constriction of the visual fields may precede the neuropathy by many years. The polyneuropathy is sensorimotor, distal, and symmetrical in distribution, affecting the legs more than the arms. All forms of sensation are reduced, often deep sensation more so than pain and thermal sense, and tendon reflexes are lost. The CSF protein is increased, sometimes markedly. Usually, the polyneuropathy develops gradually, although in some patients it has a subacute onset or, after being established for some time, a tendency to worsen fairly abruptly.

Although the nerves may not be palpably enlarged, “hypertrophic” changes with onion bulb formation are invariable pathologic features. The metabolic defect has been discovered to be in the utilization of dietary phytol; a failure of oxidation of phytanic acid—a branched-chain tetramethylated 16-carbon fatty acid—accumulates in the absence of activity of the enzyme phytanoyl-CoA-hydroxylase. The relation between the increased phytanic acid and the polyneuropathy is uncertain.

Clinical diagnosis is confirmed by the finding of increased phytanic acid in the blood of a patient with a chronic, mainly sensory neuropathy; the normal level is less than 0.3 mg/dL but in patients with this disease it constitutes 5 to 30 percent of the total fatty acids of the serum lipids. Urinary phytanic acid concentration is also raised.

Treatment Diets low in phytol may be beneficial, but this is difficult to judge, for after an acute attack there is sometimes a natural remission. The effects of plasma exchange have also been difficult to interpret. In some patients there is a very slow and gradual progression of the disease and in others a more rapid progression with death from cardiac complications.

Neuropathy, Ataxia, and Retinitis Pigmentosa, without Increase in Phytanic Acid (NARP) Like the cases reported by Tuck and McLeod, we have observed several in which the clinical picture was almost identical to that of Refsum disease but elevations in phytanic acid could not be detected. A mild ichthyosis, sensorineural deafness, ataxia of mixed tabetic-cerebellar type, areflexia, and retinitis pigmentosa were the main findings. None of our cases had a positive family history. Sural nerve biopsy showed loss of large fibers. Biochemical abnormalities in the blood or cultured fibroblasts have not been detected. There has been an identifiable mitochondrial disorder in most of the recently studied cases. This probably represents a variant of the so-called NARP syndrome, as described on page 844. It should be remarked that most mutations of mitochondrial DNA cause a myopathy with multisystem disease, but not a neuropathy. The onset of the disease has been in childhood or adolescence with slow progression.

Abetalipoproteinemia (Bassen-Kornzweig Syndrome; See also page 827) This rare autosomal recessive childhood disorder has been described in Chap. 37 with the inherited metabolic disorders

of the nervous system. It is mentioned here because the brunt of the neurologic disorder falls upon the peripheral nerves. *Acanthocytosis* of red blood cells is its identifying feature. The earliest neurologic finding is usually diminution or absence of tendon reflexes, detected as early as the second year of life. Later, when the patient is first able to cooperate in sensory testing, a loss of vibratory and position sense is found in the legs. Cerebellar signs (ataxia of gait, trunk, and extremities; titubation of the head; and dysarthria), muscle weakness, ophthalmoparesis, Babinski signs, and loss of pain and temperature sense are the other characteristic neurologic abnormalities, in more or less this order of frequency. Mental backwardness occurs in some patients. There are no signs of autonomic disorder. Irregular progression occurs over a few years and many patients are unable to stand and walk by the time they reach adolescence. (There is no relationship to acanthocytosis with chorea.)

Skeletal abnormalities include pes cavus and kyphoscoliosis, which are secondary to the early-onset neuropathy. Constriction of the visual fields and ring scotomata are manifestations of the macular degeneration and retinitis pigmentosa in some cases. Cardiac enlargement and congestive failure are serious late complications.

Neuropathologic findings consist of demyelination of peripheral nerves and degeneration of nerve cells in the spinal gray matter and cerebellar cortex. Diagnosis is confirmed by the finding of red blood cell acanthocytes, low serum cholesterol, and β (low-density)-lipoproteins. The disease is caused by defects in a triglyceride transfer protein, as discussed in Chap. 37. A deficiency of vitamin E, due to malabsorption, may be a factor, and large doses of the vitamin should be tried as therapy.

A closely related disease, also with familial hypobetalipoproteinemia, has been described by van Buchem and coworkers. It too is associated with malabsorption syndrome, ill-defined weakness, ataxia, dysesthesia of the legs, and Babinski signs. There is no sensory loss.

Tangier Disease This is a rare familial disorder of which we have seen four cases, inherited as an autosomal recessive trait. It is named for the island off the Virginia coast where the first-described patients resided. The genetic abnormality eliminates the function of the so-called ATP-cassette transporter protein. It results in a deficiency of high-density lipoprotein, low serum cholesterol, diminution of phospholipids, and high triglyceride concentrations in the serum. Perhaps because of these abnormalities, the patients are disposed to early and severe atherosclerosis. The presence of enlarged, yellow-orange (cholesterol-laden) tonsils is said to be a frequent manifestation (two of our patients had had previous tonsillectomies so that this sign was not evident). About half of the reported cases have had neuropathic symptoms, taking the form of an asymmetrical sensorimotor neuropathy that fluctuates in severity.

The sensory loss is predominantly for pain and temperature and extends over the entire body; at times it is limited to the face and upper extremities simulating syringomyelia (pseudosyringomyelia). Tactile and proprioceptive sensory modalities tend to be preserved. The polyneuropathy may come in attacks—that is to say, it is recurrent. In the two sisters reported by Engel and coworkers, the onset of symptoms was in childhood and in infancy, respectively. Muscular weakness, if present, affects either the lower or upper extremities or both, particularly the hand muscles, which may undergo atrophy and show denervation by EMG. In a small number of patients there has been facial diplegia out of proportion to weakness elsewhere. In one of our patients, the pain and tem-

perature loss was restricted to the head, neck, and arms. Nerve conduction is slowed. Tendon reflexes are often lost or diminished. Transient ptosis and diplopia have been reported.

Fat-laden macrophages are present in the bone marrow and elsewhere. No complete pathologic studies are available. There is no known treatment. Dietary measures to reduce triglycerides may help, particularly in preventing atherosclerosis, but whether they influence the neuropathy is uncertain.

Fabry Disease (Anderson-Fabry Disease; See also page 839) The genetic and metabolic aspects of this sex-linked disorder caused by deficiency of β -galactosidase have already been considered with the inherited metabolic diseases. Here we offer some additional remarks about the painful neuropathic component. It bears commenting that 10 percent of heterozygotic women display neuropathic symptoms, but usually of later onset and lesser degree than in males.

The pain, which is usually the initial symptom in childhood and adolescence, often has a burning quality or occurs in brief lancinating jabs, mostly in the fingers and toes and may be accompanied by paresthesias of the palms and soles. Changes in environmental temperature and exercise may induce pain in "crises," an identifying feature. These abnormalities are due to the accumulation of glycolipid (ceramide trihexoside) in peripheral nerves, both perineurally and intraneurally, as well as in cells of the spinal ganglia and the anterior and intermediolateral horns of the spinal cord. Ohnishi and Dyck have demonstrated a preferential loss of small myelinated and unmyelinated fibers and small neurons of dorsal root ganglia and Cable and colleagues reported autonomic changes in other cases. Involvement of the sensory ganglia and the associated degenerative changes in the afferent fibers are thought to be the likely cause of the thermally induced painful sensory phenomena (Kahn).

Later in the illness there is progressive impairment of renal function and cerebral and myocardial infarction. The characteristic dermal feature is the presence of numerous dark red macules and papules (angio keratomas), up to 2 mm in diameter, over the trunk and limbs, most closely clustered over the thighs and lower trunk and around the umbilicus (*angiookeratoma corporis diffusum*). The comprehensive review by Brady and Schiffman is recommended.

Treatment Phenytoin, carbamazepine, or gabapentin and amitriptyline may be helpful in alleviating the pain and dysesthesias. As discussed in Chap. 38, enzyme replacement therapy has become available and seems to lead to partial remission of many of the features.

Polyneuropathy of Acromegaly and Gigantism *Nerve entrapment*, particularly of the median nerve, is a well-known feature of acromegaly. Pickett and colleagues identified carpal tunnel syndrome in 56 percent of acromegalics. Also recognized as a complication of acromegaly, but not due to multiple nerve entraps, is *polyneuropathy* characterized by paresthesias, loss of tendon reflexes in the legs, and atrophy of slight degree in the distal leg muscles. Sometimes there are enlarged nerves. In the case reported by Stewart, the enlargement was the result of hypertrophic changes in the endoneurial and perineurial tissues, similar to those that occur in other so-called hypertrophic neuropathies of inflammatory or heredofamilial origin. In cases of extreme gigantism, a more severe polyneuropathy has sometimes been reported, to the point of causing Charcot joints (Daughady).

Mentioned here is a case we have observed in which a severe but slowly progressive motor neuropathy occurred in a patient with Pyle disease, a metaphyseal dysplasia that resembles acromegaly.

Metachromatic Leukodystrophy (See also Chap. 37) In this disease, the congenital absence of the degradative enzyme sulfatase leads to massive accumulation of sulfate throughout the central and peripheral nervous systems and to a lesser extent in other organs. The abnormality is transmitted as an autosomal recessive trait. Progressive cerebral deterioration is the most obvious clinical feature, but hyporeflexia, muscular atrophy, and diminished nerve conduction velocity reflect the presence of a neuropathy. Early in the course of the illness, the weakness, hypotonia, and areflexia may suggest Werdnig-Hoffmann disease; in older children there may be a complaint of paresthesias and demonstrable sensory loss. Bifacial weakness has been reported but must be rare. Sensory and motor conduction velocities are slowed. Metachromatically staining granules accumulate in the cytoplasm of Schwann cells in all peripheral nerves as well as in the cerebral white matter. There is also a loss of myelinated fibers. The measurement of arylsulfatase A activity in peripheral leukocytes or urine and biopsies of sural nerves are used to establish the diagnosis, even early in the course of the illness.

Riley-Day Familial Dysautonomia (See also Chap. 26) This disorder, inherited as an autosomal recessive trait, affects Jewish children predominantly. Familial dysautonomia is usually manifested at birth (poor sucking, failure to thrive, unexplained fever, episodes of pneumonia). Hyporeflexia and impairment or loss of pain and temperature sensation, with relative preservation of pressure and tactile sense, are the main neuropathic manifestations. Motor fibers are probably involved as well, but only to a slight degree; this is shown more effectively by reduced motor conduction velocity in peripheral nerves than it is by weakness. At a later age the neuropathy becomes overshadowed by other manifestations of the disease, notably repeated infections and abnormalities of the autonomic nervous system—lack of tears, corneal ulceration, fixed pupils, blotchiness of the skin, defective temperature control, cold hands and feet, excessive sweating, lability of blood pressure, postural hypotension, difficulty in swallowing, esophageal and intestinal dilatation, emotional instability, recurrent vomiting, and stunted growth. The tongue lacks fungiform papillae.

Nerve biopsy reveals a diminution of small myelinated and unmyelinated fibers, which explains the impairment of pain and temperature sensation. In autopsy material, sympathetic and parasympathetic ganglion cells and, to a lesser extent, nerve cells in the sensory ganglia are diminished in number. Patients excrete increased amounts of homovanillic acid and decreased amounts of vanillylmandelic acid and methoxy-hydroxyphenylglycol. Weinshilboum and Axelrod demonstrated a significant decrease in serum dopamine β -hydroxylase, the enzyme that converts dopamine to norepinephrine. The disease is caused by a mutation in a gene that expresses a kinase-associated protein (Table 46-6). There is no treatment for the disease except to provide symptomatic relief of gastrointestinal symptoms and orthostatic fainting.

Other examples of congenital polyneuropathy with absence of autonomic function, probably differing from the Riley-Day dysautonomia, have been reported. Some of these, in our experience, develop transient episodes of reflex sympathetic dystrophy. A congenital failure of development of neural elements derived from the neural crest is postulated.

Ataxia telangiectasia and Chédiak-Higashi disease are other genetic diseases with a recognized metabolic abnormality that may cause a polyneuropathy. They are described in Chap. 37, with the hereditary metabolic disorders.

Inherited (FA) Amyloid Neuropathies (See Table 46-6) As noted earlier in the discussion of acquired (primary) amyloidosis, *amyloid* is a descriptive term for any of the proteins that are deposited in filamentous beta-pleated sheets; it can be derived from a number of precursor protein sources. Peripheral neuropathy is a common and often the most prominent manifestation of amyloidosis. The polyneuropathies are of two main types—those associated with familial amyloidosis (referred to as FA) and the other associated with primary (nonfamilial) systemic deposition of amyloid (termed AL), which is derived from a circulating monoclonal protein. The acquired type has been discussed earlier under “Polyneuropathy Associated with Paraproteinemia.” The most notable difference between these two types is the absence of a significant amount of paraprotein in the inherited forms (see further on). As also commented earlier in the chapter, the amyloidosis that is secondary to chronic suppurative or inflammatory disease, referred to as AA, is an increasingly rare condition and, in any case, does not affect the nerves.

The *familial amyloid polyneuropathies* comprise several distinct groups (Table 46-6). The pattern of inheritance in all types is autosomal dominant; males and females are affected with equal frequency. Although a descriptive classification based on the ethnic origin of affected families is still in use clinically, it is now possible to categorize the diseases according to their genetic causes and the corresponding chemical structure of the abnormal protein that is deposited in the tissue as amyloid. The recent cloning of many of the amyloid protein genes has made possible not only the detection of the common transthyretin gene abnormality but should also make available diagnostic DNA tests for the other types of familial amyloidosis in the near future (see Table 46-6). Lachmann and colleagues emphasize the high frequency of genetic defects in amyloid precursor proteins and the finding in one quarter of cases of a low-level monoclonal gammopathy. Our cases have not shown a paraprotein.

Characteristic of all the amyloid polyneuropathies is the preferential involvement of small-diameter sensory and autonomic nerves and deposition of amyloid in various organs. Sensory loss, therefore, dominates the picture and pain and autonomic changes are prominent in most varieties of the disease.

The following are the recognized types of *familial amyloid neuropathy*.

1. **The Portuguese (Andrade) type** Andrade, in 1939, recognized that a chronic familial illness known as “foot disease” among the inhabitants of Oporto, Portugal, was a special type of amyloid polyneuropathy. He was not the first to have seen amyloid in degenerating nerve but deserves credit for identifying the disease as one of the heredofamilial polyneuropathies. By 1969 he had studied 148 sibships, comprising 623 individuals, among whom there were 249 with polyneuropathy. Descendants of this family have been traced to Africa, France, and Brazil. Other foci of the disease have been reported in Japan (Araki et al; Ikeda et al), the United States (Kantarjian and DeJong), Germany (Delank et al), Poland, Greece, Sweden, and northwest Ireland (Staunton and oth-
2. **Familial amyloidosis with carpal tunnel syndrome (Swiss type)** Falls and coworkers in 1955 and later Rukavina and associates described a large group of patients of Swiss stock living in Indiana who developed, in their fourth and fifth decades, a characteristic syndrome of acroparesthesias in the hands due to deposition of amyloid in the connective tissues and beneath the carpal ligaments. Similar kindreds, of German descent, were recognized in Maryland. There was sensory loss and atrophic muscle weakness in the distribution of the median nerves, which were compressed. Section of the carpal ligaments relieved the symptoms. In some of the patients, other nerves of the arms were said to have become involved later. Vitreous deposits have been observed

ers). As far as one can tell, these are separate, unrelated probands in different ethnic groups.

The age of onset of this form of familial amyloid polyneuropathy is between 25 and 35 years. The disease progresses slowly and terminates fatally in 10 to 15 or more years. The initial symptoms are usually numbness, paresthesias, and sometimes pain in the feet and lower legs. Weakness is minimal, and the tendon reflexes, although diminished, may be retained early in the course of the illness. Pain and thermal sense are reduced more than tactile, vibratory, and position sense (a “pseudosyringomyelic”) pattern. Autonomic involvement is another important characteristic—loss of pupillary light reflexes and miosis, anhidrosis, vasomotor paralysis with orthostatic hypotension, alternating diarrhea and constipation, and impotence. These autonomic changes tend to be more extensive than the sensory ones. Difficulty in walking also develops and has its basis in a combination of faulty position sense and mild muscle weakness. Later, tendon reflexes are abolished and the legs become thin. The nerves are not enlarged. Cranial nerve involvement (facial weakness and numbness, loss of taste) is a late manifestation and occurs in only a few cases.

Cases vary somewhat. Cardiac enlargement and irregularities in cardiac rhythm due to bundle branch or atrioventricular (AV) block occur early in some and late in others. A few patients have had severe amyloid heart disease from the onset (Ikeda et al). Weight loss may be pronounced, owing to anorexia and disordered bowel function and the later development of a malabsorption syndrome. The liver may become enlarged (as it may in the acquired form). Vitreous opacities (veils, specks, and strands) may progress to blindness, but this has been rare; in a few, there has been an impairment of hearing. Involvement of the CNS—manifest as behavioral abnormalities, cerebellar ataxia, and bilateral corticospinal signs—has also been reported in a few cases, but their nature and pathologic basis is controversial (Ikeda et al). A nephrotic syndrome and uremia terminate life in some patients. The CSF may be normal or the protein content may be increased (50 to 200 mg/dL); the blood is normal except for anemia caused by amyloidosis of the bone marrow.

In this and the following most common familial amyloidoses, the amyloid is derived from an inherited abnormality of serum protein transthyretin (formerly called “prealbumin”). Several different amino acid substitutions have been identified in each group. In the originally described Andrade type, methionine replaces valine at amino acid 30; this has therefore been referred to as *transthyretin amyloidosis*.

2. **Familial amyloidosis with carpal tunnel syndrome (Swiss type)** Falls and coworkers in 1955 and later Rukavina and associates described a large group of patients of Swiss stock living in Indiana who developed, in their fourth and fifth decades, a characteristic syndrome of acroparesthesias in the hands due to deposition of amyloid in the connective tissues and beneath the carpal ligaments. Similar kindreds, of German descent, were recognized in Maryland. There was sensory loss and atrophic muscle weakness in the distribution of the median nerves, which were compressed. Section of the carpal ligaments relieved the symptoms. In some of the patients, other nerves of the arms were said to have become involved later. Vitreous deposits have been observed

frequently in this form of the disease. As with the Portuguese type, an abnormal transthyretin is the basis of the deposition of amyloid.

3. **Iowa type** In 1969, van Allen described an Iowa kindred with onset, in their 30s, of a fairly severe sensorimotor neuropathy, involving the legs and then the arms. There was amyloid deposition in the testes, adrenal glands, and kidneys (the usual cause of death) as well as a high incidence of peptic ulcer disease. The amyloid in this disease is derived from apolipoprotein A-1, in which there is an amino acid substitution.
4. **Cranial neuropathy with corneal lattice dystrophy** This unusual form of amyloid neuropathy was first described in three Finnish families by Meretoja—hence the label “Finnish type.” Subsequently, it was reported from several different parts of the world in families of non-Finnish heritage. This disease usually begins in the third decade, with lattice corneal dystrophy. Vitreous opacities are not observed, and visual acuity is little affected. Peripheral neuropathy may not be evident until the fifth decade, at which time the facial nerves, particularly their upper branches, become affected. The nerves of the limbs are involved even later and to a much lesser extent than in other amyloid neuropathies. In advanced cases there is a distinctive appearance of excessive skin folds about the face, facial diparesis, dysarthria, spasticity, and dense loss of posterior column function. At postmortem examination, deposits of amyloid are found in virtually every organ, but mainly in the kidneys and blood vessels and in the perineurium of affected nerves.

The amyloid fibrils are derived from the protein gel-solin. The latter is normally an actin-binding protein, but it is also an important constituent of basement membranes, which may explain the deposition of amyloid in the cornea and skin.

Diagnosis When the characteristic painful small-fiber type of sensory disturbance and autonomic changes are coupled with a family history of the same constellation, the diagnosis is not difficult. As noted in the earlier section on the acquired paraproteinemic neuropathy, the presence of a monoclonal (rarely polyclonal) immunoglobulin in the blood is found in only a limited number of patients with familial amyloid cases and it is of a low quantity, usually just above the upper limit of normal for the immunoglobulin subclass. Otherwise, as noted by several authors, the two types of amyloid disease are quite similar and, indeed, about 10 percent of cases thought to be acquired will in the end be found to have the genetic disorder (Lachmann et al). The situation has been rectified to some extent by the availability of gene sequencing to detect mutations related to amyloid. These tests are now performed by several commercial laboratories. Such testing is justified if there is a low concentration paraprotein (or none) and a typical amyloidotic polyneuropathy and when the family history does not point to the correct diagnosis.

Pathologic Findings Amyloid deposits are demonstrable in the walls of blood vessels, the interstitial (endoneurial) tissues of the peripheral somatic and autonomic nerves, and in the spinal and autonomic ganglia and roots. There is a loss of nerve fibers, the unmyelinated and small myelinated fibers being more depleted than the large myelinated ones. The anterior horn and sympathetic ganglion cells are swollen and chromatolysed due to involvement of

their axons, and the posterior columns of the spinal cord degenerate, also on a secondary basis.

The pathogenesis of the fiber loss in familial amyloidosis, as in the acquired type, is not fully understood. On the basis of their findings in a sporadic case of amyloid polyneuropathy with diabetes mellitus, Kernohan and Woltman suggested that amyloid deposits in the walls of the small arteries and arterioles interfered with the circulation in the nerves and that amyloid neuropathy is essentially an ischemic process. In other cases, however, the vascular changes are relatively slight and the degeneration of the nerve fibers appears to be related to their compression and distortion by the endoneurial deposits of amyloid or, alternatively, there may be a direct toxic effect of the embedded amyloid. Amyloid is also seen in the tongue, gums, heart, gastrointestinal tract, kidneys, and many other organs, where it may act as a tissue toxin or has a mechanically disrupting effect on cells.

Treatment Liver transplantation has in recent years proved curative of some of the familial amyloid polyneuropathies but obviously it has no role in the acquired forms. According to Herlenius and colleagues, over 500 patients have received liver transplants for this disease with a 77 percent rate of survival, equivalent to liver transplantation for other diseases.

Neuropathies Associated with AIDS (See Chap. 33) Patients infected with HIV are prone to several types of neuropathy, including a predominantly sensory type that may be painful, a lumbosacral polyradiculopathy, cranial (mainly facial nerve) and limb mononeuropathies, CIDP, GBS, and a vasculitic mononeuritis multiplex—none of which differs from the idiopathic or conventional varieties except that there is often a pleocytosis in the spinal fluid. Unique but not infrequent patterns in this group are the CMV cauda equina neuritis syndrome and an acute or subacute painful infiltrative lymphocytic neuropathy—a component of the diffuse infiltrative lymphocytosis (DILS; Moulingier et al). Polyneuropathy may also be induced by antiviral agents that are used in the treatment of HIV infection, as discussed in Chap. 33.

Problems in Diagnosis of the Chronic Polyneuropathies

This is the group of peripheral nerve diseases that has given the present authors the most difficulty. The cause of most of the acute and many of the subacute and relapsing forms usually can be established by the clinical and laboratory methods presently available in large centers. It is the early and late chronic polyneuropathies that continue to baffle the neurologist and general physician, despite the respectable advances that have been made in the field of genetic testing.

Diagnosis of Early Chronic Polyneuropathies A *sensorimotor paralysis*, which evolves over several weeks (subacutely) or more slowly, over many months or a year or two, and involves legs more than arms and distal parts more than proximal should, in an adult, always lead to a search for diabetes, occult neoplasia (carcinoma, lymphoma, multiple myeloma, or plasmacytoma), HIV infection, paraproteinemia (including amyloid neuropathy), connective tissue disease, and CIDP. In exceptional cases, a neoplastic process remains hidden for as long as 2 or 3 years after the onset of neuropathy. In our experience an environmental toxin, endocrine disorder (except for diabetes), or nutritional cause is seldom identified, de-

spite the frequent attribution of obscure polyneuropathies to such causes. Nonetheless, history of exposure to industrial or hobbyist toxins, sociopathy or psychopathy that would lead to toxin ingestion, or foreign travel should be sought and the evaluation should include testing for heavy metals in obscure cases. Unusual causes of nutritional deficiency such as celiac-sprue disease and other mal-absorption syndromes (Whipple disease, Crohn disease, chronic hepatic disease, intestinal bypass surgery) have usually been obvious enough when present, so that the experienced clinician rarely overlooks them. Perhaps sprue is able to cause a neuropathy with minimal gastrointestinal symptoms. Vitamin B₁₂ deficiency should be sought in cases of large-fiber neuropathy. A difficult problem is that of an older person with a mild, nonprogressive sensorimotor polyneuropathy in whom there is evidence of mild hypothyroidism, marginally low vitamin B₁₂ and folic acid levels in the blood, a somewhat unbalanced diet, perhaps an excessive alcohol intake, and an abnormal glucose tolerance response. It is easy to imagine but hard to prove that any one of these factors is relevant. Vitamin replacement should be undertaken nonetheless if no other cause is found.

In the *purely or predominantly sensory polyneuropathies not due to diabetes*—some painful, some not, and some with marked ataxia—an association with occult carcinoma, an IgM or other paraproteinemia, amyloidosis, or Sjögren syndrome are the primary considerations. The problem of a mild sensory neuropathy in an elderly patient was discussed earlier on page 1151. Rarely, a milder sensory neuropathy may be seen with biliary cirrhosis. When the symptoms are confined to the feet and legs, hereditary sensory neuropathy must always be considered if the condition is long standing.

Intoxications with pyridoxine or metals account for a few chronic sensory neuropathies. Despite all these considerations, we still regularly encounter patients in whom the cause is not disclosed by any of the available tests. We have watched helplessly as some of these patients become reduced to a bed and wheelchair existence and others suffer from pain until they turn to and become dependent on opiates.

In our experience, the *subacute and chronically evolving demyelinating neuropathies* that are suspected clinically and then confirmed by slowed conduction velocity, conduction block, and relatively normal needle EMG studies generally turn out to be variants of CIDP, some with a paraproteinemia. Often the electrophysiologic tests point to a combined axonal and demyelinating process, the latter reflected in prolonged distal latencies, conduction slowing or block, and loss of late responses. Marked weakness and reduced muscle action potential amplitudes in the face of minimal denervation, even if present in only a few nerves, also indicate at least a component of focal demyelination. Most of the mixed axonal-demyelinating cases in which one eventually arrives at a diagnosis will also be related to an immune (paraproteinemic) or inflammatory (CIDP) process; for the moment, it is useful to place these in the demyelinating category since many will respond to the same measures as are used in the treatment of purely demyelinating CIDP.

Laboratory tests that are useful in the investigation of this group of neuropathies are listed in Table 46-7.

Diagnosis of Late Chronic Polyneuropathies The majority of the more chronic and very gradually progressive polyneuropathies (i.e., evolving over 10 or more years) prove to be heredofamilial or sporadic mutations of the genes that are responsible for the in-

Table 46-7

Laboratory tests for the investigation of subacute and chronic polyneuropathies—in addition to electromyography^a

Serum glucose, glucose tolerance test, and glycosylated hemoglobin-A _{1C} (diabetes)
Anti-Hu antibody (paraneoplastic neuropathies)
Immunoelectrophoresis or immunofixation of serum and urine (paraproteinemic and amyloid neuropathies)
Anti-myelin-associated glycoprotein and antisulfatide antibodies (chronic immune sensory neuropathies)
Anti-GM ₁ antibody (multifocal motor conduction block)
Vitamin B ₁₂ and methylmalonic acid levels (B ₁₂ deficiency or nitrous oxide exposure)
Human immune deficiency virus antibody
Lyme antibody
Heavy metal concentrations in blood and tissue (toxic neuropathies)
Blood-urea-nitrogen
Thyroid hormone
Sedimentation rate, ANA, cryoglobulins, c-ANCA, rheumatoid factor, anti-SSA/SSB Sjögren antibodies, eosinophil count (vasculitides), antigliadin antibodies (sprue)
Serum carotene, vitamin E, pyridoxine levels (nutritional deficiencies and vitamin excess)
Genetic testing for Charcot-Marie-Tooth disease and for hereditary liability to pressure palsy and brachial plexopathy (inherited neuropathies)
Spinal fluid protein determination and cell content (chronic inflammatory demyelinating polyneuropathy, neoplastic and granulomatous meningitis)

^a The use of each test is guided by clinical circumstances.

herited types. The observations of Dyck and coworkers, referred to in the introduction to this chapter, are of interest in this respect. In a series of 205 patients who were referred to the Mayo Clinic with neuropathies of unknown cause, 86 were found to have an inherited form of the disease. With appropriate genealogic data, the diagnoses of the hypertrophic polyneuropathy of Dejerine-Sottas and the peroneal muscular atrophy of Charcot-Marie-Tooth can usually be made on clinical grounds alone (high arches, chronicity, etc.). Sporadic cases are more difficult. Many of the patients who have consulted us in adulthood for an obscure polyneuropathy report having had operations on their feet for these reasons but the connection to a genetic neuropathy had not been previously made. Additional hints are frequent sprained ankles and the need to tape the ankles during adolescence in order to run or participate in sports. Dyck and associates found that direct examinations of the patients' children, parents, and other close relatives—using all available clinical data, EMG, nerve conduction studies, CSF examination, and nerve and muscle biopsy—were often successful in revealing a hereditary basis for the neuropathy. We, too, have found that in perplexing cases, routine examination of other family members, searching specifically for dropped ankle jerks and muted-knee reflexes, foot abnormalities, or atrophy of leg muscles, has clarified the diagnosis. DNA testing for the classic forms of Charcot-Marie-Tooth disease is now available from commercial laboratories and has increased the diagnostic certainty.

Slowly progressive polyneuropathy with features of central

nervous system degeneration, particularly cerebellar ataxia, most often has a genetic basis but a small number are found to be due to a genetic metabolic disorder such as a leukodystrophy.

In contrast, a few young patients have come to our attention in whom a gradually progressive polyneuropathy that evolved over almost a decade turned out to be an acquired chronic inflammatory demyelinating condition rather than the expected genetic type. The absence of a family history of neuropathy or of high arches, and heterogeneous slowing of both nerve conduction velocities and reductions in motor amplitudes on the EMG, provided hints to the acquired nature of the condition.

Finally, it should be conceded again that even after the most assiduous clinical and laboratory investigation of patients with chronic neuropathy, at least one quarter of these disorders remain unexplained.

Problems in Diagnosis of Recurrent or Relapsing Polyneuropathy

Several types of neuropathy are particularly prone to recurrence: CIDP, Refsum disease, Tangier disease, and porphyria, in which the attacks recur spontaneously or are precipitated by the administration of barbiturates or other drugs. Repeated toxic exposure can do the same. Approximately 2 percent of patients with GBS have one or more relapses, in which the clinical and pathologic changes differ in no meaningful way from those of the acute monophasic form of the disease. Some instances of mononeuritis multiplex, especially when associated with cryoglobulinemia, are characterized by remission and relapse over many years, although the remissions are incomplete. A common cause of relapse is the withdrawal of corticosteroids in CIDP patients who are dependent on these drugs; similarly, lapses in the treatment of paraproteinemic neuropathies cause similar fluctuations in symptoms. Enlargement of nerves may occur with repeated attacks, and it is probable that some patients classed originally as having one form of Dejerine-Sottas hypertrophic neuropathy fall into this category. Also, it is obvious that patients who have recovered from an episode of alcoholic-nutritional or toxic polyneuropathy will develop a recurrence of their disease if they again subject themselves to intoxication or nutritional deficiency.

Neuropathic symptoms that fluctuate in relation to environmental factors such as cold (cryoglobulinemia), heat (Fabry and Tangier diseases), or intermittent exposure to heavy metal or other type of poisoning may simulate an inherently relapsing polyneuropathy.

MONONEUROPATHY, MONONEUROPATHY MULTIPLEX, AND PLEXOPATHY

The distinguishing feature of this group of neuropathies is that either one or several individual peripheral nerves or a plexus are involved by a disease process. The diagnosis rests on the finding of motor, reflex, or sensory changes confined to the territory of a single nerve; of several individual nerves affected in a random manner (*mononeuritis* or *mononeuropathy multiplex*); or of a plexus of nerves or part of a plexus (*plexopathy*). Certain neuropathies of this type—traceable to polyarteritis nodosa and other vasculitides, leprosy, sarcoid, or diabetes—have already been discussed and, indeed, are the main causes of the mononeuritis pattern. In addition to the signs of mononeuritis multiplex, pain, sometimes local

erythema over the infarction, and inconsistently elevated CSF protein are the main features; in certain of these diseases there is a slight CSF pleocytosis (e.g., HIV, Lyme disease). A subacute or chronic inflammatory neuropathy and the multifocal motor neuropathy caused by antibodies to GM₁ should also be considered.

In identifying a process as due to single or multiple mononeuropathies, the reader should refer to Table 46-1 (page 1118), which lists the roots, nerves, and muscles that are involved in particular movements and Table 46-4 which gives the main etiologies of mononeuritis multiplex.

Brachial Plexus Neuropathies

Brachial plexus neuropathies, or “brachial plexopathies,” usually unilateral, comprise an interesting group of neurologic disorders. Most develop without apparent cause and manifest themselves by sensorimotor derangements ascribable to one or more of the cords of the plexus. Some are due to infiltration by tumor, compression, obscure infections (possibly viral), and the delayed effects of radiotherapy. Others, of obvious cause, result from trauma in which the arm is hyperabducted or the shoulder violently separated from the neck. Difficult births are an important source of such traction injuries of the plexus but their nature is also evident. Rarely, the brachial plexus or other peripheral nerves may be damaged at the time of an electrical injury, either from lightning or from a household or industrial source (see page 1056). There may be impairment of function of the brachial plexus or portions thereof developing many months or years after radiation therapy. Direct compression of parts of the plexus by adjacent skeletal anomalies (cervical rib, fascial bands, narrowed thoracic outlet) or infiltration by breast or apical lung tumors represents another category of brachial plexus injury. A subcutaneous or intramuscular injection of vaccine or foreign serum was in the past sometimes followed by a brachial plexopathy, usually partial. There are also plexus lesions of presumed toxic nature, such as those following heroin injection. Granulomatous diseases such as sarcoid and secondary inflammatory processes related to lymphoma may implicate a plexus.

More common is an idiopathic *brachial plexus neuritis* of obscure origin, also called *Parsonage-Turner syndrome* discussed below. It stands apart as a special clinical entity, often difficult to distinguish from other types of brachial and axillary pain. Some of these cases, surprisingly, are familial; others occur in small outbreaks, but most are sporadic.

In assessing the type and degree of plexus injury, electrophysiologic testing is of particular importance. Early after a traumatic injury or other acute disease of the plexus, the only electrophysiologic abnormality may be an absence of late responses (F wave). After 7 to 10 days or more, as the process of wallerian degeneration proceeds, sensory potentials are progressively lost and the amplitudes of compound muscle action potentials are variably reduced. Fibrillation potentials, indicative of denervation, then begin to appear in the corresponding muscles. Even later, usually after several weeks, signs of reinnervation can be detected. In more chronic cases, all of these features are evident when the patient is first studied. The pattern of denervated muscles then allows a distinction to be made between a plexopathy, radiculopathy, and mononeuritis multiplex based on the known patterns of muscle innervation (see Table 46-1). If denervation changes are found in the paraspinal muscles, the source of weakness and pain is in the intraspinal roots, proximal to the plexus. (In this case, the sensory potentials are retained.) This localization is corroborated by finding

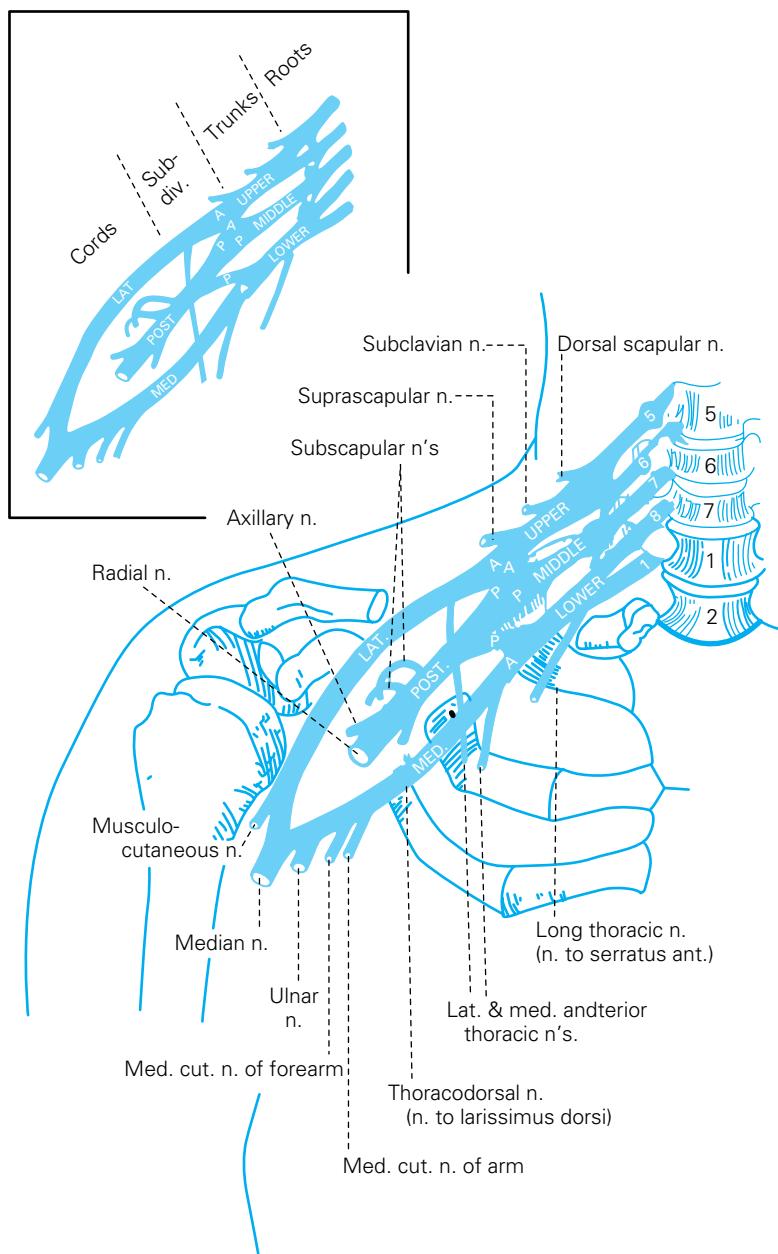

Figure 46-5. Diagram of the brachial plexus: the components of the plexus have been separated and drawn out of scale. Note that peripheral nerves arise from various components of the plexus: roots (indicated by cervical roots 5, 6, 7, 8, and thoracic root 1); trunks (upper, middle, lower); divisions (anterior and posterior); and cords (lateral, posterior, and medial). The median nerve arises from the heads of the lateral and medial cords. (From Haymaker and Woodhall by permission.)

preserved sensory potentials in nerves that are unaffected by lesions central to the ganglion. MRI may expose infiltrative lesions of the plexus, but small nodular lesions may escape detection and one then defers to the clinical data if the circumstances suggest an infiltrative or compressive lesion.

For the anatomic plan of the brachial (and lumbosacral) plexus and their relations to blood vessels and bony structures, Fig. 46-5 and one of the more detailed monographs on the peripheral nerves should be consulted. For the illustration of individual nerves, the manual of Devinsky and Feldmann and the one published by the Guarantors of Brain listed in the references proved helpful.

For quick orientation, it is enough to remember that the brachial plexus is formed from the anterior and posterior divisions of cervical roots 5, 6, 7, and 8 and the first thoracic nerve roots. The fifth and sixth cervical roots merge into the upper trunk, the seventh root forms the middle trunk, and the eighth cervical and first thoracic roots form the lower trunk. Each trunk divides into an anterior and posterior division. The posterior divisions of each trunk unite to form the posterior cord of the plexus. The anterior divisions of the upper and middle trunks unite to form the lateral cord. The anterior division of the lower trunk forms the medial cord. Two important nerves emerge from the upper trunk (dorsal scapular nerve to the rhomboid and levator scapulae muscles, and long thoracic nerve to the anterior serratus). The posterior cord gives rise mainly to the radial nerve. The medial cord gives rise to the ulnar nerve, medial cutaneous nerve to the forearm, and medial cutaneous nerve to the upper arm. This cord lies in close relation to the subclavian artery and apex of the lung and is the part of the plexus most susceptible to traction injuries and to compression by tumors that invade the costoclavicular space. The median nerve is formed by the union of parts of the medial and lateral cords.

Lesions of the Whole Plexus The entire arm is paralyzed and hangs uselessly at the side; the sensory loss is complete below a line extending from the shoulder diagonally downward and medially to the middle third of the upper arm. Biceps, triceps, radial, and finger reflexes are abolished. The usual cause is vehicular trauma.

Upper Brachial Plexus Paralysis This is due to injury to the fifth and sixth cervical nerves and roots, the most common causes of which are forceful separation of the head and shoulder during difficult delivery, pressure on the supraclavicular region during anesthesia, immune reactions to injections of foreign serum or vaccines, and idiopathic brachial plexitis (see later). The muscles affected are the biceps, deltoid, supinator longus, supraspinatus and infraspinatus, and, if the lesion is very proximal, the rhomboids. The arm hangs at the side, internally rotated and extended at the elbow. Movements of the hand and forearm are unaffected. The prognosis for spontaneous recovery is generally good, though this may be incomplete; injuries of the upper brachial plexus and spinal roots occurring at birth (Erb-Duchenne palsy) may persist throughout life.

Lower Brachial Plexus Paralysis This is commonly the result of traction on the abducted arm in a fall or during an operation on the axilla, infiltration or compression by tumors extending from the apex of the lung (superior sulcus or Pancoast syndrome), or compression by cervical ribs or bands. Injury may occur during birth, particularly with breech deliveries (Dejerine-Klumpke paralysis). There is weakness and wasting of the small muscles of the hand and a characteristic clawhand deformity. Sensory loss is limited to the ulnar border of the hand and the inner forearm; if the first thoracic motor root is involved, there may be an associated paral-

ysis of the cervical sympathetic nerves with a Horner syndrome. Invasion of the lower plexus by tumors is usually painful; postradiation lesions are more likely to cause paresthesias without pain (Lederman and Wilbourn).

Infraclavicular Lesions Involving Cords of the Brachial Plexus

(See Fig. 46-5) A lesion of the *lateral cord* causes weakness of the muscles supplied by the musculocutaneous nerve and the lateral root of the median nerve; it manifests mainly as a weakness of flexion and pronation of the forearm. The intrinsic muscles of the hand innervated by the medial root of the median nerve are spared. A lesion of the *medial cord* of the plexus causes weakness of muscles supplied by the medial root of the median nerve and the ulnar nerve. The effect is that of a combined median and ulnar nerve palsy. A lesion of the *posterior cord* results in weakness of the deltoid muscle, extensors of the elbow, wrist, and fingers, and sensory loss on the outer surface of the upper arm.

One group of infraclavicular injuries, often iatrogenic, results from damage to the subclavian or axillary vessels and the formation of pseudoaneurysms or hematomas. Small puncture wounds—as might occur with catheterization of the subclavian vein, anesthetic block of the brachial plexus, or transaxillary arteriography—are likely to produce this type of injury. Compression of the plexus usually evolves subacutely, up to 3 weeks, although once started, the deterioration may be rapid. Prompt recognition of the condition and early decompression are essential.

Other frequent causes of injury to the cords are dislocation of the head of the humerus, direct axillary trauma (stab wounds), pressure of a cervical rib or band, and supraclavicular compression during anesthesia. All cords of the plexus may be injured, or they may be affected in various combinations.

Costoclavicular (Thoracic Outlet) Syndrome This is discussed in Chap. 11 (page 186).

Brachial Neuritis, Brachial Plexitis (Neuralgic Amyotrophy, Parsonage-Turner Syndrome) This illness, of obscure nature, may develop abruptly in an otherwise healthy individual; it may also complicate an infection, an injection of vaccine or antibiotic, childbirth, surgical procedures of any type, or the use of heroin. Magee and DeJong in 1960 and Tsairis and coworkers in 1972 reported large series of cases and amplified a well-known clinical picture that the clinicians had observed repeatedly and called acute brachial neuritis. The term *neuralgic amyotrophy* was applied to this symptom complex by Parsonage and Turner, who wrote extensively on the subject. Their term for the condition is not entirely inappropriate, since the clinical and EMG findings suggest a lesion of the peripheral nerves of the shoulder girdle and upper arm rather than the cords of the plexus. Actually, the exact site of the pathologic changes has not been established. Our patients have nearly all been adults ranging from 20 to 65 years of age. Males may be slightly more susceptible.

Beginning as an ache or deep burning in and around the shoulder, centered over the deltoid, at the root of the neck or base of the skull, and suspected at first of being only a “wry” neck, or neck muscle strain, the pain rapidly becomes more severe. The onset can be remarkably abrupt and occasionally awakens the patient from sleep. It is made worse by movements that involve the muscles in the region, and the patient searches for a comfortable position. Often, narcotics are required to suppress the pain. After a period of 1 to 10 days there is a rapid development of muscular weakness and,

thereafter, sensory and reflex impairment. With the development of weakness, the pain begins to subside. In a few cases, the neurologic disorder occurs with little or no antecedent pain. Possibly in some there is pain that is not followed by demonstrable weakness. A small proportion of cases are bilateral at the outset, or the opposite side is affected in rapid sequence.

Unlike restricted radicular lesions, which almost never cause complete paralysis of a muscle, certain muscles involved in brachial neuritis—such as the serratus anterior, deltoid, biceps, or triceps—may be totally or almost totally paralyzed, sometimes in isolation (see later). Rarely are all the muscles of the arm involved (4 of 99 cases of Tsairis et al). Most of the neurologic deficits in our cases have been localized around the shoulder and upper arm; only rarely has the hand been affected predominantly. Either the biceps or triceps reflex may be abolished. In a few of our cases there has been an additional median, radial, anterior or posterior interosseous nerve palsy that can be detected and isolated by EMG to a site distal to the plexus (see later). Such patients usually have no fever, leukocytosis, or increased sedimentation rate. Occasionally there is a mild pleocytosis (10 to 50 white blood cells per cubic millimeter) and slightly increased protein in the CSF but most cases have a normal formula and sampling of CSF is not necessary for diagnosis.

Recovery of paralysis and restoration of sensation are usually complete in a matter of 6 to 12 weeks but sometimes not for a year or longer. In only about 10 percent of cases is there residual weakness and wasting of the affected muscles, and a similar number have had a recurrence some time later on the same or the opposite side. A number of our elderly patients with this condition have had little recovery of motor function in over 5 years.

Motor nerve conduction becomes impaired in 7 to 10 days as described earlier. The lesions are presumably of axonal type, and electrophysiologic features of denervation follow. A small proportion of cases are bilateral, usually sequentially, rather than simultaneously, and recurrences have been reported.

There are almost certainly *highly restricted forms* that affect only one or two nerves of the brachial plexus as mentioned earlier. The most common of these is an isolated palsy of the serratus anterior (long thoracic nerve). The suprascapular, axillary, posterior interosseous, and phrenic nerves are other common sites of solitary neuritis; pain is common in the region of the axilla or shoulder but it is probable that the same disorder occurs in a painless fashion. In the case of a unilateral phrenic nerve paralysis, there is mild dyspnea on exertion and one hemidiaphragm is found to be elevated on the chest film. When the process is not progressive and no mediastinal lesion can be detected, a phrenic palsy can be assumed to fall into this idiopathic category.

Duchowny and colleagues have described a patient in whom a typical brachial neuritis occurred as part of a febrile illness that proved to be due to CMV infection, and the same has been observed rarely in patients with AIDS. A few outbreaks of brachial neuritis have been recorded and prompted the suggestion that the Coxsackie virus is the cause. Whether Lyme infection can cause brachial neuritis is unsettled but we believe we have seen at least one instance, probably more of a cervical radiculopathy; there was a pleocytosis in the CSF. The therapeutic use of interleukin-2 and interferon has apparently precipitated a few cases. Formerly, when animal anti-sera were in common use, this entity was rather frequent, but now this is seldom seen. In the modern era it has been seen after injection of tetanus toxoid, typhoid-paratyphoid vaccine, and triple vaccine (pertussis, diphtheria, and tetanus).

Plexitis also occurs as an uncommon idiopathic complication of the *postpartum state* (Lederman and Wilbourn). Some of these are repetitive or bilateral and some are familial, but otherwise the plexitis has no distinguishing features from the idiopathic type of brachial neuritis. The heredofamilial variety is described later.

One must differentiate brachial plexitis from the following conditions: (1) spondylosis or ruptured disc with root involvement, particularly the C5 and C6 roots, in which paralysis is rarely as severe as it is in plexitis; (2) brachialgia from bursitis, labral tear, or “rotator cuff” syndrome; (3) polymyalgia rheumatica; (4) entrapment neuropathies, particularly of the subscapular or dorsal scapular nerve; (5) carcinomatous plexopathy; (6) radiation plexopathy; and, rarely (7) sarcoid and other granulomatous infiltrations. Dissection of the vertebral artery dissection may rarely simulate the pain and weakness of brachial neuritis (Berrier et al). The special case of plexopathy in patients with a genetic proclivity to pressure palsies is discussed below.

Pathologic data are sparse, but Suarez and coworkers have reported collections of intense mononuclear inflammation in fascicles of the plexus obtained by biopsy. Perivascular lymphocytes were found in the endoneurial space and, less so, in the epineurium. The disease has not been reproduced in the experimental animal. Therapy is purely symptomatic, but we have often embarked on a course of steroids and, in a few cases, other immunosuppressants when the illness continued to advance over many weeks. Corticosteroids have a beneficial effect on pain and have also been successful in some cases of lumbosacral plexitis for which reason this medication is favored by Suarez and colleagues.

Heredofamilial Brachial Plexopathy (Hereditary Neuralgic Amyotrophy, HNA) Rarely, an acute and painful *recurrent brachial neuropathy* occurs in a familial pattern. The inheritance is autosomal dominant, and the attacks, which are painless, occur most commonly in the second and third decades of life. The authors have observed this syndrome in three generations of a family, some members having had three to five attacks at ages ranging from 3 to 45 years. Lower cranial nerve involvement and mononeuropathies in other limbs were conjoined in some instances (see Taylor). Attacks may be spontaneous or precipitated by compression, slight stretching, or minor trauma in the region of the plexus. In one family, attacks have been triggered by events that activate the immune system (fevers, infections, surgical procedures). In several such families, there are subtle characteristic facial features including narrowed and horizontally positioned eyes and a long nasal bridge (Modigliani face). Cleft palate and unusual skin folds and creases have been observed in other kindreds (Jeannet et al).

The clinical course is usually benign with good recovery of each episode but residual deficits may accumulate after recurrent attacks. We have also had experience with the contemporaneous onset of brachial plexitis in an adult brother and sister who shared the same household but had no family history of a similar problem. A shared exposure to viral or environmental agents was suspected. In Dutch families affected by the disease, Alfen and colleagues point out that some patients experience a more chronic and undulating course rather than discrete attacks.

Madrid and Bradley have examined the sural nerves from two patients with familial recurrent brachial neuropathy. In teased single nerve fibers, they found sausage-like segments of thickened myelin and redundant loops of myelin with secondary constriction of the axon. In addition, nerve fibers showed a considerable degree of segmental demyelination and remyelination. They called this aberration of myelin formation “tomaculous” neuropathy (from *to-*

maculum, “sausage”). These changes were not observed in the sural nerve of a sporadic case of recurrent acute brachial plexus neuropathy but they are now appreciated as relatively nonspecific.

The genetic basis for this is not established precisely but genetic linkage studies map the disease to human chromosome 17q25 in many families. Another cause of recurrent brachial palsy, or of derivative syndromes involving nerves in the arms, is hereditary neuropathy with pressure palsies (HNPP) discussed in the earlier section on inherited neuropathies. As commented there, the gene defect is also on chromosome 17, but it is not the one associated with familial brachial neuritis (see Chance et al). Some confusion has arisen because CMT1A, HNPP, and the familial brachial palsy disease all have chromosome 17 defects. Pressure palsies in HNPP are painless, and there is usually an underlying and slowly advancing polyneuropathy. In some families, such as the one reported by Thomas and Ormerod, the distinction between HNA and HNPP was difficult since the recurrent brachial plexopathies were painful (consistent with the former) but there was also a painless multifocal sensory neuropathy (consistent with the latter).

Brachial Neuropathy following Radiation Therapy This is usually a complication of irradiation of the axilla for carcinoma of the breast. Stoll and Andrews studied a group of 117 such patients who were treated with high-voltage, small-field therapy and had received either 6300 or 5775 cGy in divided doses. Of those receiving the larger dose, 73 percent developed weakness and sensory loss in the hand and fingers between 4 and 30 months after treatment, most of them after 12 months. In one autopsied case, the brachial plexus was ensheathed in dense fibrous tissue; distal to this zone, both myelin and axons had disappeared (secondary to Wallerian degeneration), presumably as a result of entrapment of nerves in fibrous tissue; possibly a vascular factor was also operative.

Kori and coworkers, who analyzed the brachial plexus lesions in 100 patients with cancer, also found that doses exceeding 6000 cGy were associated with radiation damage. Usually the upper plexus was involved and was associated with a painless lymphedema. In patients who received lower doses, the development of brachial plexopathy usually indicated tumor infiltration; these lesions affected the lower plexus more than the upper; they were often painful and accompanied by a Horner syndrome (see also Lederman and Wilbourn). Rarely, radiation may give rise, many years later, to a malignant tumor of nerve or the surrounding connective tissue, a sarcoma in one case familiar to us. Myokymic discharges and fasciculations are particularly suggestive of radiation damage.

Herpes Zoster Plexitis, Neuritis, and Ganglionitis (See Chap. 33)

This organism is perhaps the best-defined infectious cause of the listed syndromes, but its identification is usually obvious. Cases are known in which radicular pain precedes the eruption by many days or in which shingles do not appear, thereby simulating a herniated disc (Zoster sine herpete). These conditions are discussed with the other viral infections of the nervous system.

Brachial Mononeuropathies

(See Table 46-1)

Long Thoracic Nerve (of Bell) This nerve is derived from the fifth, sixth, and seventh cervical nerves and supplies the serratus

anterior muscle, which fixates the lateral scapula to the chest wall. Paralysis of this muscle results in an inability to raise the arm over the head and winging of the medial border of the scapula when the outstretched arm is pushed forward against resistance. The nerve is injured most commonly by carrying heavy weights on the shoulder or by strapping the shoulder on the operating table. As stated earlier, the neuropathy sometimes followed immunization and may be the only affected nerve in a brachial plexus neuropathy of either the inherited or idiopathic variety (Phillips).

Suprascapular Nerve This nerve is derived from the fifth (mainly) and sixth cervical nerves and supplies the supraspinatus and infraspinatus muscles. Lesions may be recognized by the presence of atrophy of these muscles and weakness of the first 15 degrees of abduction (supraspinatus) and of external rotation of the arm at the shoulder joint (infraspinatus). The latter is tested by having the patient flex the forearm and then, pinning the elbow to the side, asking him to swing the forearm backward against resistance. This nerve is often involved as part of a brachial plexus neuropathy of either the sporadic or inherited type. It may be affected during infectious illnesses and may be injured in gymnasts or as a result of local pressure, from carrying heavy objects on the shoulder ("meat-packer's" neuropathy). An entrapment syndrome has also been reported; it is characterized by pain and weakness on external rotation of the shoulder joint with atrophy of the infraspinatus muscle (Table 46-8). Decompression of the nerve where it enters the spinoglenoid notch relieves the condition.

Axillary Nerve This nerve arises from the posterior cord of the brachial plexus (mainly from the C5 root, with a smaller contribution from C6) and supplies the teres minor and deltoid muscles. It may be involved in dislocations of the shoulder joint, fractures of the neck of the humerus, serum- and vaccine-induced neuropathies, and brachial neuritis; in other instances, no cause may be apparent. The anatomic diagnosis depends on recognition of pa-

ralysis of abduction of the arm (in testing this function, the angle between the side of the chest and the arm must be greater than 15 degrees and less than 90 degrees), wasting of the deltoid muscle, and slight impairment of sensation over the outer aspect of the shoulder.

Musculocutaneous Nerve The origin of this nerve is from the fifth and sixth cervical roots. It is a branch of the lateral cord of the brachial plexus and innervates the biceps brachii, brachialis, and coracobrachialis muscles. Lesions of the nerve result in wasting of these muscles and weakness of flexion of the supinated forearm. Sensation may be impaired along the radial and volar aspects of the forearm (lateral cutaneous nerve). Isolated lesions of this nerve are usually the result of fracture of the humerus.

Radial Nerve This nerve is derived from the sixth to eighth (mainly the seventh) cervical roots and is the distal extension of the posterior cord of the brachial plexus. It innervates the triceps, brachioradialis, and supinator muscles and continues below the elbow as the posterior interosseous nerve, which innervates the extensor muscles of the wrist and fingers, the abductor of the thumb, and the extensors of the fingers at both joints. A complete proximal radial nerve lesion results in paralysis of extension of the elbow, flexion of the elbow with the forearm midway between pronation and supination (due to paralysis of the brachioradialis muscle), supination of the forearm, extension of the wrist and fingers, and extension and abduction of the thumb in the plane of the palm. If the lesion is confined to the posterior interosseous nerve, only the extensors of the wrist and fingers are affected. Sensation is impaired over the posterior aspects of the forearm and over a small area on the radial aspect of the dorsum of the hand.

The radial nerve may be compressed in the axilla ("crutch" palsy) but more frequently at a lower point, where the nerve winds around the humerus (see Table 46-8); pressure palsies incurred during an alcoholic stupor and fractures of the humerus commonly injure the nerve at the site of injury. It is susceptible to lead intoxication and is frequently involved as part of a neuralgic amyotrophy.

Median Nerve This nerve originates from the fifth cervical to the first thoracic roots but mainly from the sixth cervical root and is formed by the union of the medial and lateral cords of the brachial plexus. It innervates the pronators of the forearm, long finger flexors, and abductor and opponens muscles of the thumb and is a sensory nerve to the palmar aspect of the hand. Complete interruption of the median nerve results in inability to pronate the forearm or flex the hand in a radial direction, paralysis of flexion of the index finger and terminal phalanx of the thumb, weakness of flexion of the remaining fingers, weakness of opposition and abduction of the thumb in the plane at a right angle to the palm (abductor and flexor pollicis brevis), and sensory impairment over the radial two-thirds of the palm and dorsum of the distal phalanges of the index and third fingers. The nerve may be injured in the axilla by dislocation of the shoulder and in any part of its course by stab, gunshot, or other types of wounds. Incomplete lesions of the median nerve between the axilla and wrist may result in causalgia (see further on).

Carpal Tunnel Syndrome Compression of the median nerve at the wrist (*carpal tunnel syndrome*) is the most common disorder affecting the median nerve and the most frequent nerve entrapment syndrome. This is usually due to excessive use of the hands and occupational exposure to repeated trauma. Infiltration of the transverse carpal ligament with amyloid (as occurs in multiple mye-

Table 46-8
Entrapment neuropathies

NERVE	SITE OF ENTRAPMENT
Suprascapular	Spinoglenoid notch
Lower trunk or medial cord of brachial plexus	Cervical rib or band at thoracic outlet
Median	
Wrist	Carpal tunnel
Elbow	Between heads of pronator teres (pronator syndrome)
Ulnar	
Wrist	Guyon's canal (ulnar tunnel)
Elbow	Bicipital groove, cubital tunnel
Posterior interosseous nerve	Radial tunnel—at point of entrance into supinator muscle (arcade of Frohse)
Lateral femoral cutaneous (meralgia paresthetica)	Inguinal ligament
Obturator	Obturator canal
Posterior tibial	Tarsal tunnel; medial malleolus—flexor retinaculum
Interdigital plantar (Morton metatarsalgia)	Plantar fascia: heads of third and fourth metatarsals

loma) or thickening of connective tissue in rheumatoid arthritis, acromegaly, amyloidosis, mucopolysaccharidosis, and hypothyroidism are less commonly identified causes. It is not uncommon for the condition to make its appearance during pregnancy. In elderly individuals, the cause of the carpal tunnel syndrome is often not apparent. According to Kremer and colleagues, it was McArdle, in 1949, who first suggested that the cause of this syndrome was a compression of the median nerve at the wrist and that the symptoms would be relieved by division of the flexor retinaculum forming the ventral wall of the carpal tunnel.

Dysesthesias and pain in the fingers, referred to for many years as "acroparesthesiae" and attributed to cervical ribs, came to be recognized as a syndrome of median nerve compression only in the early 1950s. The syndrome is essentially a sensory one; the loss or impairment of superficial sensation affects the palmar aspect of the thumb, and the index, and middle fingers (especially the index finger) and may or may not split the ring finger (splitting does not occur with a plexus or root lesion). The paresthesias are characteristically worse during the night. As pointed out in Chap. 11, the pain in carpal tunnel syndrome may radiate into the forearm and even into the region of the biceps and rarely to the shoulder. Weakness and atrophy of the abductor pollicis brevis and other median-innervated muscles occur in only the most advanced cases of compression. Electrophysiologic testing confirms the diagnosis by demonstrating prolonged sensory conduction across the wrist and explains cases in which operation has failed (see also the review by Stevens).

Several provocative tests are useful. The Phalen maneuver consists of hyperflexion of the wrist for 30 to 60 s—usually performed by opposing the outer surfaces of the hands with the wrists flexed. The Tinel sign is elicited by lightly tapping the volar aspect of the wrist at the transverse carpal ligament (distal to the first wrist crease). Both of these tests are meant to elicit pain or paresthesias over the digits innervated by the median nerve. The sensitivity of these tests is close to 50 percent but their specificity is considerably higher. Other tests involving prolonged pressure over the median nerve have been devised but they are of uncertain value, e.g., Durken's test of the Phelan maneuver combined with digital compression of the nerve.

Treatment Surgical division of the carpal ligament with decompression of the nerve is curative but is required only in severe and protracted cases. Splinting of the wrist, to avoid flexion, almost always relieves the discomfort but denies the patient the full use of the hand for some time. It is a useful temporizing measure, however, as is the injection of hydrocortisone into the carpal tunnel. Studies of oral corticosteroids have given conflicting results. Treatment of an underlying condition such as arthritis, hypothyroidism, possibly diabetes, is often helpful. Some patients have benefited, paradoxically, from the stopping of corticosteroids or estrogen. Also, some practitioners favor the use of nonsteroid anti-inflammatory medication but we have been generally unimpressed with the results. Most often, splinting and local steroid injections are very satisfactory in the short-term, especially if the symptoms are of recent onset.

Another less common site of compression of the median nerve is at the elbow, where the nerve passes between the two heads of the pronator teres, or just above that point behind the bicipital aponeurosis. It gives rise to the pronator syndrome, in which forceful pronation of the forearm produces an aching pain (see Table 46-8). There is weakness of the abductor pollicis brevis and opponens muscles and numbness of the first three digits and palm.

Ulnar Nerve This nerve is derived from the eighth cervical and first thoracic roots. It innervates the ulnar flexor of the wrist, the ulnar half of the deep finger flexors, the adductors and abductors of the fingers, the adductor of the thumb, the third and fourth lumbricals, and muscles of the hypothenar eminence. Complete ulnar paralysis is manifest by a characteristic clawhand deformity; wasting of the small hand muscles results in hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints. The flexion deformity is most pronounced in the fourth and fifth fingers, since the lumbrical muscles of the second and third fingers, supplied by the median nerve, counteract the deformity. Sensory loss occurs over the fifth finger, the ulnar aspect of the fourth finger, and the ulnar border of the palm.

The ulnar nerve is vulnerable to pressure in the axilla from the use of crutches, but it is most commonly injured at the elbow by fracture or dislocation involving the joint. *Delayed ("tardive") ulnar palsy* may occur many months or years after an injury to the elbow that had resulted in a cubitus valgus deformity of the joint. Because of the deformity, the nerve is stretched in its groove over the ulnar condyle, and its superficial location renders it vulnerable to compression. A shallow ulnar groove, quite apart from abnormalities of the elbow joint, may expose the nerve to compressive injury. Anterior transposition of the ulnar nerve is a simple and effective form of treatment for these types of ulnar palsy. Compression of the nerve may occur just distal to the medial epicondyle, where it runs beneath the aponeurosis of the flexor carpi ulnaris (*cubital tunnel*). Flexion at the elbow causes a narrowing of the tunnel and constriction of the nerve. This type of ulnar palsy is treated by incising the aponeurotic arch between the olecranon and medial epicondyle. Yet another site of ulnar nerve compression is in the ulnar tunnel, at the wrist. Prolonged pressure on the ulnar part of the palm may result in damage to the deep palmar branch of the ulnar nerve, causing weakness of small hand muscles but no sensory loss. This site is most often implicated in patients who hold tools or implements tightly in the hand for long periods (we have seen it in machinists and professional cake decorators). The lesion is localizable by nerve conduction studies.

A characteristic syndrome of burning pain and associated symptoms (causalgia) may follow incomplete lesions of the ulnar nerve (or other major nerves of the limbs) and is described further on.

Lumbosacral Plexus and Crural Neuropathies

The twelfth thoracic, first to fifth lumbar, and first, second, and third sacral spinal nerve roots compose the lumbosacral plexuses and innervate the muscles of the lower extremities (Fig. 46-6 and Table 46-1). The following are the common plexus and crural nerve palsies.

Lumbosacral Plexus Lesions Extending as it does from the upper lumbar area to the lower sacrum and passing near several lower abdominal and pelvic organs, this plexus is subject to a number of special injuries and diseases, most of them secondary. The cause of involvement may be difficult to ascertain because the primary disease is often not within reach of the palpating fingers, either from the abdominal side or through the anus and vagina; even refined radiologic techniques may not reveal it. Diagnosis involves exclusion of spinal root (cauda equina) lesions by EMG, examination of CSF, computed tomography (CT) myelography, and

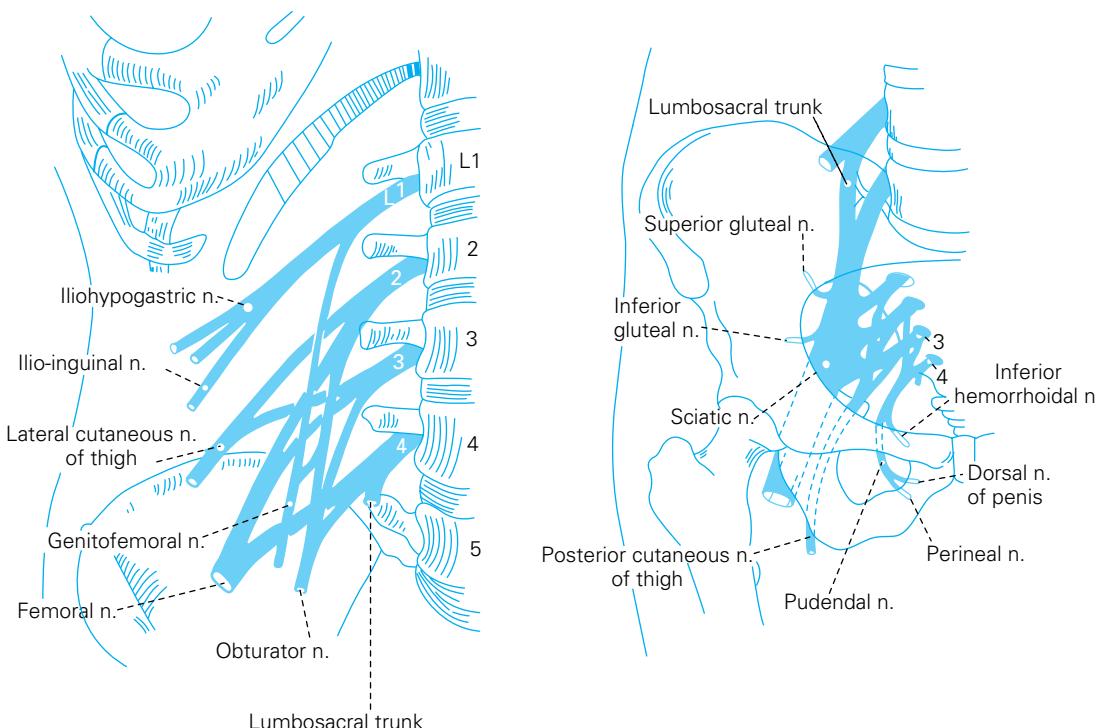

Figure 46-6. Diagram of the lumbar plexus (left) and the sacral plexus (right). The lumbosacral trunk is the liaison between the lumbar and the sacral plexuses. (From Haymaker and Woodhall, *Peripheral Nerve Injuries*, 2nd ed. Philadelphia, Saunders, 1953, by permission.)

MRI. The clinical findings help to focus studies on the appropriate part of the lumbosacral plexus.

The main effects of upper lumbar plexus lesions are weakness of flexion and adduction of the thigh and extension of the leg, with sensory loss over the anterior thigh and leg; these effects must be distinguished from the symptoms and signs of femoral neuropathy (see later). Lower plexus lesions weaken the posterior thigh, leg, and foot muscles and abolish sensation over the first and second sacral segments (sometimes the lower sacral segments also). Lesions of the entire plexus, which occur infrequently, cause a weakness or paralysis of all leg muscles, with atrophy, areflexia, anesthesia from the toes to the perianal region and autonomic loss with warm, dry skin. Usually there is edema of the leg as well.

The types of lesions that involve the lumbosacral plexus are rather different from those affecting the brachial plexus. Trauma is a rarity except with massive pelvic, spinal, and abdominal injuries because the plexus is so well protected. Occasionally a pelvic fracture will damage the sciatic nerve as it issues from the plexus. In contrast, some part of the plexus may be damaged during surgical procedures on abdominal and pelvic organs, often for reasons that may not be entirely clear. For example, hysterectomy has on a number of occasions led to neurologic consultation in our hospitals because of numbness and weakness of the anterior thigh. Either the cords of the upper part of the plexus or the femoral nerve was compressed by retraction against the psoas muscle or, in vaginal hysterectomy (when thighs are flexed, abducted, and externally rotated), the femoral nerve was compressed against the inguinal ligament. A similar type of injury may be associated with childbirth. Lumbar sympathectomy has also been associated with upper plexus lesions, of which the most disabling sequelae are burning pain and hypersensitivity of the anterior thigh. Appendectomy, pelvic explorations, and hernial repair may

injure branches of the upper plexus (ilioinguinal, iliohypogastric, and genitofemoral nerves), with severe pain and slight sensory loss in the distribution of one of these nerves. The pain may last for months or a year or more.

The lumbar plexus may be compressed by an aortic atherosclerotic aneurysm. Usually there is pain that radiates to the hip, the anterior thigh, and occasionally the flank. Slight weakness in hip flexion and altered sensation over the anterior thigh are found on examination. Plexus involvement with tumors is commonplace and at times presents special difficulties in diagnosis. Carcinoma of either the cervix or prostate may seed itself along the perineural lymphatics and cause pain in the groin, thigh, knee, or back without much in the way of sensory, motor, or reflex loss. The pain is more often unilateral than bilateral. The CSF and spinal canal (by MRI) are normal. Testicular, uterine, ovarian, and colonic tumors or retroperitoneal lymphomas, by extending along the paravertebral gutter, impinge various parts of the lumbosacral plexus. Instances of endometriosis that involve the plexus have also been reported. The neurologic symptoms are projected at a distance in the leg and may or may not be confined to the territory of any one nerve. Pelvic and rectal examinations may be negative, and CT scanning and MRI may be necessary to show such lesions. If all these examinations are negative, exploratory laparotomy may have to be undertaken.

In cancer patients, it is sometimes difficult to distinguish the effects of radiation on the lumbosacral plexus from those of metastatic tumor, as is the case in relation to the brachial plexus. Again, the earliest symptom in metastatic lumbosacral plexopathy is usually pain, whereas in radiation plexopathy it is weakness (Thomas et al); the same as pertains in the brachial plexus. Plexopathy from metastatic tumor is usually unilateral and detectable by CT scanning; radiation plexopathy was usually bilateral and not evident in

CT scans. Fasciculations and myokymia are more likely to be seen in patients with radiation plexopathy, which seemingly occurs more frequently in patients with diabetic neuropathy.

Reference has already been made to femoral nerve injury during parturition, but other *puerperal complications* are also observed. Back pain in the latter part of pregnancy is common, but there are rare instances in which the patient complains of severe pain in the back of one or both thighs during labor and after delivery has numbness and weakness of the leg muscles, with diminished ankle jerks. *Parturitional lumbosacral plexus injuries* occur with a frequency of 1 per 2000 deliveries. This type of plexus injury is usually unilateral and is manifest by pain in the thigh and leg and symptoms and signs of involvement of the superior gluteal and sciatic nerves (Feasby et al). The attribution of these symptoms to pressure of the fetal head on the sacral plexus(es) is conjectural. A limited plexopathy, occurring after difficult vaginal delivery, mainly impairs sensation in the perineum and sphincteric function (Ismael et al). The perineal muscles may show signs of denervation. Protrusion of an intervertebral disc may also occur during delivery. ***Idiopathic Lumbosacral Plexitis*** In addition to a diabetic type, an idiopathic *neuralgic amyotrophy* or *lumbosacral plexitis*, analogous to the brachial variety, is observed from time to time. Bradley and coworkers have recorded such cases. After causing widespread unilateral or bilateral sensory, motor, and reflex changes in a leg, lumbosacral plexitis may leave the patient with dysesthesias as troublesome as those that follow herpes zoster (which may also occur at this level). Some patients have had an exploration of the cauda equina (for ruptured disc), even though loss of sweating and warmth of the feet should have indicated interruption of autonomic fibers by lesions in peripheral nerves. (Lesions that are confined to nerve roots spare autonomic functions.) The sedimentation rate may be elevated. Immunosuppressant drugs were possibly beneficial in 4 of 6 cases (Bradley et al). Sarcoidosis is another cause and may be responsive to corticosteroids.

Diabetic amyotrophy, due to involvement of the lumbar plexus, has a vascular origin, probably inflammatory as discussed in an earlier section (page 1135), and there are also nondiabetic vascular lesions that give rise to identical lumbar and upper leg pain and weakness in proximal muscles. The plexus lesions of polyarteritis nodosa, unilateral or bilateral, may also be manifest as a mononeuropathy multiplex. Mononeuropathy multiplex in diabetic patients is more frequent in our experience when there is an associated occlusive vascular disease of the lower extremities. Diabetic mononeuropathy multiplex is discussed in an earlier part of this chapter and protruded intervertebral disc syndromes are described in Chap. 11.

Lateral Cutaneous Nerve of the Thigh This is a sensory nerve that originates from the second and third lumbar roots and supplies the anterolateral aspect of the thigh, from the level of the inguinal ligament almost to the knee. The nerve penetrates the psoas muscle, crosses the iliacus, and passes into the thigh by coursing between the attachments of the lateral part of the inguinal ligament to just anterior to the anterior superior iliac spine. Compression (entrapment) may occur at the point where it passes between the two prongs of attachment of the inguinal ligament.

Compression of the nerve results in uncomfortable paresthesias and sensory impairment in its cutaneous distribution, a common condition known as *meralgia paresthetica* (*meros*, "thigh"). Usually numbness and mild sensitivity of the skin are the only symptoms, but occasionally there is a persistent distressing burning

pain. Perception of touch and pinprick are reduced in the territory of the nerve; there is no weakness of the quadriceps or diminution of the knee jerk. The symptoms are characteristically worsened in certain positions and after prolonged standing or walking. Occasionally, for an obese person, sitting is the most uncomfortable position. Obesity, pregnancy, and diabetes mellitus may be contributory factors. Most often the neuropathy is unilateral; Ecker and Woltman found only 20 percent of their cases to be bilateral.

Most of our patients with *meralgia paresthetica* request no treatment once they learn of its benign character. Weight loss and adjustment of restrictive clothing or correction of habitual postures that might compress the nerve are sometimes helpful. A few with the most painful symptoms have demanded a neurectomy or section of the nerve, but it is always wise to perform a lidocaine block first, so that the patient can decide whether the persistent numbness is preferable. In one specimen of nerve obtained at operation, we found a discrete traumatic neuroma. Hydrocortisone injections at the point of entrapment may have helped in a few cases.

Obturator Nerve This nerve arises from the third and fourth and to a lesser extent the second lumbar roots. It supplies the adductors of the thigh and contributes to the innervation of the internal and external rotators. The adductors have the added function of flexing the hip. The nerve may be injured by the fetal head or forceps during the course of a difficult labor or compressed by an obturator hernia. Rarely, it is affected with diabetes, polyarteritis nodosa, and osteitis pubis and by retroperitoneal spread of carcinoma of the cervix, uterus, and other tumors (Rogers et al).

Femoral Nerve This nerve is formed from the second, third, and fourth lumbar roots. Within the pelvis it passes along the lateral border of the psoas muscle and enters the thigh beneath Poupart's ligament, lateral to the femoral artery. Branches arising within the pelvis supply the iliacus and psoas muscles. Just below Poupart's ligament the nerve splits into anterior and posterior divisions. The former supplies the pectenous and sartorius muscles and carries sensation from the anteromedial surface of the thigh; the posterior division provides the motor innervation to the quadriceps and the cutaneous innervation to the medial side of the leg from the knee to the internal malleolus.

Following injury to the femoral nerve, there is weakness of extension of the lower leg, wasting of the quadriceps muscle, and failure of fixation of the knee. The knee jerk is abolished. If the nerve is injured proximal to the origin of the branches to the iliacus and psoas muscles, there is weakness of hip flexion. The adductor of the thigh (innervated by the obturator nerve) is spared, distinguishing femoral neuropathy from an L3 radiculopathy.

The most common cause of femoral neuropathy is diabetes. The nerve may also be involved by pelvic tumors. Not uncommon is injury of the nerve during pelvic operations. Usually this is the result of improper placement of retractors, which may compress the nerve directly or indirectly by undue pressure on the psoas muscle. Bleeding into the iliacus muscle or the retroperitoneum, observed in patients receiving anticoagulants and in hemophiliac patients, is a relatively common cause of isolated femoral neuropathy (Goodfellow et al). The presenting symptom of iliacus hematoma is pain in the groin spreading to the lumbar region or thigh, in response to which the patient assumes a characteristic posture of flexion and lateral rotation of the hip. A palpable mass in the iliac fossa and the signs of femoral nerve compression (quadriceps weakness and loss of knee jerk) follow in a day or two. Infarction

of the nerve may occur in the course of diabetes mellitus and polyarteritis nodosa. Not infrequently acute femoral neuropathy is of indeterminate cause.

Sciatic Nerve This nerve is derived from the fourth and fifth lumbar and first and second sacral roots, for which reason a ruptured disc at any of these levels may simulate sciatic neuropathy (sciatica). The sciatic nerve supplies motor innervation to the hamstring muscles and all the muscles below the knee through its two divisions, the tibial and peroneal nerves (see later); the sciatic nerve conveys sensory impulses from the posterior aspect of the thigh, the posterior and lateral aspects of the leg, and the entire sole. In complete sciatic paralysis, the knee cannot be flexed and all muscles below the knee are paralyzed. Weakness of gluteal muscles and pain in the buttock and posterior thigh point to nerve involvement in the pelvis. Lesions beyond the sciatic notch spare the gluteal muscles but not the hamstrings. Partial compressive lesions are more common and tend to involve peroneal-innervated muscles more than tibial ones, giving the impression of a peroneal palsy.

As mentioned, rupture of one of the lower lumbar intervertebral discs is perhaps the most common cause of sciatica, although it does not directly involve the sciatic nerve. The associated motor and sensory findings allow localization of the root compression (L4-5 disc compressing L5 root: pain in posterolateral thigh and leg with numbness over the inner foot and weakness of dorsiflexion of the foot and toes; L5-S1 disc compressing S1 root: pain in posterior thigh and leg, numbness of lateral foot, weakness of foot dorsiflexion and loss of ankle jerk) as discussed in Chap. 11.

The sciatic nerve is commonly injured by fractures of the pelvis or femur, fracture/dislocation of the hip, gunshot wounds of the buttock and thigh, and the injection of toxic substances into the lower gluteal region. Total hip arthroplasty is another common cause. Tumors of the pelvis (sarcomas, lipomas) or gluteal region may compress the nerve. Sitting for a long period with legs flexed and abducted (lotus position) under the influence of narcotics or barbiturates or lying flat on a hard surface in a sustained stupor may severely injure one or both sciatic nerves or branches thereof. The nerve may be involved by neurofibromas and infections and by ischemic necrosis in diabetes mellitus and polyarteritis nodosa. Cryptogenic forms also occur and are actually more frequent than those of identifiable cause. Partial lesions of the sciatic nerve occasionally result in causalgia (see further on).

The common Morton neuromas cause interdigital or intermetatarsal pain and can be detected by MRI. It is subject to surgical section. Also mentioned here is the distressingly painful compression of the plantar branches of the sciatic nerve.

Common Peroneal Nerve Just above the popliteal fossa the sciatic nerve divides into the tibial nerve (*medial, or internal, popliteal nerve*) and the common peroneal nerve (*lateral, or external, popliteal nerve*). The latter swings around the head of the fibula to the anterior aspect of the leg, giving off the *superficial peroneal nerve* which provides musculocutaneous branches (to the peroneal muscles) and to the *deep peroneal nerve* (formerly called *anterior tibial nerve*). Branches of the latter supply the dorsiflexors of the foot and toes (anterior tibialis, extensor digitorum longus and brevis, and extensor hallucis longus muscles) and carry sensory fibers from the dorsum of the foot and lateral aspect of the lower half of the leg. There was weakness of dorsiflexion of the foot in all of the 116 cases of common peroneal neuropathy reported by Katirji and

Wilbourn, and numbness of the dorsum of the foot was present in most cases. Weakness of eversion of the foot is usually demonstrable; inversion, a function of the L-5 root and the tibial nerve, is spared and the ankle jerk is normal, unless affected by another process. Foot eversion must be tested with the ankle passively dorsiflexed to 90 degrees. Pain is variable; it was quite severe in a few of our patients.

Pressure during an operation or sleep or from tight plaster casts, obstetric stirrups, habitual and prolonged crossing of the legs while seated, and tight knee boots are the most frequent causes of injury to the common peroneal nerve. The point of compression of the nerve is where it passes over the head of the fibula. Emaciation in patients with cancer or AIDS increases the incidence of these types of compressive injury. The nerve may also be affected in diabetic neuropathy and injured by fractures of the upper end of the fibula. A Baker cyst, which consists of inflamed synovium extending into the retropopliteal space may compress the nerve, and it may be damaged by muscle swelling or small hematomas behind the knee in asthenic athletes. The prognosis is generally good in cases of partial paralysis.

Tibial Nerve This, the other of the two divisions of the sciatic nerve (it divides in the popliteal fossa), supplies all of the calf muscles—i.e., the plantar flexors and invertors of the foot and toes—after which it continues as the posterior tibial nerve. This nerve passes through the tarsal tunnel, an osseofibrous channel that runs along the medial aspect of the calcaneus and is roofed by the flexor retinaculum. The tunnel also contains the tendons of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles and the vessels to the foot. The posterior tibial nerve terminates under the flexor retinaculum and divides into medial and lateral plantar nerves (supplying the small muscles of the foot).

Complete interruption of the tibial nerve results in a calcaneo-ovalgus deformity of the foot, which can no longer be plantarflexed and inverted. There is loss of sensation over the plantar aspect of the foot.

The posterior tibial nerve may be compressed in the *tarsal tunnel* (an entrapment syndrome as discussed later) by thickening of the tendon sheaths or the adjacent connective tissues or by osteoarthritic changes. Tingling pain and burning over the sole of the foot develop after standing or walking for a long time. Pain in the ankle or foot is added in some cases and the pain may be referred proximally along the sciatic nerve. Pressure over the nerve in the inferior malleolar region produces pain, which radiates to the terminal distributions of the nerve. Usually there is no motor deficit. Relief is obtained by severing the flexor retinaculum.

Entrapment Neuropathies

Reference has been made in several places in the preceding pages to the main entrapment neuropathies. A nerve passing through a tight canal is trapped and subjected to constant movement or pressure, forces not applicable to nerves elsewhere. The epineurium and perineurium become greatly thickened, strangling the nerve, with the additional possibility of demyelination. Function is gradually impaired, sensory more than motor, and the symptoms fluctuate with activity and rest. The most frequently compressed nerves are the median, ulnar, peroneal, tibial, and plantar in approximately that order. It is well to keep in mind the systemic processes that enhance pressure palsies by infiltration of the nerve or surrounding

tissues. The main ones are hypothyroidism, amyloid, pregnancy, and hereditary liability to pressure palsies.

Listed in Table 46-8 are the more common entrapment neuropathies and the locations of compression. Detailed accounts of these disorders are contained in the monographs of Dawson and colleagues and of Asbury and Gilliat.

Causalgia and Reflex Sympathetic Dystrophy

One unfortunate result of partial injury of a peripheral nerve is the delayed appearance of severe pain roughly in the distribution of the affected nerve. This complex problem, which consists of burning pain termed *causalgia* and associated local trophic and autonomic changes that are subsumed under the term *reflex sympathetic dystrophy*, are discussed further in Chap. 8 in the context of other pain syndromes.

Traumatic Interruption of Nerves

The management of such lesions is best delegated to specialized neurosurgeons, but several aspects involve the neurologist. Surgical advances have allowed the successful apposition of severed nerve ends. The current recommendations are that end-to-end suturing of the stumps within 72 h should repair a sharp and clean division. In cases where the nerve is found on exploration to be bluntly severed with ragged ends, most surgeons recommend tacking the free ends to adjacent connective tissue planes and attempting repair in 2 to 4 weeks. The majorities of injuries, however, are blunt and retain some continuity of the nerve. If such continuity across the traumatized region can be demonstrated by electrophysiologic examination, operation is not necessary. In the absence of improvement in the clinical and electrophysiologic features after several months (up to 6 months for plexus lesions), surgical repair may facilitate limited healing.

CHAPTER 47

DISEASES OF THE CRANIAL NERVES

The cranial nerves are susceptible to a number of special diseases, some of which never affect the spinal peripheral nerves. For this reason alone they deserve to be considered separately. Certain of the cranial nerves and their disorders have already been discussed: namely, disorders of olfaction, in Chap. 12; of vision and extraocular muscles, in Chaps. 13 and 14; of cochlear and vestibular function, in Chap. 15; and craniofacial pain in Chap. 10. There remain to be described the disorders of the facial (VII) nerve and of the lower cranial nerves (IX to XII), as well as certain aspects of disordered trigeminal (V) nerve function. These are considered here.

The Fifth, or Trigeminal, Nerve

Anatomic Considerations The fifth nerve (Fig. 47-1) is a mixed sensory and motor nerve. It conducts sensory impulses from the greater part of the face and head; from the mucous membranes of the nose, mouth, and paranasal sinuses; and from the cornea and conjunctiva. It also innervates the dura of the anterior and middle cranial fossae. The cell bodies of the sensory part of the nerve lie in the gasserian, or semilunar, ganglion. This, the largest sensory ganglion in humans, lies in the medial part of the middle cranial fossa at the base of the cranium. The central axons of the ganglion cells form the sensory root. These fibers, on entering the mid pons, divide into short ascending and long descending branches. The former are concerned mainly with tactile and light pressure sense and synapse with second-order neurons in the principal sensory nucleus. Proprioceptive afferents from facial muscles and the masseter terminate in the mesencephalic nucleus. The fibers that mediate pain and temperature sensation do not end in these nuclei but form the unique anatomy of the long descending branches of the spinal trigeminal tract. The latter pathway, which contains both facilitatory and inhibitory fibers, together with its nucleus, extends from the junction of the pons and medulla to the uppermost segments (C2 or C3) of the spinal cord (as evidenced by the relief of facial pain after medullary trigeminal tractotomy). The spinal nucleus is a continuation of the spinal tract of Lissauer and substantia gelatinosa; the main sensory nucleus is a continuation of the nucleus of the medial lemniscus. From all parts of the principal trigeminal sensory and spinal nuclei, second-order fibers cross to the opposite side and ascend to the thalamus. They come to lie in the most medial part of the spinothalamic tract and lateral part of the medial lemniscus. These systems of fibers are called the *trigeminothalamic tract*. In addition, the secondary trigeminal neurons project to the facial and hypoglossal nuclei bilaterally, the salivatory nuclei, the cuneate nuclei of the upper cervical segments, and other cranial nerve nuclei. The main sensory and spinal trigeminal nuclei receive fibers from the reticular formation, the thalamus, the nucleus solitarius, and the sensory cortex.

The peripheral branches of the gasserian ganglion form the three sensory divisions of the nerve. The first (ophthalmic) division passes through the superior orbital fissure; the second (maxillary) division leaves the middle fossa through the foramen rotundum; and the third (mandibular), through the foramen ovale.

The motor portion of the fifth nerve, which supplies the masseter and pterygoid muscles, has its origin in the trigeminal motor nucleus in the midpons; the exiting fibers pass underneath the gasserian ganglion and become incorporated into the mandibular nerve. The masseter and pterygoid muscles are utilized in chewing and are implicated in a number of brainstem reflexes, the best known of which is the jaw jerk. Tapping the chin with the jaw muscles relaxed stimulates proprioceptive afferents that terminate in the mesencephalic nucleus of the midbrain, which sends collaterals to the motor nucleus of the fifth nerve and causes the masseters to contract. This reflex is enhanced in spastic bulbar (pseudobulbar) palsy. Another pontine reflex that utilizes afferent trigeminal sensory nerves is the blink reflex. Tapping of the brow or bridge of the nose evokes bilateral blink through activation of the orbicularis oculi muscles (facial nerve efferents). Touching the eyelids and cornea (corneal reflex) does the same.

Because of their wide anatomic distribution, complete interruption of both the motor and sensory fibers of the trigeminal nerve is rarely observed. In contrast, partial affection of the trigeminal nerve, particularly of the sensory part, is not uncommon, the main symptoms being numbness and pain. The various cranial nerve and brainstem syndromes in which the fifth nerve is involved are listed in Tables 47-1, 31-4, and 34-3, the last in relation to stroke syndromes of the brainstem.

Diseases Affecting the Fifth Nerve A variety of diseases may affect the peripheral branches of the trigeminal nerves, the gasserian (semilunar) ganglion, and the roots (sensory and motor). These have been ably described by Hughes. The role of the nerve in the genesis of migraine is discussed in Chap. 10.

Trigeminal Neuralgia (see also page 161) The most frequent, and at the same time the most elusive disease of the fifth nerve from the standpoint of its pathologic basis, is *trigeminal neuralgia (tic douloureux)*, which is also discussed in Chap. 10. This condition has been known since ancient times, having been described by Arateus in the first century A.D., by John Locke in 1677, by Nicolaus Andre in 1756, and by John Fothergill in 1776 (according to Katusic et al). The overall incidence rate for both sexes combined is 4.3 per 100,000 persons per year, but it is higher for women than for men (in a ratio of 3:2) and is much higher in the elderly. The mean age of onset is 52 to 58 years for the idiopathic form and 30 to 35 years for the symptomatic forms, the latter being caused by trauma or vascular, neoplastic, and demyelinative diseases. In the last decade it has become apparent, mainly from the work of Jannetta, that a proportion of cases is due to compression of trigeminal nerve rootlets by small branches of the basilar artery. This compression causes demyelination of the proximal nerve root (see Love and Coakham).

The paroxysmal nature of the facial pain, its unilaterality and tendency to involve the second and third divisions of the trigeminal nerve, an intensity that makes the patient grimace or wince (tic), the presence of an initiating or trigger point, the lack of demonstrable sensory or motor deficit, and its response in more than half

of the cases to carbamazepine, phenytoin, and other similar drugs are characteristic. The diagnosis of "idiopathic" trigeminal neuralgia and its differentiation from other forms of intermittent facial pain described below—as well as from cluster headache, dental neuralgia, temporomandibular pain, and atypical facial pain—is usually not difficult, especially if there is a trigger point and no demonstrable evidence of sensory or motor impairment. The vascular compressive form, still usually subsumed in the category of idiopathic, is difficult to diagnose without exposure at operation. The treatment of trigeminal neuralgia is considered on page 163.

In rare instances, trigeminal neuralgia is preceded or accompanied by hemifacial spasm, a combination that Cushing called *tic convulsif*. This may be indicative of a tumor (cholesteatoma), an aneurysmal dilatation of the basilar artery, or one of its branches, or an arteriovenous malformation that compresses both the trigeminal and facial nerves. Trigeminal neuralgia and glossopharyngeal neuralgia (pain in the tonsillar region, see page 163 and further on) may also be combined in these disease states, but these conditions are more often idiopathic.

Trigeminal Neuropathies and Neuritis Of the conditions that damage the branches of the trigeminal nerve, facial and cranial injuries and fractures are probably the most common but they do not often come to the attention of neurologists. The most superficial branches of the nerve—the supratrochlear, supraorbital, and infraorbital—are the ones usually involved. The sensory loss is present from the time of the injury, and partial regeneration may be attended by constant pain, often demanding nerve block or sectioning.

Of the various inflammatory and infectious diseases that affect the trigeminal nerves or ganglia, *herpes zoster* ranks first (pages 163 and 642). Persistent pain after herpetic infection of the fifth nerve is a serious problem, not responding well to any type of treatment. This subject is discussed in Chap. 10. *Herpes simplex virus* has been isolated from the ganglion in as many as 50 percent of routine autopsies, but in nearly all patients this virus is associated only with lesions of the skin and lips. Middle ear infections and osteomyelitis of the apex of the petrous bone may spread to the ganglion and root, also implicating the sixth cranial nerve (*Gradenigo syndrome*). Human immunodeficiency virus (HIV) infection has not been clearly implicated in infection of the fifth nerve (as it has in the seventh nerve), but reactivation of latent herpes zoster is seen with acquired immune deficiency syndrome (AIDS).

The trigeminal root may be compressed or invaded by intracranial meningiomas, acoustic neuromas, trigeminal neuromas (Fig. 47-2), cholesteatomas, and chordomas and by tortuous branches of the basilar artery. Sinus tumors and metastatic disease may also implicate the nerve, causing pain and a gradually progressive sensory loss. The ophthalmic division of the fifth nerve may be involved in the wall of the cavernous sinus in combination with the third, fourth, and sixth nerves by a variety of processes, including thrombosis of the cavernous sinus. Tumors of the sphenoid bone (myeloma, metastatic carcinoma, squamous cell carcinoma, and lymphoepithelioma of the nasopharynx) may involve branches of the trigeminal nerve at their foramina of entry or exit. The mandibular division may be compressed by the roots of an impacted third molar (wisdom) tooth. Several times the authors

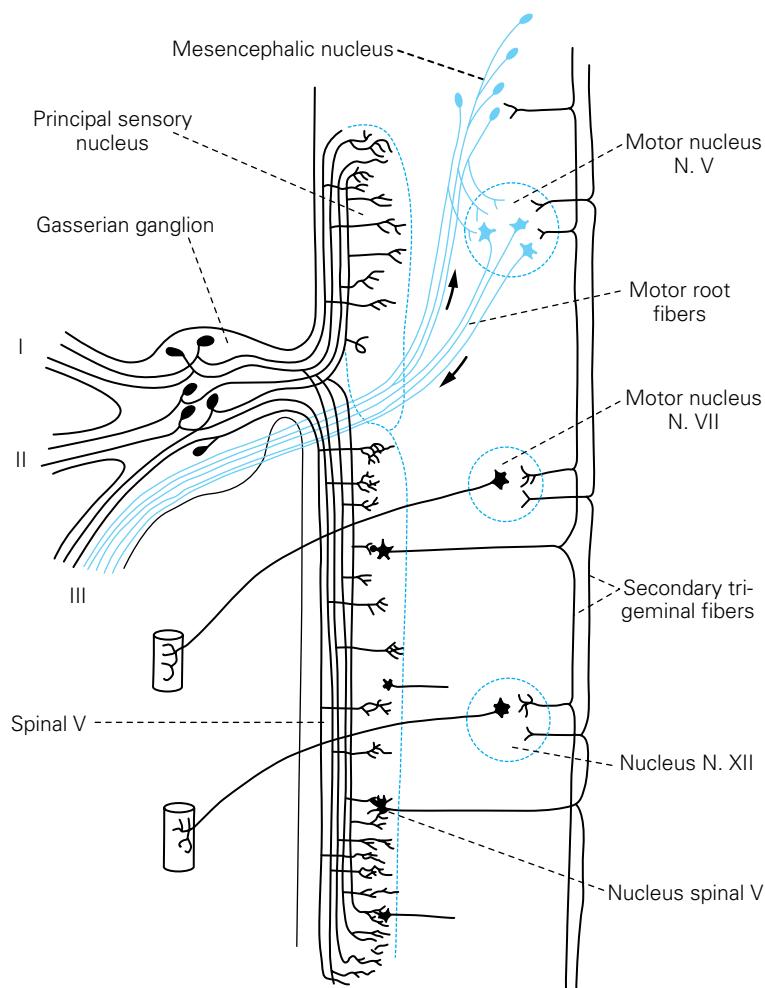

Figure 47-1. Scheme of the trigeminal nuclei and some of the trigeminal reflex arcs. I, ophthalmic division; II, maxillary division; III, mandibular division. (Originally from Ramon y Cajal S: *La Textura del Sistema Nervioso del Hombre y los Vertebrados*, Madrid, Moya, as adapted from Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1982, by permission.)

have observed numbness of the chin and lower lip (infiltration of the mental nerve) as the first indication of metastatic carcinoma of the breast and prostate and from multiple myeloma. Massey and colleagues have described 19 such cases ("numb-chin" syndrome). An unusual perineural spread of tumor from squamous cell skin cancers of the face is discussed further on, under "Multiple Cranial Nerve Palsies."

Neurologists often encounter instances of slowly evolving unilateral or bilateral trigeminal neuropathy in which sensory impairment is confined to the territory of the trigeminal nerve, sometimes associated with pain and paresthesias and disturbances of taste. Loss of facial sensation can occur as part of a widespread sensory neuropathy that occurs as a remote effect of cancer or as part of Sjögren disease (pages 586 and 1141). More common is an association between *isolated trigeminal neuropathy* and immune-mediated connective tissue disease. Of 22 such cases described by Lecky and colleagues, 9 had either scleroderma or mixed connective tissue disease, and a similar number had either organ- or non-organ-specific serum autoantibodies. The symptoms may involve the other side years later. Hughes has also reported cases of trigeminal neuropathy with scleroderma, lupus erythematosus,

Table 47-1

Extramedullary cranial nerve syndromes (See also Tables 31-4 and 34-3)

SITE	CRANIAL NERVES INVOLVED	EPONYMIC SYNDROME	USUAL CAUSE
Sphenoidal fissure	III, IV, ophthalmic, V, VI	Foix	Invasive tumors of sphenoid bone, aneurysms
Lateral wall of cavernous sinus	III, IV, ophthalmic (occasionally maxillary), V, VI	Tolosa-Hunt	Aneurysms or thrombosis of cavernous sinus; invasive tumors from sinuses and sella turcica; sometimes recurrent, benign granulomatous reactions, responsive to steroids
Retrosphenoidal space fossa	II, III, IV, V, VI	Jaccoud	Large tumors of middle cranial
Apex of petrous bone	V, VI	Gradenigo	Petrositis, tumors of petrous bone
Internal auditory meatus	VII, VIII		Tumors of petrous bone (dermoids, etc.), acoustic neuroma
Pontocerebellar angle	V, VII, VIII, and sometimes IX		Acoustic neuromas, meningiomas
Jugular foramen	IX, X, XI	Vernet	Tumors and aneurysms
Posterior laterocondylar space	IX, X, XI, XII	Collet-Sicard	Tumors of parotid gland, carotid body; secondary and lymph node tumors, tuberculous adenitis, carotid artery dissection
Posterior retroparotid space	IX, X, XI, XII, and Horner syndrome	Villaret	Same as above, and granulomatous lesions (sarcoid, fungi)
Posterior retroparotid space	X and XII, with or without XI	Tapia	Parotid and other tumors of, or injuries to, the high neck

and Sjögren disease. We have seen several patients with Sjögren disease in whom the trigeminal neuropathy and the associated antibodies or inflammation of the minor salivary glands were evident well before the characteristic sicca syndrome or other systemic manifestations of the disease. The condition may remain troublesome for years. Pathologic data are limited but point to an inflammatory lesion of the trigeminal ganglion or sensory root. Stilbamidine and trichloroethylene are known to cause sensory loss, tingling, burning, and itching exclusively in the trigeminal sensory territory.

Spillane and Wells stressed an isolated trigeminal neuropathy (it has been called *Spillane's trigeminal neuritis* in some texts). Four of their 16 patients had an associated paranasal sinusitis, but subsequent reports have failed to substantiate a causal relationship between sinusitis and cranial neuritis. One wonders how many of these individuals had connective tissue disease. A less common form of idiopathic trigeminal sensory neuropathy with which we have limited experience has a more acute onset and a tendency to resolve completely or partially, in much the same manner as Bell's palsy, with which it is sometimes associated (Blau et al). A recurrent variety of uncertain origin has been reported in the dental literature. We have had experience with two patients whose facial numbness was a component of an upper cervical disc syndrome that included numbness on the same side of the body. Cases such as these are reported sporadically in the literature.

A pure unilateral *trigeminal motor neuropathy* is a clinical rarity. Chia has described five patients in whom an aching pain in the cheek and unilateral weakness of mastication were the main features. Electromyography (EMG) showed denervation changes in the ipsilateral masseter and temporalis muscles. The outcome was favorable.

In most cases of trigeminal neuropathy except those due to tumor and herpes zoster, the results of gadolinium-enhanced magnetic resonance imaging (MRI) are normal, as is the cerebrospinal

fluid (CSF). The function of the nerve may be studied by the electrical recording of blink reflexes. A few laboratories have developed an evoked potential test specifically of the trigeminal nerve. The difficult problem of chronic facial pain is discussed in Chap. 10.

Facial numbness also occurs with diverse conditions affecting the spinal nucleus of the trigeminal nerve, but in these cases there are additional signs of brainstem or upper cervical cord disease.

The Seventh, or Facial, Nerve

Anatomic Considerations The seventh cranial nerve is mainly a motor nerve supplying all the muscles concerned with facial expression on one side. The sensory component is small (the nervus intermedius of Wrisberg); it conveys taste sensation from the anterior two-thirds of the tongue and, variably, cutaneous sensation from the anterior wall of the external auditory canal. The taste fibers at first traverse the lingual nerve (a branch of the trigeminal mandibular) and then join the chorda tympani, which conveys taste sensation via the facial nerve to the nucleus of the tractus solitarius. Secretomotor fibers innervate the lacrimal gland through the greater superficial petrosal nerve and the sublingual and submaxillary glands through the chorda tympani (Fig. 47-3).

Several other anatomic facts are worth remembering. The motor nucleus of the seventh nerve lies ventral and lateral to the abducens nucleus, and the intrapontine fibers of the facial nerve partly encircle and pass ventrolaterally to the abducens nucleus before emerging from the pons, just lateral to the corticospinal tract. At their juxtaposition in the floor of the upper fourth ventricle, the sixth and seventh nerves may be affected simultaneously by a vascular or infiltrative lesion. The facial nerve enters the internal auditory meatus with the acoustic nerve and then bends sharply forward and downward around the anterior boundary of the vestibule of the inner ear. At this angle (*genu*) lies the sensory ganglion

Figure 47-2. Trigeminal neuroma (schwannoma) that caused only minor sensory changes on the face, as seen on a gadolinium-enhanced MRI. The dumbbell-shaped tumor is pinched at the foramen ovale.

(named *geniculate* because of its proximity to the genu). The nerve continues in its own bony channel, the facial canal, within which, just distal to the geniculate ganglion, it provides a branch to the pterygopalatine ganglion, i.e., the greater superficial petrosal nerve; somewhat more distally, it gives off a small branch to the stapedius muscle and is joined by the chorda tympani. It makes its exit from the skull at the stylomastoid foramen, then passes through the parotid gland and subdivides into five branches that supply the facial muscles, the stylomastoid muscle, the platysma, and the posterior belly of the digastric muscle.

A complete interruption of the facial nerve at the stylomastoid foramen paralyzes all muscles of facial expression. The corner of the mouth droops, the creases and skin folds are effaced, the forehead is unfurrowed, the palpebral fissure is widened, and the eyelids will not close. Upon attempted closure of the lids, both eyes roll upward (Bell's phenomenon), but the one on the paralyzed side remains visible. The lower lid sags also, and the punctum falls away from the conjunctiva, permitting tears to spill over the cheek. Food collects between the teeth and cheek, and saliva may dribble from the corner of the mouth. The patient complains of a heaviness or numbness and sometimes an aching pain in the face, but sensory loss can usually not be demonstrated. Taste, however, is intact because the lesion is beyond the site where the chorda tympani has separated from the main trunk of the facial nerve.

If the lesion is in the facial canal above the junction with the chorda tympani but below the geniculate ganglion, all the preceding symptoms occur; in addition, taste is lost over the anterior two-thirds of the tongue on the same side. If the nerve to the stapedius muscle is involved, there is hyperacusis (painful sensitivity to loud sounds). With a stethoscope in the patient's ears, a tuning fork at the bell is louder on the side of the paralyzed stapedius muscle. If the geniculate ganglion or the motor root proximal to it is involved, lacrimation and salivation may be reduced. Lesions at this point may also affect the adjacent eighth nerve, causing deafness, tinnitus, or dizziness.

Bell's Palsy The most common disease of the facial nerve is Bell's palsy (incidence rate of 23 per 100,000 annually, according

to Hauser et al). The disorder affects men and women more or less equally and occurs at all ages and all times of the year. There is controversy regarding an increased incidence in women during the third trimester of pregnancy, particularly in the 2 weeks preceding delivery and in the first 2 weeks postpartum; up to a threefold increase has been cited by some authors, but others have failed to find this disproportionate number of cases. Supporting a proclivity for facial palsy are scattered reports of a recurrence with each pregnancy. Bell's palsy is probably more common in diabetic patients and possibly in those with hypertension than in the healthy population.

As one might expect, the opportunity to examine the facial nerve in the course of Bell's palsy occurs very rarely. Only a handful of such cases are on record, all showing varying degrees of degeneration of nerve fibers. One case was said to show inflammatory changes, but these may have been misinterpreted (see Karnes).

Regarding the causation of Bell's palsy, a viral agent has long been suspected as discussed by Baringer. Only in the past few years, however, has such a mechanism been established with a reasonable degree of certainty for the majority of cases formerly considered to be idiopathic. Burgess and colleagues identified the genome of herpes simplex virus (HSV) in the geniculate ganglion of an elderly man who died 6 weeks after the onset of Bell's palsy. Murakami and coworkers, using the polymerase chain reaction (PCR) technique to amplify viral genomic sequences, identified HSV type I in the endoneurial fluid surrounding the seventh nerve in 11 of 14 cases of Bell's palsy; the fluid was obtained during surgical decompression of the nerve in ostensibly severe cases. The same investigators have produced facial paralysis by inoculating HSV into the ears and tongues of mice; virus antigens were then found in the facial nerve and geniculate ganglion. Varicella zoster virus (VZV) was not found in any of the Bell's palsy patients but was isolated from patients with the Ramsay Hunt syndrome (page 642 and further on, page 1183). Control patients with fracture or infections of the temporal bone yielded neither HSV or VZV gene sequences. In the light of these findings, the term *idiopathic facial paralysis*, until now the accepted synonym for Bell's palsy, is not entirely appropriate and perhaps *herpes simplex* or *herpetic facial paralysis* should be adopted.

The onset of Bell's palsy is acute; about one-half of the cases attain maximum paralysis in 48 h and practically all within 5 days. Pain behind the ear may precede the paralysis by a day or two and in a few patients is quite intense and persistent. In only a small proportion of patients, a hypesthesia in one or more branches of the trigeminal nerve can be demonstrated. The explanation of this finding is not clear. Impairment of taste is present to some degree in most patients but rarely persists beyond the second week of paralysis. As indicated earlier, this indicates that the lesion has extended to or above the point where the chorda tympani fibers join the facial nerve. Hyperacusis or distortion of sound in the ipsilateral ear indicates paralysis of the stapedius muscle. Unlike the fifth nerve in cases of idiopathic trigeminal neuritis, the facial nerve in Bell's palsy often displays enhancement on the gadolinium-enhanced MRI. Correspondingly, there is a mild increase of lymphocytes and mononuclear cells in the CSF in a few instances. Cases with more pronounced contrast enhancement of the facial nerve have a worse prognosis (Kress). Presumably, the enhancement reflects inflammation and swelling within the course of the facial nerve.

Fully 80 percent of patients recover within a month or two.

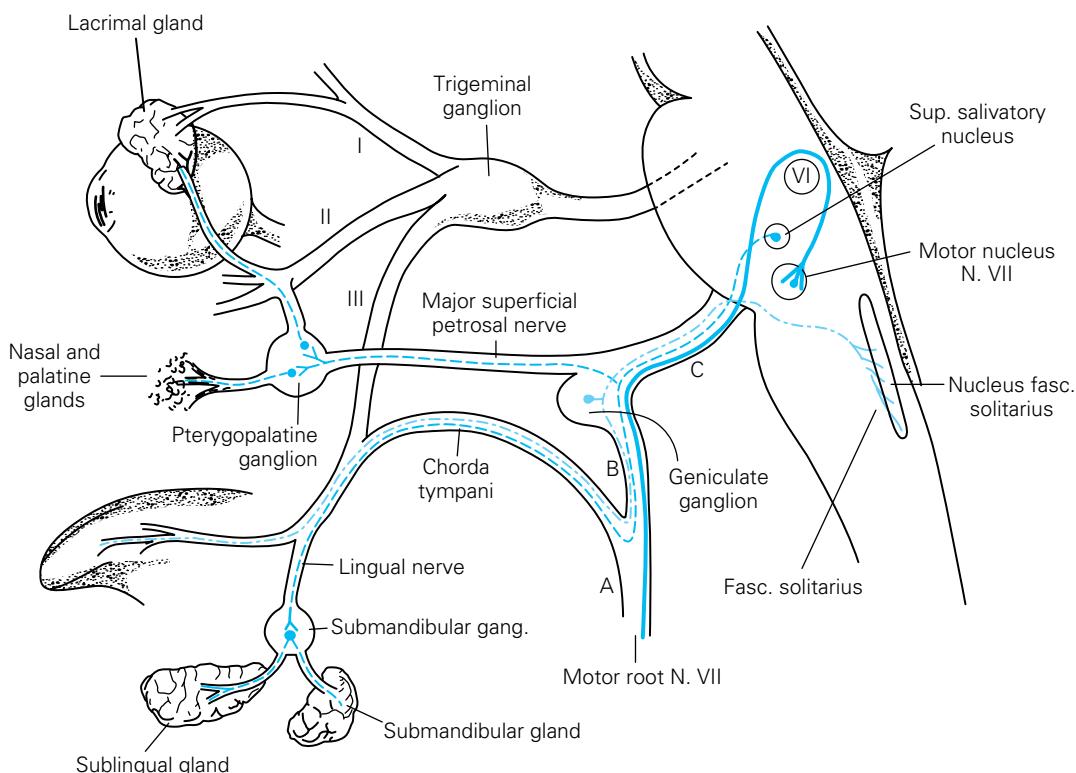

Figure 47-3. Scheme of the seventh cranial (facial) nerve. The motor fibers are represented by the heavy black line. Parasympathetic fibers are represented by regular dashes; special visceral afferent (taste) fibers are represented by long dashes and dots. A, B, and C denote lesions of the facial nerve at the stylomastoid foramen, distal to the geniculate ganglion, and proximal to the geniculate ganglion. Disturbances resulting from lesions at each of these sites are described in the text. (From Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1982, by permission.)

Recovery of taste precedes recovery of motor function; if the former occurs in the first week, it is a good prognostic sign. Early recovery of some motor function in the first 5 to 7 days is the most favorable prognostic sign. Electromyography may be of value in distinguishing temporary conduction defects from a pathologic interruption of nerve fibers; if there is evidence of denervation after 10 days, one may expect a long delay in the onset of recovery, measured in terms of months. Recovery then proceeds by regeneration of nerve, a process that may take 2 years or longer and is often incomplete.

Idiopathic Bell's palsy is said to recur in 8 percent of cases (van Amstel and Devriese; Pitts et al), presumably as a result of reactivation of the latent herpesvirus. The palsy reemerges during an infection or pregnancy or for no apparent reason. The interval between episodes is unpredictable but has been 10 years, on average. Other recurrent forms of facial paralysis occur with Lyme disease and sarcoidosis, and in a familial variety as mentioned below.

Treatment Protection of the eye during sleep, massage of the weakened muscles, and a splint to prevent drooping of the lower part of the face are the measures generally employed in the management of such cases. There is no evidence that surgical decompression of the facial nerve is effective, and it may be harmful. The administration of prednisone (40 to 60 mg/day, or an equivalent corticosteroid) during the first week to 10 days after onset has been beneficial in most trials. These medications are thought to decrease the possibility of permanent paralysis from swelling of the nerve in the tight facial canal.

The finding of viral genome surrounding the seventh nerve suggests that antiviral agents may be useful in the management of Bell's palsy. However, several small trials have suggested that acyclovir, used alone, is no more effective than corticosteroids (De Diego et al). The use of both medications together remains under study. A retrospective report indicated that the outcome was better in 94 individuals with Bell's palsy who were treated with acyclovir and prednisolone as compared to 386 treated only with prednisolone (Hato). Axelsson and associates similarly found that 56 patients treated with valacyclovir and prednisone had a somewhat better result than did the control patients. These data agree broadly with earlier studies suggesting benefit from the combined antiviral and steroid treatments (Adour et al). Given these reports, our impression is that treatment with steroids and acyclovir may be advisable, particularly early in the illness, but the small differences in outcome between groups in the aforementioned studies do not make this approach a necessity. In appropriate circumstances, testing should be undertaken for infectious causes that would require alternative therapy (e.g., Lyme, HIV, and perhaps mycoplasma). The treatment of facial palsy due to VZV (Ramsay Hunt syndrome) with antiviral drugs is discussed later.

Other Causes of Facial Palsy Lyme disease commonly involves the facial nerve, as indicated on pages 768 and 1140. The mechanism is still uncertain but it is not thought to be attributable to a direct spirochetal infection. The diagnosis is likely when there has been a tick bite with well-documented erythema migrans or arthri-

tis. Several of our Lyme-infected patients have had almost simultaneous facial palsy and sensory polyneuropathy. Human immunodeficiency virus infection is another well-known infectious cause of facial palsy. The facial palsy of both Lyme and HIV infections is associated with a pleocytosis in the spinal fluid. Serologic and CSF examination may be useful if there is suspicion of either process. Rarely, chickenpox in children may be followed in 1 to 2 weeks by facial paralysis. Tuberculous infection of the mastoid and middle ear or of the petrous bone is a cause of facial paralysis in parts of the world where this infection is particularly common. Facial palsy may occur in infectious mononucleosis and was observed occasionally in poliomyelitis. The facial nerve is frequently involved in leprosy. Bilateral involvement of the facial nerve is commented on below.

The *Ramsay Hunt syndrome*, due presumably to herpes zoster of the geniculate ganglion, consists of a facial palsy associated with a vesicular eruption in the external auditory canal, other parts of the cranial integument, and mucous membrane of the oropharynx. This infection may be initially indistinguishable from Bell's palsy since, in some studies, the vesicles were not apparent for days, or never appeared. Often the eighth cranial nerve is affected as well, causing nausea, vertigo, and deafness (see pages 263 and 642). Murakami et al have shown that the virus can be detected, even before the emergence of typical vesicles, by collecting exudate from the skin of the pinna on a Schirmer strip (otherwise used to quantitate tearing) and applying PCR techniques. In this way, in a manner of a few hours, they documented VZV infection in 71 percent of patients with Ramsay Hunt syndrome without vesicles. Treatment with a combination of corticosteroids (prednisone 60 mg daily for 3 to 5 days) and acyclovir (800 mg 5 times daily for a week) has been recommended based on a randomized trial (Whitley et al), but this requires confirmation. The review by Sweeney and Gilden is recommended to the interested reader.

Tumors of the parotid gland or ones that invade the temporal bone (carotid body, cholesteatoma, and dermoid) or granulomatosis at the base of the brain (histiocytosis) may produce a facial palsy; the onset is insidious and the course progressive. Fracture of the temporal bone (usually with damage to the middle or internal ear), otitis media, and middle ear surgery are relatively uncommon causes. The orientation of the petrous fracture determines prognosis (see page 749). Acoustic neuromas, neurofibromas, glomus jugulare tumors, and aneurysmal dilatations of the vertebral or basilar artery may involve the facial nerve. Pontine lesions, most often vascular or neoplastic, may cause facial palsy, usually in conjunction with other neurologic signs. The rare form of amyloidosis associated with crystal lattice deposits in the cornea may involve the facial nerves. Weakness of only a portion of the facial musculature, associated with numbness in the same region, may be the result of perineural tumor invasion by squamous cell or other skin cancers (see further on, under "Multiple Cranial Nerve Palsies"). An autosomal dominant syndrome of facial palsy, multiple truncal café-au-lait spots, and mild developmental delay has been described by Johnson and colleagues.

Bilateral Facial Palsy Bell's palsy may be bilateral, but only rarely is the involvement on the two sides simultaneous. The truly contemporaneous appearance of *bilateral facial paralysis* (facial diplegia) is most often a manifestation of the Guillain-Barré syndrome (GBS) and may also occur in Lyme disease and rarely with HIV infection (page 644). There are numerous other causes of bilateral facial palsy, all of them infrequent (Keane). It is reported

in approximately 7 of every 1000 patients with sarcoidosis although our impression is that it is more frequent. When acute in onset with sarcoidosis it has been referred to as *uveoparotid fever*, or *Heerfordt syndrome*. In typical cases of sarcoid the paralysis on each side tends to be separated by weeks or longer. Mononucleosis may affect both sides almost simultaneously; this is probably a form of GBS. Bifacial palsy is also a feature of the Möbius syndrome (page 873). Even less common is the *Melkersson-Rosenthal syndrome*, consisting of the triad of recurrent facial paralysis, facial (particularly labial) edema, and, less constantly, plication of the tongue. The syndrome begins in childhood or adolescence and may be familial. Biopsy of the lip may reveal a granulomatous inflammation. Causes of *recurrent Bell's palsy* have been listed earlier and are summarized by Pitts and colleagues.

Supranuclear Forms of Facial Paralysis All forms of nuclear or peripheral facial palsy must be distinguished from the supranuclear type. In the latter, the frontalis and orbicularis oculi muscles are involved less than those of the lower part of the face or not at all, since the corticopontine innervation of the upper facial muscles is bilateral, and that of the lower facial muscles mainly contralateral (a finding attributed to Broadbent, see page 46). In supranuclear lesions there may also be a dissociation of emotional and voluntary facial movements; often, some degree of paralysis of the arm and leg or an aphasia (in dominant hemisphere lesions) is conjoined. A developmental malformation of the perisylvian regions of the cortex may present as facial diplegia and pharyngeal paralysis, essentially a pseudobulbar palsy.

Muscles innervated by the facial nerve may be affected by lesions of the supranuclear pathways, which disinhibit or otherwise derange brainstem reflex activity. In the condition referred to as "apraxia of the eyelids," the patients cannot close the eyelids voluntarily, but they will still close reflexively in response to stimulation of the supraorbital branch of the trigeminal nerve (by a tap on the brow or bridge of the nose or by touching the cornea). As described in Chap. 45, under "Blink Reflexes," these are trigeminofacial reflexes. Actually, the blink reflex is expressed by two electrical responses, one early and mainly ipsilateral (termed *R1*) and the other late and bilateral (*R2*). The late response (to a tap on the brow), which is lost in Parkinson disease and is enhanced in pseudobulbar palsy, utilizes large fiber bundles in the supraorbital nerves; the early response (corneal reflex) utilizes the small fiber bundles in the long ciliary nerves. Derangement of one of these reflexes or of the jaw jerk is found in 25 percent of patients with multiple sclerosis. In pseudobulbar palsy, tapping the tendinous insertions into the orbicularis oris elicits a buccal (trigeminofacial) reflex, which may spread to cause closure of the eyes.

Facial Hemiatrophy (Parry-Romberg syndrome) An obscure disorder is the *facial hemiatrophy of Romberg*. It occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one or both sides of the face. It usually begins in adolescence or early adulthood and is slowly progressive. In its advanced form, the affected side of the face is gaunt and the skin thin, wrinkled, and rather dark; the hair may turn white and fall out, and the sebaceous glands become atrophic; the muscles and bones are not involved as a rule. The condition is a form of *lipodystrophy*, but the localization within a myotome indicates the operation of some neural factor (possibly a growth factor) of unknown nature. A variegated coloration of the iris and a congenital oculosympathetic paralysis are found in some cases. Rarely certain

central nervous system abnormalities (mainly focal seizures and ventricular dilatation), referable to the homolateral hemisphere, are conjoined (Hosten). The significance of these associations is unclear. Wilson and Hoxie have pointed out the frequent coexistence of facial asymmetry in adults with congenital or early-onset superior oblique palsy and compensatory head tilt or torticollis.

If the peripheral facial paralysis has existed for some time and return of motor function has begun but is incomplete, a kind of contracture (in reality a continuous diffuse myokymic contraction) may appear. The palpebral fissure becomes narrowed, and the nasolabial fold deepens. Attempts to move one group of facial muscles result in contraction of all of them (associated movements, or synkinesis). Spasms of facial muscles may develop and persist indefinitely, being initiated by every facial movement. With the passage of time, the corner of the mouth and even the tip of the nose may become pulled to the affected side. This is a special acquired form of hemifacial spasm, the more common variety of which is described below.

Anomalous regeneration of the seventh nerve fibers, following Bell's palsy or other injury, may result in other curious disorders that represent limited types of synkineses. The most common is the "jaw-winking" phenomenon (also called Wartenberg's or inverse Marcus-Gunn sign), in which jaw movements, especially lateral movements (engaging the pterygoid muscle), cause an involuntary closure of the eyelid ipsilateral to the movement. If regenerating fibers originally connected with the orbicularis oculi become connected with the orbicularis oris, closure of the lids may cause a retraction of the corner of the mouth; or if visceromotor fibers originally innervating the salivary glands later come to innervate the lacrimal gland, anomalous tearing (crocodile tears) occurs whenever the patient salivates. A similar mechanism explains gustatory sweating of the cheek and upper lip.

Hemifacial Spasm The facial muscles on one side may be involved in painless irregular clonic contractions of varying degree (*hemifacial spasm*). This condition develops in the fifth and sixth decades, affects women more than men, and it usually proves to be due to a compressive lesion of the facial nerve, most often by a tortuous branch of the basilar artery that lies on the ventral surface of the pons and forms a loop under the proximal nerve. Less often the cause of compression is a basilar artery aneurysm, or an acoustic nerve tumor or meningioma. The spasm usually begins in the orbicularis oculi muscle and gradually spreads to other muscles on that side of the face, including the platysma. The paroxysm may be induced or aggravated by voluntary and reflexive movements of the face.

There was for a time controversy concerning the pathogenesis of hemifacial spasm. Jannetta attributed all cases to a compression of the root of the facial nerve by an aberrant looped blood vessel. Microsurgical decompression of the root with the interposition of a pledget between the vessel and the root has relieved the facial spasm in most of his cases. These results have been corroborated by Barker and associates in a series of 705 patients followed post-operatively for an average period of 8 years; 84 percent achieved an excellent result. An even higher rate of benefit was obtained in a prospective series by Illingworth and colleagues (cure of 81 of 83 patients).

The pathophysiology of the spasm is believed to be focal demyelination nerve root compression. The demyelinated axon is theorized to activating adjacent nerve fibers by ephaptic transmission ("artificial" synapse of Granit et al). Another possible source of the

spasm is spontaneous ectopic excitation arising in injured fibers. Nielsen and Jannetta have shown that ephaptic transmission disappears after the nerve is decompressed.

Treatment Surgical decompression of a vascular loop, which involves exploration of the posterior fossa, carries some small risk. The facial muscles may be weakened, sometimes permanently. Another complication has been deafness due to injury of the adjacent eighth nerve. Also, there is a modest risk of recurrence of the spasms, usually within 2 years of the operation (Piatt and Wilkins). Operative success depends on tight dural closure to prevent CSF leakage from the posterior fossa.

The authors suggest that patients with idiopathic hemifacial spasm should first be treated medically. Alexander and Moses noted that carbamazepine (Tegretol) in a dosage of 600 to 1200 mg/day controlled the spasm in two thirds of the patients. Baclofen or gabapentin can be tried if carbamazepine fails. Some patients cannot tolerate these drugs, have only brief remissions, or fail to respond; they may be treated with botulinum toxin injected into the orbicularis oculi and other facial muscles. The hemifacial spasms are relieved for 4 to 5 months and injections can be repeated without danger. Some patients have been injected repeatedly for more than 5 years without apparent adverse effects. Failing these conservative measures, surgery is quite appropriate.

Other Disorders of the Facial Nerve *Facial myokymia* is a fine rippling activity of all the muscles of one side of the face mentioned above. It develops most often in the course of multiple sclerosis or a brainstem glioma. It has also occurred after other diseases of the facial nerve, e.g., in GBS, in which case it is usually bilateral. We have seen it more often in the recovery stage than in the early phase of GBS. The fibrillary nature of the involuntary movements and their arrhythmicity tend to distinguish them from the coarser intermittent facial spasms and contracture, tics, tardive dyskinesia, and clonus. The EMG pattern is one of spontaneous asynchronous discharge of adjacent motor units, appearing singly or in doublets or triplets at a rate varying from 30 to 70 cycles per second. Demyelination of the intrapontine part of the facial nerve and possibly supranuclear disinhibition of the facial nucleus have been the postulated mechanisms. But the observation of facial myokymia in GBS informs us that the abnormal movement may have its origin in a lesion at any point along the nerve (see pages 1194 and 1278 for further discussion of myokymia).

A clonic or tonic contraction of one side of the face may be the sole manifestation of a cerebral cortical seizure. Involuntary recurrent spasm of both eyelids (*blepharospasm*) may occur with almost any form of dystonia but is most frequent in elderly persons as an isolated phenomenon, and there may be varying degrees of spasm of the other facial muscles (see page 93). Relaxant and tranquilizing drugs are of little help in this disorder, but injections of botulinum toxin into the orbicularis oculi muscles give temporary or lasting relief. A few of our patients have been helped (paradoxically) by L-dopa; baclofen, clonazepam, and tetrabenazine in increasing doses may be helpful. In the past, failing these measures, the periorbital muscles were destroyed by injections of doxorubicin or surgical myectomy (Hallett and Daroff). With the advent of botulinum treatment, there is no longer a need to resort to these extreme measures. In some cases, blepharospasm subsides spontaneously. Rhythmic unilateral myoclonia, akin to palatal myoclonus, may be restricted to facial, lingual, or laryngeal muscles.

Hypersensitivity of the facial nerve occurs in hypocalcemic

tetany; spasm of the facial muscles is elicited by tapping in front of the ear (Chvostek sign).

The Ninth, or Glossopharyngeal, Nerve

Anatomic Considerations This nerve arises from the lateral surface of the medulla by a series of small roots that lie just rostral to those of the vagus nerve. The glossopharyngeal, vagus, and spinal accessory nerves leave the skull together through the jugular foramen and are then distributed peripherally. The *ninth nerve* is mainly sensory, with cell bodies in the inferior, or petrosal, ganglion (the central processes of which end in the nucleus solitarius) and the small superior ganglion (the central fibers of which enter the spinal trigeminal tract and nucleus). Within the nerve are afferent fibers from baroreceptors in the wall of the carotid sinus and from chemoreceptors in the carotid body. The baroreceptors are involved in the regulation of blood pressure, and chemoreceptors are responsible for the ventilatory responses to hypoxia. The somatic efferent fibers of the ninth nerve are derived from the nucleus ambiguus, and the visceral efferent (secretory) fibers, from the inferior salivatory nucleus. These fibers contribute in a limited way to the motor innervation of the striated musculature of the pharynx (mainly of the stylopharyngeus, which elevates the pharynx), the parotid gland, and the glands in the pharyngeal mucosa. A discussion of its role in swallowing is found on page 476.

It is commonly stated that this nerve mediates sensory impulses from the faucial tonsils, posterior wall of the pharynx, and part of the soft palate as well as taste sensation from the posterior third of the tongue. However, an isolated lesion of the ninth cranial nerve is a rarity, and the effects are not fully known. In one personally observed case of bilateral surgical interruption of the ninth nerves, verified at autopsy, there had been no demonstrable loss of taste or other sensory or motor impairment. This suggests that the tenth nerve may be responsible for these functions, at least in some individuals. The role of the ninth nerve in the reflex control of blood pressure and ventilation has been alluded to earlier but referable clinical manifestations from damage of this cranial nerve are infrequent except perhaps for syncope as noted below.

One may occasionally observe a glossopharyngeal palsy in conjunction with vagus and accessory nerve involvement due to a tumor in the posterior fossa or an aneurysm of the vertebral artery. The nerves are compressed as they pass through the jugular foramen. Hoarseness due to vocal cord paralysis, some difficulty in swallowing, deviation of the soft palate to the sound side, anesthesia of the posterior wall of the pharynx, and weakness of the upper trapezius and sternomastoid muscles make up the clinical picture (see Table 47-1, jugular foramen syndrome). On leaving the skull, the ninth, tenth, and eleventh nerves lie adjacent to the internal carotid artery, where they can be damaged by a dissection of that vessel.

Glossopharyngeal Neuralgia (see also page 163) This disorder first described by Weisenburg in 1910 resembles trigeminal neuralgia in many respects except that the unilateral stabbing pain is localized to one side of the root of the tongue and throat. It is far less common than trigeminal neuralgia. Sometimes the pain overlaps the vagal territory beneath the angle of the jaw and external auditory meatus. It may be triggered by coughing, sneezing, swallowing, and pressure on the tragus of the ear. Temporary blocking of the pain by anesthetizing the tonsillar fauces and posterior pharynx with 10% lidocaine spray is diagnostic. Rarely, herpes zoster

may involve the glossopharyngeal nerve. Fainting as a manifestation of vagoglossopharyngeal neuralgia is described on page 325.

The same drugs that have been found helpful in the treatment of tic douloureux may be used to treat glossopharyngeal neuralgia, but their efficacy has been difficult to judge. Regarding vascular compression of the nerve, Resnick and colleagues have reported the results of microvascular decompression of the ninth nerve in 40 patients; in 32 of these, relief of symptoms was complete and was sustained during an average follow-up of 4 years; 3 patients remained with permanent weakness of structures thought to be innervated by the ninth nerve. A similar high rate of success has been achieved by others. If syncope is associated with the pain, it can be expected to cease with abolition of the attacks of pain. Syncope can also occur when the ninth nerve is involved by tumors of the parapharyngeal space; most of these are squamous cell carcinomas and both the ninth and tenth nerves are implicated. Section of rootlets of the ninth nerve has reportedly reduced or abolished the episodes of fainting in these cases.

The Tenth, or Vagus, Nerve

Anatomic Considerations This nerve has an extensive sensory and motor distribution and important autonomic functions. It has two ganglia: the *jugular*, which contains the cell bodies of the somatic sensory nerves (innervating the skin in the concha of the ear), and the *nodose*, which contains the cell bodies of the afferent fibers from the pharynx, larynx, trachea, esophagus, and thoracic and abdominal viscera. The central processes of these two ganglia terminate in relation to the nucleus of the spinal trigeminal tract and the tractus solitarius, respectively. The motor fibers of the vagus are derived from two nuclei in the medulla—the nucleus ambiguus and the dorsal motor nucleus. The former supplies somatic motor fibers to the striated muscles of the larynx, pharynx, and palate; the latter supplies visceral motor fibers to the heart and other thoracic and abdominal organs. The distribution of vagal fibers is illustrated in Fig. 47-4, and their participation in swallowing is described on page 476.

Complete interruption of the intracranial portion of one vagus nerve results in a characteristic paralysis. The soft palate droops on the ipsilateral side and does not rise in phonation. The uvula deviates to the normal side on phonation, but this is an inconstant sign in disease. There is loss of the gag reflex on the affected side and of the *curtain movement* of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying “ah.” The voice is hoarse, often nasal, and the vocal cord on the affected side lies immobile in a “cadaveric” position, i.e., midway between abduction and adduction. With partial lesions, movements of abduction are affected more than those of adduction (Semon’s law). There may be a loss of sensation at the external auditory meatus and back of the pinna. Usually no change in visceral function can be demonstrated. If the pharyngeal branches of both vagi are affected, as in diphtheria, the voice has a nasal quality, and regurgitation of liquids through the nose occurs during the act of swallowing.

Diseases Affecting the Vagus Complete bilateral paralysis is said to be incompatible with life, and this is probably true if the nuclei are entirely destroyed in the medulla by poliomyelitis or some other disease. However, in the cervical region, both vagi have been blocked with procaine in the treatment of intractable asthma without mishap. Moreover, Johnson and Stern report a case of bi-

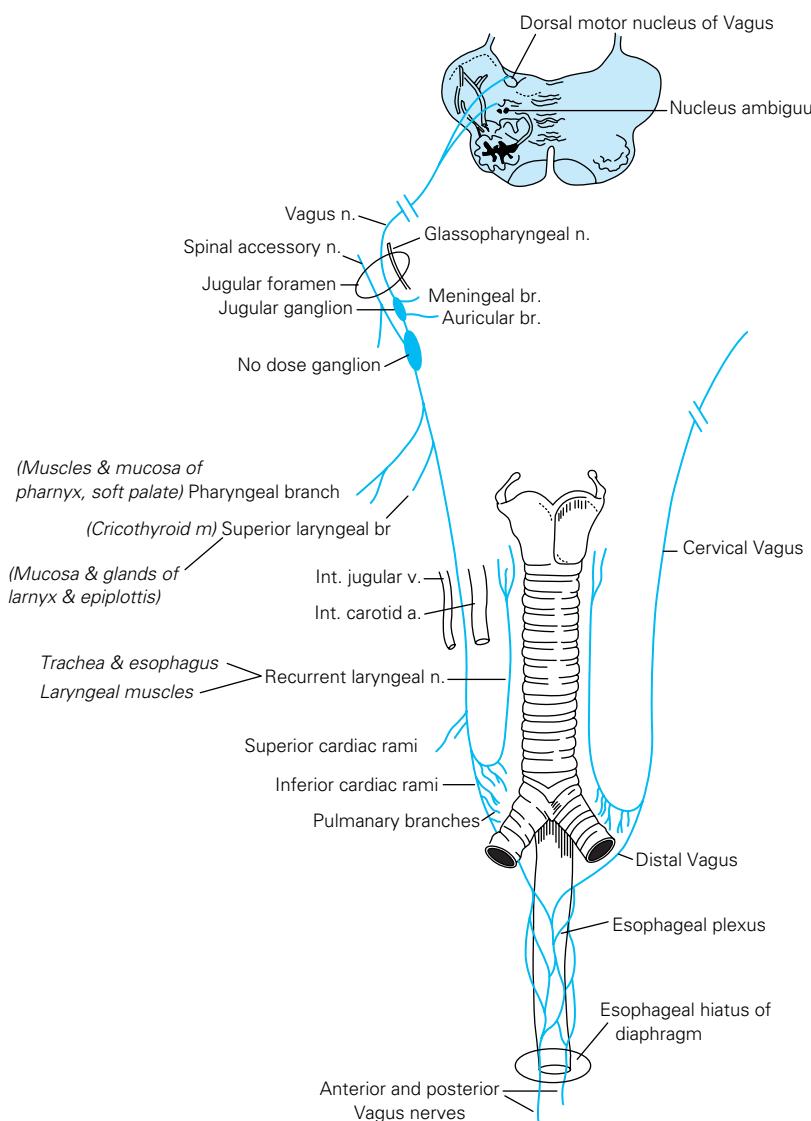

Figure 47-4. Anatomic features of the vagus nerve. Note the relationship to the spinal-accessory and glossopharyngeal nerves at the jugular foramen and the long course of the left recurrent laryngeal nerve, which is longer than the right and hooks around the aortic arch [not shown].

lateral vocal cord paralysis in association with familial hypertrophic polyneuropathy, and Plotz relates the history of three brothers with congenital laryngeal abductor paralysis due to bilateral dysgenesis of the nucleus ambiguus. Bannister and Oppenheimer have called attention to defects of phonation and laryngeal stridor as early features of autonomic failure in multiple system atrophy (page 925). We have seen several such patients in whom stridor was a prominent feature of the illness, in one patient for 7 months before other features of the disease became evident.

The vagus nerve may be implicated at the meningeal level by tumors and infectious processes and within the medulla by vascular lesions (e.g., the lateral medullary syndrome of Wallenberg or a cavernous angioma), by motor system disease, and occasionally by tumors. Dysphagia is then invariably present. Herpes zoster may attack this nerve, either alone or together with the ninth nerve as part of a jugular foramen syndrome. The vagus is often affected along with the glossopharyngeal nerve in spontaneous dissection of the carotid artery at the base of the skull. The vagus nerves may

be damaged in the course of thyroid surgery and may be involved in cases of advanced alcoholic or diabetic neuropathy. Polymyositis and dermatomyositis, which cause hoarseness and dysphagia by direct involvement of laryngeal and pharyngeal muscles, thereby simulate disease of the vagus nerves.

A fact of some importance is that the left recurrent laryngeal nerve, because of its long course under the aortic arch, may be damaged as a result of thoracic disease. There is no dysphagia with lesions at this point in the nerve since the branches to the pharynx (but not to the larynx) have already been given off. For this reason, an aneurysm of the aortic arch, an enlarged left atrium, mediastinal lymph nodes from bronchial carcinoma, and a mediastinal or superior sulcus lung tumor are much more frequent causes of an isolated (left) vocal cord palsy than are intracranial diseases.

It is estimated that in one-quarter to one-third of all cases of paralysis of the recurrent laryngeal nerve no cause can be established, i.e., they are idiopathic. The highest incidence is in the third decade, and males are more susceptible than females. Of the 21 cases reported by Blau and Kapadia, 5 recovered completely and 5 partially within a few months; no other disease appeared in the 8-year period that followed. Palsies of the superior and recurrent laryngeal nerves, occurring as part of isolated vagal neuropathies, have been described by Berry and Blair. A few were bilateral, and again, the majority of the cases were idiopathic and had much the same prognosis as isolated palsies of the recurrent laryngeal nerve.

Laryngeal neuralgia is a rare entity, in which paroxysms of pain are localized over the upper portion of the thyroid cartilage or hyoid bone on one or both sides. It is evoked by coughing, yawning, talking, or sneezing. In the case reported by Brownstone and coworkers it was relieved by carbamazepine.

Diagnosis When confronted with a case of vocal cord palsy, the physician is advised to determine the site of the lesion. If intramedullary, there are usually ipsilateral cerebellar signs, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Bernard-Horner syndrome (Table 34-3). If the lesion is extramedullary but intracranial, the glossopharyngeal and spinal accessory nerves are frequently involved as well (jugular foramen syndrome, see Table 47-1). If extracranial in the posterior laterocondylar or retroparotid space, there may be a combination of ninth, tenth, eleventh, and twelfth cranial nerve palsies and a Bernard-Horner syndrome. Combinations of these lower cranial nerve palsies, which have a variety of eponymic designations (see Table 47-1), are caused by various tumors, both primary and metastatic, or by chronic inflammations or granulomas involving lymph nodes at the base of the skull. If there is no palatal weakness and no pharyngeal or palatal sensory loss, the lesion is below the origin of the pharyngeal branches, which leave the vagus nerve high in the cervical region. The usual site of disease is then the mediastinum.

The Eleventh, or Spinal Accessory, Nerve

Anatomic Considerations This is a purely motor nerve, of spinal rather than cranial origin. Its fibers arise from the anterior horn cells of the upper four or five cervical segments and enter the skull through the foramen magnum. Intracranially, the accessory nerve travels for a short distance with the part of the tenth nerve that is derived from the caudalmost cells of the nucleus ambiguus; together, the two roots are referred to as the *vagal-accessory nerve* or *cranial root of the accessory nerve*. The two roots leave the skull through the jugular foramen. The aberrant vagus fibers then rejoin the main trunk of the vagus, and the fibers derived from the cervical segments of the spinal cord form an “external ramus” and innervate the ipsilateral sternocleidomastoid and trapezius muscles. Only the somatic motor fibers constitute the accessory nerve in the strict sense. In patients with torticollis, however, division of the upper cervical motor roots or the spinal accessory nerve has often failed to ablate completely the contraction of the sternocleidomastoid muscle. This suggests a wider innervation of the muscle, perhaps by fibers of apparent vagal origin that join the accessory nerve for passage through the jugular foramen.

A complete lesion of the accessory nerve results in weakness of the sternocleidomastoid muscle and upper part of the trapezius (the lower part of the trapezius is innervated by the third and fourth cervical roots through the cervical plexus). Weakness can be demonstrated by asking the patient to shrug his shoulders; the affected side will be found to be weaker, and there will often be evident atrophy of the upper part of the trapezius. With the arms at the sides, the shoulder on the affected side droops and the scapula is slightly winged; the latter defect is accentuated with lateral movement of the arm (with serratus anterior weakness, winging of the scapula is more prominent and occurs on forward elevation of the arm). When the patient turns his head forcibly against the examiner’s hand, preferably starting with the head deviated to the opposite side, the sternocleidomastoid of the opposite side does not contract firmly beneath the fingers. This muscle can be further tested by having the patient press his head forward against resistance or lift his head from the pillow.

Motor system disease, poliomyelitis, syringomyelia, and spinal cord tumors may involve the cells of origin of the spinal accessory nerve. In its intracranial portion, the nerve is usually affected along with the ninth and tenth cranial nerves by herpes zoster or by lesions of the jugular foramen (glomus tumors, neurofibromas, metastatic carcinoma, jugular vein thrombosis). Tumors at the foramen magnum may also damage the nerve. In the posterior triangle of the neck, the eleventh nerve can be damaged during surgical operations and by external compression or injury. Compressive-invasive lesions of this nerve may be visualized by computed tomography or MRI of the posterior cervical space.

A benign disorder of the eleventh nerve, akin to Bell’s palsy, has been described by Spillane and by Eisen and Bertrand. It begins with pain in the low lateral neck that subsides in a few days and is followed by weakness and atrophy in the distribution of the nerve. Also, a recurrent form of spontaneous accessory neuropathy has been described (Chalk and Isaacs). About one quarter to one third of eleventh nerve lesions are estimated to be of this idiopathic type; most but not all of the patients recover.

Bilateral sternocleidomastoid and trapezius palsy, which occurs with primary disease of muscles—e.g., polymyositis and muscular dystrophy—may be difficult to distinguish from a bilateral affection

of the accessory nerves or the motor nuclei (progressive bulbar palsy). The supranuclear innervation of the spinal accessory nuclei is apparently mainly ipsilateral as evidenced by contraversive turning of the head during a seizure, the result of contraction of the ipsilateral sternocleidomastoid muscle. Whether this is attributable to a direct ipsilateral tract, or to double crossing, is not known.

The Twelfth, or Hypoglossal, Nerve

Anatomic Considerations This is also a pure motor nerve, which supplies the somatic musculature of the tongue. It arises as a series of rootlets that issue from the ventral medulla between the pyramid and inferior olive complex. The nerve leaves the skull through the hypoglossal foramen and innervates the genioglossus muscle, which acts to protrude the tongue; the styloglossus, which retracts and elevates its root; and the hyoglossus, which causes the upper surface to become convex. Complete interruption of the nerve results in paralysis of one side of the tongue. The tongue curves slightly to the healthy side as it lies in the mouth, but on protrusion it deviates to the affected side, owing to the unopposed contraction of the healthy genioglossus muscle. By pushing against the tongue in the cheek, one can judge the degree of weakness. The tongue also cannot be moved with natural facility causing difficulty with handling food in the mouth. The denervated side becomes wrinkled and atrophied, and fasciculations and fibrillations can be seen.

Lesions of the hypoglossal nerve roots are rare. Occasionally an intramedullary lesion, usually a stroke, damages the emerging fibers of the hypoglossal nerve, corticospinal tract, and medial lemniscus (Table 34-3). The result is paralysis and atrophy of one side of the tongue, together with spastic paralysis and loss of vibration and position sense in the opposite arm and leg. Poliomyelitis and motor system disease may destroy the hypoglossal nuclei. Lesions of the basal meninges and of the occipital bones (tumor invasion platybasia, invagination of the occipital condyles, Paget disease) may involve the nerve in its extramedullary course, and it is sometimes damaged in operations on the neck. A dissecting aneurysm of the carotid artery was shown by Goodman and coworkers to have compressed the hypoglossal nerve, with resultant weakness and atrophy of the tongue. Rare instances of temporal arteritis and Takayasu arteritis affecting the carotid artery and adjacent twelfth nerve have been described. Lance and Anthony have described the simultaneous occurrence of nuchal-occipital pain and ipsilateral numbness of the tongue, provoked by the sudden, sharp turning of the head and termed it the *neck-tongue syndrome*. The phenomenon is attributed to compression, in the atlantoaxial space, of the second cervical root, which carries some of the sensory fibers from the tongue, via the hypoglossal nerve, to the C2 segment of the spinal cord.

It is worth mentioning here that the tongue may be red and smooth in vitamin deficiency states. *Glossodynia* (burning pain of the tongue, burning mouth syndrome, page 165), a condition most frequently seen in the elderly and unexplained in young women, may or may not be accompanied by redness and dryness, but not by weakness. A habit of tongue-thrusting and teeth-clenching is often associated. The ascription of these motor abnormalities to a psychogenic mechanism does not agree with the authors’ experience (see Quinn).

Syndrome of Bulbar Palsy

This syndrome is the result of weakness or paralysis of muscles that are supplied by the motor nuclei of the lower brainstem, i.e.,

the motor nuclei of the fifth, seventh, and ninth to twelfth cranial nerves. (Strictly speaking, the motor nuclei of the fifth and seventh nerves lie outside the “bulb,” which is the old name for the medulla oblongata.) Involved are the muscles of the jaw and face; the sternocleidomastoids and upper parts of the trapezius; and the muscles of the tongue, pharynx, and larynx. If weakness develops rapidly, as may happen in GBS, diphtheria, or poliomyelitis, there is no time for muscle atrophy. Myasthenia gravis, inclusion body myopathy, and polymyositis may on rare occasions produce such a picture but motor neuron disease is the most common course. When the latter disease is isolated to the bulbar muscles, it has been called *progressive bulbar palsy*. The more chronic diseases—e.g., progressive bulbar palsy and Kennedy bulbospinal atrophy (forms of motor system disease) and the childhood form of Fazio-Londe—result in marked wasting and fasciculation of the facial, tongue, sternocleidomastoid, and trapezius muscles. All of these disorders must be differentiated from pseudobulbar palsy (see page 426).

MULTIPLE CRANIAL NERVE PALSYES

As one can readily understand, several cranial nerves may be affected by a single disease process. The first clinical problem that arises is whether the lesion lies within or outside the brainstem. Lesions lying on the surface of the brainstem or at the base of the skull are characterized by involvement of adjacent cranial nerves (often occurring in succession and sometimes painful) and by late and only slight, if any, involvement of the long sensory and motor pathways. These are discussed below and listed in Table 47-1 by their eponymic designations. The opposite is true of intramedullary, intrapontine, and intramesencephalic lesions; lesions within the brainstem that involve cranial nerves often produce a crossed-sensory or motor paralysis (cranial nerve signs on one side of the body and tract signs on the opposite side). In this way, a number of distinctive brainstem syndromes, to which eponyms have been attached, are produced. These are listed in Table 34-3. An extramedullary lesion is more likely to cause bone erosion or to be associated with encroachment on cranial nerves (seen radiographically). The special problems of multiple cranial nerve palsies of the ocular motor nerves are addressed in Chap. 14.

Involvement of multiple cranial nerves outside the brainstem may be the result of trauma (obviously sudden in onset); localized infections such as herpes zoster (less acute onset); Lyme disease as reported by Schmutzhard and colleagues; cytomegalovirus (CMV) infection in an AIDS patient; Wegener granulomatosis, sarcoidosis, or other types of granulomatous disease (subacute onset); or compression by tumors and saccular aneurysms (more chronic development with pain). *The sequential painless affection of contiguous or noncontiguous nerves over several days or weeks is particularly characteristic of meningeal carcinomatosis or lymphomatosis.* The eighth nerve is commonly incorporated in neoplastic meningeal infiltrations. Among the solid tumors that cause local compression of nerves, neurofibromas, schwannomas (acoustic neuroma), meningiomas, cholesteatomas, carcinomas, cordomas, and chondromas have all been observed. Nasopharyngeal carcinoma (Schmincke tumor or lymphoepithelioma) may implicate several cranial nerves in succession by invading the base of the skull (mainly the fifth and sixth but also higher nerves; Fig. 47-5), as do basilar invagination and Chiari malformation. Several lower cranial nerves may be involved on one side by a carotid artery dissection. In France, a successive involvement of all cranial nerves on one side has been called the *Garcin syndrome*, or hemibasal

Figure 47-5. Nasopharyngeal carcinoma invading the anterior base of the skull and causing third and fifth nerve palsies. Coronal CT scan with bone windows.

syndrome. It has been reported in chondromas and chondrosarcomas of the clivus but may occur with nasopharyngeal carcinomas as well. The main causes of multiple cranial nerve palsies of extramedullary origin are listed in Table 47-2.

Multiple or single cranial nerve palsies of abrupt onset may precede or accompany infectious mononucleosis and sometimes other viral or mycoplasmal diseases. DeSimone and Snyder have assembled a series of 20 such cases associated with mononucleosis; bilateral facial paralysis was the most common presentation, bilateral optic neuritis the next, and in three cases, three or four cranial nerves were involved. The prognosis is excellent. The question of

Table 47-2
Causes of extramedullary multiple cranial nerve palsies

Meningeal processes

- Carcinomatous and lymphomatous meningitis
- Infectious radiculitis (tuberculous, fungal, syphilitic, Lyme)
- Idiopathic pachymeningitis

Lesions affecting nerves at the skull base

- Metastasis of solid tumor or lymphomatous infiltration
- Local spread from nasopharyngeal tumor, chordoma, sarcoma
- Trauma
- Vascular occlusion or dissection (carotid artery dissection, jugular vein thrombosis)
- Paget disease, basilar invagination, Arnold-Chiari and other bony disorders

Processes within nerves

- Perineural invasion of spindle cell, basal cell, parotid, and squamous cell cancer
- Granulomas and infectious diseases (Listeria, sarcoid, Wegener granulomatosis, diphtheria, HIV, Lyme disease, CMV infection in AIDS, Sjögren syndrome, idiopathic)
- Herpes zoster and other viral and postinfectious inflammatory lesions (Guillain-Barré syndrome)
- Mixed connective tissue disease

Idiopathic

- Tolosa-Hunt-like syndrome affecting nonorbital nerves
- Melkersson-Rosenthal syndrome

viral infections of cranial nerves is always raised by acute neuropathies of the facial, trigeminal, and auditory nerves, especially when the condition is bilateral, involves several nerves in combination, or is associated with a pleocytosis in the spinal fluid. Actually, the only proved viral etiology in this group of cases is that of herpes simplex and herpes zoster infections causing Bell's palsy, as discussed earlier. Since perceptive deafness, vertigo, and other cranial nerve palsies have been observed in conjunction with the postinfectious encephalomyelitides of *Mycoplasma*, varicella, measles, rubella, mumps, and scarlet fever they probably share an immune-mediated mechanism. However, as discussed in Chaps. 33 and 36, new techniques that identify small components of the genome of these organisms indicate that some cases formerly thought to be postinfectious in nature may be true infections of the nerve. The same may be said of the single and multiple cranial nerve palsies that are sometimes associated with HIV and CMV infections. Nothing is known of the pathology of the cranial nerve lesion or has a virus been isolated in these latter infections. Treatment of the parainfectious cases is symptomatic; fortunately the prognosis for recovery is excellent. The main causes of bilateral facial palsy have been discussed earlier in the chapter. A purely motor disorder of the facial and oropharyngeal muscles without atrophy always raises the question of myasthenia gravis.

From time to time one observes an acute form of *multiple cranial neuropathy of undetermined cause*. Juncos and Beal reported on 14 cases of this type, along with 6 well-documented cases of the Tolosa-Hunt orbitocavernous sinus syndrome with oculomotor palsies (see page 234). In the former group, the onset was with facial pain and headache (temporofrontal), followed within days by abducens palsy (12 of 14), oculomotor palsy (6 of 14), trigeminal palsy (5 of 14), facial weakness (4 of 14), and less often by involvement of the eighth, ninth, and tenth cranial nerves (unilaterally in most instances). Increased protein of CSF and pleocytosis occurred in several. The prompt relief of pain upon administration of steroids was similar to that obtained in the Tolosa-Hunt syndrome. The mode of recovery, which usually occurred within a few months, was also much the same in the two groups of patients. Juncos and Beal concluded that the clinical features of the two groups overlapped and that their separation into two syndromes was arbitrary. We have seen a relapsing form of this illness in young adults, responsive on each occasion to steroids. Numerous tests of the CSF by polymerase chain reaction revealed no viruses. Conceivably, some of these cases represent a variant form of GBS, inasmuch as they may be preceded by a nonspecific infection and accompanied by areflexia, evanescent paresthesias or weakness of the extremities, and an elevated CSF protein without pleocytosis. Others probably are examples of the entity described by Juncos and Beal, possibly reflecting a granulomatous process in the pachymeninges. As a more chronic affliction, we have observed 10 cases in which cranial nerves were affected sequentially over a period of many years (*polyneuritis cranialis multiplex*). Two were later found to have tuberculosis of cervical lymph nodes (presumably

scrofula), and three had sarcoidosis. No cause was determined in the rest. Symonds had similar experience. It is usually worth obtaining a biopsy of an enlarged cervical lymph node in these circumstances. Corticosteroid treatment seemed to have been helpful in our cases.

The special case of painless multiple oculomotor palsies is discussed in Chap. 14. The main causes are GBS, botulism, myasthenia gravis, thyroid ophthalmopathy, and diphtheria. In cases of chronic evolution, oculopharyngeal dystrophy and mitochondrial myopathy (progressive external ophthalmoplegia) must also be considered.

In cases of *Tolosa-Hunt* syndrome in which the orbital or cavernous sinus has been biopsied, a nonspecific granuloma has been found. *Sarcoid* and *tuberculosis* have been the causes of a few cases, as noted earlier. In *Wegener granulomatosis*, multiple cranial nerve palsies, usually lower ones, are reported. The administration of cyclophosphamide has led to remission (page 732).

The *cavernous sinus syndrome*, discussed on pages 229 and 735, consists of various combinations of oculomotor palsies and upper trigeminal sensory loss, usually accompanied by signs of increased pressure or inflammation of the venous sinus. The third, fourth, fifth, and sixth cranial nerves are affected first on one side only, but any of the processes that infiltrate or obstruct the sinus may spread to the other side. The main causes are septic or aseptic thrombosis of the venous sinus due to trauma, hypercoagulable states, or adjacent infections in adjacent structures, carotid artery aneurysm, and neoplastic infiltration. Keane summarized his experience with an astonishing 151 instances of cavernous sinus syndrome and found trauma and surgical procedures to be the most common causes, followed by neoplasms (specifically those originating in the nasopharynx), pituitary tumors, metastases, and lymphomas; our experience has tended more toward local infectious causes in diabetic patients and hypercoagulable states.

A special cause of multiple cranial nerve palsies that has been brought to our attention is an infiltration along the distal nerves in the skin and subcutaneous tissues by squamous cell carcinomas of the face, especially the spindle cell and other atypical varieties of tumor. This type of perineural spread first causes very restricted unilateral palsies related to the superficial branches of the fifth and seventh cranial nerves in one region of the face and then extends to the base of the skull and to the ventral brainstem. According to Clouston and colleagues, who present 5 cases in detail, the initial symptoms are usually pain and numbness in the area underlying the skin lesion and facial weakness confined to the same regions of the face; this pattern is a result of the proximity of fifth and seventh nerve branches in the skin and subcutaneous tissues. Various combinations of oculomotor palsies may follow as a result of tumor entry into the orbit via the infraorbital branch of the maxillary nerve. Occasionally there is no pain. We have also observed a similar regional pattern of extracranial involvement of trigeminal and facial nerves with an infiltrative mixed-cell tumor of the parotid gland.

CHAPTER 48

PRINCIPLES OF CLINICAL MYOLOGY: DIAGNOSIS AND CLASSIFICATION OF DISEASES OF MUSCLE AND NEUROMUSCULAR JUNCTION

GENERAL CONSIDERATIONS

Skeletal, or voluntary, muscle constitutes the principal organ of locomotion as well as a vast metabolic reservoir. Disposed in more than 600 separate muscles, this tissue makes up as much as 40 percent of the weight of adult human beings. An intricacy of structure and function undoubtedly accounts for its diverse susceptibility to disease, for which reason the main anatomic and physiologic facts are provided as an introduction to the following several chapters on muscle disease. For the purposes of exposition, diseases of the neuromuscular junction are presented in the chapters that follow (Chap. 53).

A single muscle is composed of thousands of muscle fibers that extend for variable distances along its longitudinal axis. Each fiber is a relatively large and complex multinucleated cell varying in length from a few millimeters to several centimeters (34 cm in the human sartorius muscle) and in diameter from 10 to 100 μm . Some fibers span the entire length of the muscle; others are joined end to end by connective tissue. Each muscle fiber is enveloped by an inner plasma membrane (the sarcolemma) and an outer basement membrane. The multiple nuclei of each fiber (cell), which are oriented parallel to its longitudinal axis and may number in the thousands, lie beneath the plasma membrane (sarcolemma)—hence they are termed *subsarcolemmal* or just *sarcolemmal nuclei*.

The cytoplasm (sarcoplasm) of the cell is abundant and contains myofibrils, various organelles such as mitochondria and ribosomes; each myofibril is enveloped in a membranous net, the sarcoplasmic reticulum (SR; Fig. 45-2). Extensions of the plasma membrane into the fiber form the transverse tubular system (T tubules), which are extracellular channels of communication with the intracellular sarcoplasmic reticulum. The SR and T tubules are anatomically independent but functionally related membrane systems. The junctional gap between the T tubules and SR is occupied by protein formations that are attached to the SR and are referred to as *junctional feet*; the latter have been identified as ryanodine receptors and are responsible for the release of calcium from the SR, which is a critical step in exciting the muscle (see Franzini-Armstrong).

The myofibrils themselves are composed of longitudinally oriented interdigitating filaments (myofilaments) of contractile proteins (actin and myosin), additional structural proteins (titin and nebulin), and regulatory proteins (tropomyosin and troponin). The series of biochemical events by which these proteins, under the influence of calcium ions, accomplish the contraction and relaxation of muscle is described in Chap. 45. Droplets of stored fat, glycogen, various proteins, many enzymes, and myoglobin, the lat-

ter imparting the red color to muscle, are contained within the sarcoplasm or its organelles.

Although the muscle fiber represents an indivisible anatomic and physiologic unit, disease may affect only one part of it, leaving the remainder to become dysfunctional or to atrophy, degenerate, or regenerate, depending on the nature and severity of the disease process.

The individual muscle fibers are surrounded by delicate strands of connective tissue (endomysium), which provide their support and permit unity of action. Capillaries, of which there may be several for each fiber, and nerve fibers, lie within the endomysium. Muscle fibers are bound into groups or *fascicles* by similar reticular tissue and sheets of collagen (perimysium), which bind together groups of fascicles and also surround the entire muscle (epimysium). The latter connective tissue tunics are also richly vascularized; different types of muscle have different arrangements of arteries and veins; fat cells are embedded within the interstices. The muscle fibers are attached at their ends to tendon fibers, which in turn connect with the skeleton. By this means, muscle contraction maintains posture and imparts movement.

Other notable characteristics of muscle are its natural mode of contraction—i.e., through neural innervation—and the necessity of intact innervation for the maintenance of its normal tone and trophic state. Each muscle fiber receives a nerve twig from a motor nerve cell in the anterior horn of the spinal cord or nucleus of a cranial nerve; the nerve twig joins the muscle fiber at the *neuromuscular junction* or *motor end plate*. As was pointed out on page 39, groups of muscle fibers with a common innervation from one anterior horn cell constitute the *motor unit*, which is the basic physiologic unit in all reflex, postural, and voluntary activity.

Embedded in the surface membrane are several types of ion channels that are responsible for maintaining the electrical potential and propagating depolarizing currents across the muscle membrane. Diseases of these channels are discussed in Chap. 54. Also constituting a large part of the membrane is a series of anchoring structural proteins, the nature of which have been thoroughly elucidated only in the past few decades. These are described in detail in relation to the muscular dystrophies in Chap. 50.

Acetylcholine (ACh), ACh receptors, and acetylcholinesterase (AChE), all of which play a special role in neuromuscular transmission, are concentrated at the neuromuscular junction. ACh is synthesized in the motor nerve terminal and stored in vesicles as packets, or “quanta,” each containing a relatively fixed number of molecules (about 10,000). Quanta of ACh are released at the nerve ending, diffuse into the narrow synaptic cleft, and combine with specialized receptors on the postsynaptic membrane. On the postsynaptic side of the synapse, the released ACh binds to ligand-

gated cation channels, which are concentrated at the peaks of the neuromuscular clefts. This creates a current that propagates toward the bottom of the cleft and opens voltage-gated sodium channels and results in a depolarizing potential of the muscle membrane. Small numbers of quanta of ACh are released spontaneously, producing miniature end-plate potentials (MEPPs) of about 0.5 mV. A nerve impulse arriving at the presynaptic distal axon causes an ingress of calcium into the nerve terminal through voltage-gated calcium channels, thereby triggering the release of many ACh quanta and producing a much larger end-plate potential (EPP). This wave of depolarization is propagated along the sarcolemma and transverse tubules to the interior of the fibers and leads to muscle contraction (see Chap. 45). The process of ACh release is terminated by action of the enzyme AChE, which breaks down ACh at the neuromuscular junction. AChE is concentrated at the bottom of the synaptic cleft. For the details of exocytosis of the synaptic vesicles and their reconstitution the reader is referred to the chapter on transmitter release in the text of Kandel and colleagues.

In addition to motor nerve endings, muscle contains several types of sensory endings, all of them mechanoreceptors: free nerve endings subserve the sensation of deep pressure-pain; Ruffini and pacinian corpuscles are pressure sensors; and the Golgi tendon organs and muscle spindles are tension receptors and participate in the maintenance of muscle tone and reflex activity (page 40). The Golgi receptors are located mainly at the myotendon junctions; pacinian corpuscles are localized at the tendon site but are also found sparsely in muscle itself. Muscle spindles are specialized groups of small muscle fibers that regulate muscle contraction and relaxation, as described on page 40. All these receptors are present in highest density in muscles that are involved in fine movements.

All muscles are not equally susceptible to disease, despite the apparent similarity of their structure. In fact, practically no disease affects all muscles in the body, and each has a characteristic topography within the musculature. The topographic differences between diseases provide incontrovertible evidence of structural or physiologic differences between muscles that are not presently disclosed by the light or electron microscope, i.e., all the factors responsible for the selective vulnerability of certain muscles are not known. Several hypothetical explanations come to mind. One may relate simply to fiber size; consider, for example, the large diameter and length of the fibers of the glutei and paravertebral muscles in comparison with the smallness of the ocular muscle fibers. The number of fibers composing a motor unit may also be of significance; in the ocular muscles, a motor unit contains only 6 to 10 muscle fibers (some even less), but a motor unit of the gastrocnemius contains as many as 1800 fibers. Also, the eye muscles have a much higher metabolic rate and a richer content of mitochondria than the large trunk muscles. Differences in patterns of vascular supply may permit some muscles to withstand the effects of vascular occlusion better than others. Histochemical studies of skeletal muscles have disclosed that within any one muscle, there are subtle metabolic differences between fibers—certain ones (type 1 fibers) being richer in oxidative and poorer in glycolytic enzymes, and others (type 2 fibers) being the opposite. Moreover, the distribution of certain structured proteins may alter the topography of disease expression; for example, the eye muscles do not contain dystrophin, a submembrane protein that is deficient in Duchenne and related forms of muscular dystrophy, which explains the muscles' lack of involvement in these diseases. In addition, the endomysial fibroblasts of eye muscles contain an abundance of glycosaminoglycans, which may render them susceptible to thyroid diseases. Diseases

of the neuromuscular junction show a distribution of weakness in relation to the density of these junctions in different muscles. Doubtless other differences will be discovered.

These anatomic and biochemical properties of muscle also suggest some of the ways in which this tissue can be affected by disease. Thus, one may envisage causative agents or genetic defects that affect different components of sarcoplasm: the filamentous proteins; the mitochondrial enzymes; the sarcoplasmic reticulum; the specialized channels for the entry of calcium, sodium, or chloride; the transverse tubules; or the sarcolemma itself. Finally, the endomysial connective tissue could be the primary pathway in disease, since it so closely invests the muscle fiber.

Normal muscle is endowed with a population of embryonic muscle precursor cells, known as "satellite cells," and as a result possesses a remarkable capacity to regenerate, a point often forgotten. It has been estimated that enough new muscle can be generated from a piece of normal muscle the size of a pencil eraser to provide normal musculature for a 70 kg adult. However, with complete destruction of the muscle fiber the regenerative capacity is greatly impaired. Destructive processes of the muscle fiber, e.g., inflammatory or metabolic, are usually followed by fairly complete restoration of the muscle cells provided that some part of each fiber has survived and the endomysial sheaths of connective tissue have not been severely disrupted. Unfortunately, many pathologic processes of muscle are chronic and unrelenting. Under such conditions, any regenerative activity fails to keep pace with the disease and the loss of muscle fibers is permanent. The bulk of the muscle is then replaced by fat and collagenous connective tissue, as typically seen in the muscular dystrophies.

APPROACH TO THE PATIENT WITH MUSCLE DISEASE

The number and diversity of diseases of striated muscle greatly exceeds the number of symptoms and signs by which they express themselves clinically; thus, different diseases share certain common symptoms and even syndromes. To avoid excessive repetition in the description of individual diseases, we shall discuss in one place all their clinical manifestations, a subject that is appropriately called *clinical myology*.

The physician is initially put on the track of a myopathic disease by eliciting complaints of muscle weakness or fatigue, pain, limpness or stiffness, spasm, cramp, twitching, or a muscle mass or change in muscle volume. Of these, the symptom of weakness is by far the most frequent and at the same time the most elusive. As remarked in Chap. 24, when speaking of weakness, the patient often means excessive fatigability. Although fatigability may be a feature of muscle diseases—particularly those affecting the neuromuscular junction, such as myasthenia gravis—it is far more frequently a complaint of patients with chronic systemic disease or with anxiety and depression. Rather than relying on the patient's report to distinguish between fatigability and weakness, it is often more informative to observe the patient during the performance of certain common activities, such as walking, running, climbing stairs, and arising from a sitting, kneeling, squatting, or reclining position. Difficulty in performing these tasks as described below signifies weakness rather than fatigue. The same is true of difficulty in working with the arms above shoulder level. Particular complaints may reveal a localized muscle weakness; e.g., drooping of the eyelids, diplopia and strabismus, change in facial expression and voice, and difficulty in chewing, closing the mouth, and swal-

lowing indicate a paresis of the levator palpebrae, extraocular, facial, laryngeal, masseter, and pharyngeal muscles, respectively. Of course, these impairments of muscle function may be due to a neuropathic or central nervous system (CNS) disturbance rather than to a myopathic one, but usually these conditions can be separated by the basic methods of neurology indicated further on in this chapter and in Chaps. 3 and 24.

Evaluation of Muscle Weakness and Paralysis

Reduced strength of muscle contraction—manifest by diminished power of single contractions against resistance (peak power) and during the sustained performance of prolonged or repetitive movements (i.e., endurance)—are the indubitable signs of muscle disease. In such testing, the physician may encounter difficulty in enlisting the patient's cooperation. The tentative, hesitant performance of the asthenic or hypersuggestible individual or the hysterical or malingeringer poses difficulties that can be surmounted by the techniques described in Chap. 3. In infants and small children, who cannot follow commands, one assesses muscle power by the resistance to passive manipulation or by observing performance while the patient is engaged in certain activities. The patient may be reluctant to fully contract the muscles in a painful limb, and indeed pain itself may cause a reflex diminution in the power of contraction (algesic paresis). Estimating the strength of isometric contractions that do not require the painful part to be moved is a way around this difficulty. Sometimes the weakness of a group of muscles becomes manifest only after a period of activity; e.g., the feet and legs may "drag" only after the patient has walked a long distance. The physician, upon being told this by the patient, should attempt to conduct the examination under circumstances that duplicate the complaints.

Weakness of muscle contraction acquires added significance when it is associated with other abnormalities such as tenderness or atrophy of muscle, change in tendon reflexes, twitching, and spasm. Also, severe weakness of certain muscle groups results in abnormalities of posture and gait. A waddling gait indicates weakness of the medial glutei (or dysplasia of hip joints); excessive lumbar lordosis and protuberance of the abdomen indicate weakness of the iliopsoas and abdominal muscles; kyphoscoliosis points to an asymmetrical weakness of the paravertebral muscles; and flaring of the shoulder blades is a sign of weakness of the lower trapezii, serratus magnus, and rhomboid muscles. Equinovarus deformities of the feet may be the result of fibrous contracture (pseudocontracture) of the calf muscles.

Ascertaining the extent and severity of muscle weakness requires a systematic examination of the main groups of muscles. The patient is asked to contract each group with as much force as possible, while the examiner opposes the movement and offers a graded resistance in accordance with the degree of residual power (isokinetic contraction). Alternatively, the patient is asked to produce a maximal contraction, and the examiner estimates power by the force needed to "break" or overcome it (isometric contraction or maximum voluntary isometric contraction). If the weakness is unilateral, one has the advantage of being able to compare it with the strength on the normal side. If it is bilateral, the physician must refer to his concept of what constitutes normalcy, based on experience in muscle testing. With practice, one can distinguish true weakness from unwillingness to cooperate, feigned or neurasthenic weakness, and inhibition of movement by pain. These methods of

manual muscle testing, while adequate in most clinical situations, may not be sufficiently refined for the evaluation of certain muscle diseases, particularly if serial examinations are required to determine the course of the disease and the effects of therapy.

In order to quantitate the degree of weakness, a rating scale may be required. Most widely used is the one proposed by the Medical Research Council (MRC) of Great Britain, which recognizes six grades of muscle strength, as follows:

- 0—Complete paralysis
- 1—Minimal contraction
- 2—Active movement with gravity eliminated
- 3—Weak contraction against gravity
- 4—Active movement against gravity and resistance
- 5—Normal strength

Further gradations may be added, specified as 4+ for barely detectable weakness and 4– for easily detected weakness, 3+ and 3–, and so on. This allows for 10 gradations of power.

The ocular, facial, lingual, pharyngeal, laryngeal, cervical, shoulder, upper arm, lower arm and hand, truncal, pelvic, thigh, and lower leg and foot muscles are examined sequentially. In the case of muscle disease it is most convenient to test the same muscle from each side. The anatomic significance of each of the actions tested—i.e., what roots, nerves, and muscles are involved—can be determined by referring to Table 46-1. A practiced examiner can survey the strength of these muscle groups in 2 to 3 min. A word of caution: in manually resisting the patient's attempts to contract the large and powerful trunk and girdle muscles, the examiner may fail to detect slight degrees of weakness, particularly in well-muscled individuals. These muscle groups are best examined by having the patient squat and kneel and then assume the erect posture, arise from and step onto a stool without using the hands, walk on his toes and heels, and lift a heavy object (e.g., *Harrison's Principles of Internal Medicine*) over his head. The strength of muscles of the hand can also be quantified with a dynamometer; for research purposes, similar but more sophisticated devices exist for other muscle groups (see Fenichel et al.).

Qualitative Changes in the Contractile Process

In the *myasthenic states* there is a rapid failure of contraction in the most affected muscles during sustained or repetitive activity. For instance, after the patient looks upward at the ceiling for a few minutes, the eyelids progressively droop; closing the eyes and resting the levator palpebrae muscles, causes the ptosis to lessen or disappear. Similarly, holding the eyes in a far lateral position will induce diplopia and strabismus. These effects, in combination with restoration of power by the administration of neostigmine or edrophonium (Tensilon), are the most valuable clinical criteria for the diagnosis of myasthenia gravis as described in Chap. 53.

In addition to myasthenic weakness, there are other abnormalities that may be discovered by observing, during one or a series of maximal actions of a group of muscles, the speed and efficiency of contraction and relaxation. In myxedema, for example, a stiffness and slowness of contraction in a muscle such as the quadriceps may be seen on change in posture (*contraction myoedema*); often it is associated with prolonged duration of the tendon reflexes and myoedema, which can be elicited by direct percussion of a muscle. Slowness in relaxation of muscles is another feature of hypothy-

roidism, accounting for the complaint of uncomfortable tightness of proximal limb muscles. A curious *rippling phenomenon* in muscles called *myokymia*, inherited as an autosomal dominant trait, has been observed in several families (Chap. 55). After a period of relaxation, a stiffening and rippling occurs in the contracting or stretched muscles. The stiffness is reduced by dantrolene but not by tocainamide. Acquired forms of myokymia are due to diverse processes, in particular nerve injury and regeneration (especially in the face, as noted in Chap. 47), hypothyroidism, and obscure causes such as thymoma.

A prolonged failure of relaxation following contraction of a muscle is characteristic of the *myotonic phenomenon*, which typifies certain diseases—congenital myotonia (of Thomsen), myotonic dystrophy, and the paramyotonia of Eulenberg (Chap. 54). True myotonia, with its prolonged discharge of membrane action potentials, requires strong contraction to elicit, is more evident after a period of relaxation, and tends to disappear with repeated contractions (pages 1265 and 1363). *Paradoxical myotonia* refers to an increase in the degree of myotonia during a series of contractions (the reverse of what happens in the usual type of myotonia). It also occurs in some cases of Eulenberg paramyotonia. This persistence of contraction is demonstrable also by tapping a muscle (*percussion myotonia*), a phenomenon easily distinguished from the electrically silent local bulge (*myoedema*) induced by tapping the muscle of a myxedematous or cachetic patient and from the brief fascicular contraction that is induced by tapping a normal or partially denervated muscle; the latter is referred to as *idiomuscular contraction*. It should be noted that in patients with hyperactive tendon reflexes, striking the muscle rather than its tendon can elicit a stretch reflex.

An increment in power with a series of several voluntary contractions in the absence of myotonia is a feature of the *inverse myasthenic (Lambert-Eaton) syndrome*, which is associated in about 50 percent of cases with small-cell carcinoma of the lung. The same increment occurs in botulism. In both instances there is an electromyographic (EMG) equivalent—a rapid increase in the voltage of a series of action potentials upon appropriate stimulation (pages 1101 and 1259).

The effect of cold on muscle contraction may also prove informative; either paresis or myotonia, lasting for a few minutes, may be evoked or enhanced by cold. This is most prominent in the paramyotonia of Eulenberg, but it may occur to some degree in all the other myotonic disorders.

Myotonia and myoedema must also be distinguished from the recruitment and spread of involuntary spasm induced by strong and repeated contractions of limb muscles in patients with mild or localized tetanus, with the “stiff-man” syndrome (Chap. 55), and with dystonias of various types. These are not primary muscle phenomena but are neural in origin, due to an abolition of inhibitory mechanisms.

The repeated contraction of forearm or leg muscles after the application of a tourniquet (exceeding arterial pressure) to the proximal part of a limb will often elicit latent tetany (carpopedal spasms). Its special mode of development in conditions that decrease the concentration of ionized calcium—as well as its duration, its enhancement by hyperventilation, and the association of tingling, prickling paresthesias—separate tetany from ordinary cramp and also from true physiologic contracture.

In practice, the term *contracture* is applied (somewhat indiscriminately, as discussed below) to all states of fixed muscle shortening. Several distinct types can be recognized. In *true physiologic contracture* a group of muscles, after a series of strong contractions,

may remain shortened for many minutes because of failure of the metabolic mechanism necessary for relaxation; in this shortened state, the EMG remains relatively silent, in contrast to the high-voltage, rapid discharges observed with cramp, tetanus, and tetany. True contracture occurs in McArdle disease (phosphorylase deficiency), in which it is induced or aggravated by the ischemia created by a tourniquet arterial occlusion, in phosphofructokinase deficiency and possibly in another disease, as yet undefined, where ischemia has no effect and phosphorylase seems to be present. Yet another type of exercise-induced contracture, described originally by Brody, has been attributed by Karpati and coworkers to a deficiency of calcium adenosine triphosphatase in the sarcoplasmic reticulum. These various forms of contracture are described further in Chap. 55. True contracture needs to be distinguished from paradoxical myotonia (see earlier) and from cramp, which in certain conditions (dehydration, tetany, pathologic cramp syndrome, amyotrophic lateral sclerosis) may be initiated by one or a series of strong voluntary muscle contractions.

It is appropriate here to comment on *pseudocontracture* (*myostatic or fibrous contracture*) for which the term *contracture* is used in general medicine. This is the common form of muscle and tendon shortening that follows prolonged fixation and complete inactivity of the normally innervated muscle (as in a broken limb immobilized by a cast or flaccid weakness of a limb that is allowed to remain immobile). Here the shortened state of the muscle and tendons, which may persist for days or weeks, has no clearly established anatomic, physiologic, or chemical basis. Fibrosis of muscle, a state following chronic fiber loss and immobility of muscle, is another cause of muscle shortening. Depending on the predominant position, certain muscles are both weakened and shortened. Flexor fibrous contracture of the arms is a prominent feature of the Emery-Dreifuss form of muscular dystrophy. It also accounts for the rigidity and kyphoscoliosis of the spine, which are so frequently a part of myopathic diseases. The latter state is distinguished from *ankylosis* by the springy nature of the resistance, coincident with increased tautness of muscle and tendon during passive motion, and from *Volkmann contracture*, in which there is evident fibrosis of muscle and surrounding tissues due to ischemic injury, usually after a fracture of the elbow.

Arthrogryposis (multiplex congenita), described on page 1244, is another form of fibrous contracture involving multiple muscle groups. This is a syndrome of the newborn that occurs in association with several different nerve and muscle diseases that have two features in common—an onset during intrauterine life and an alteration of the neural or muscular apparatus that results in muscular weakness. In other words, contractures and fixity of the limbs in arthrogryposis are the result of immobility of the developing joints, consequent upon muscle weakness during fetal development. Most often the cause is a loss or failure of development of anterior horn cells, as in Werdnig-Hoffman disease, but the abnormality may be in the nerve roots, peripheral nerves, or motor end plates, which paralyzes groups of muscles, or in the muscle itself. The *rigid spine syndrome* in children is yet another form of fibrous contracture, due presumably to an unusual axial muscular dystrophy.

Topography or Patterns of Myopathic Weakness

In almost all the diseases under consideration, some muscles are affected and others spared, each disease displaying its own pattern.

Restated, the topography or distribution of involvement tends to be alike in all patients with the same disease. Thus, the pattern of weakness is a central diagnostic attribute of muscular disease as it is for the various diseases of the peripheral nervous system discussed in Chap. 46, but the configurations differ in important ways between disease of the muscles and of the nerves.

The following patterns of muscle involvement constitute a core of essential clinical knowledge in this field:

1. *Ocular palsies presenting more or less exclusively as ptosis, diplopia, and strabismus.* As a rule, primary diseases of muscle do not involve the pupil, and in most instances their effects are bilateral. In lesions of the third, fourth, or sixth cranial nerves, the neural origin is disclosed by the pattern of ocular muscle palsies, abnormalities of the pupil, or both. When weakness of the orbicularis oculi (muscles of eye closure) is added to weakness of eye opening (levator palpebrae; ptosis), it nearly always signifies myasthenia gravis and occasionally, a rare primary disease of muscle (progressive external ophthalmoplegia).

The most frequent causes of *subacute and chronic development of relatively pure* affection of the muscles of eye movement are myasthenia gravis, progressive external ophthalmoplegia, oculopharyngeal muscular dystrophy, and exophthalmic (hyperthyroid) ophthalmopathy. In progressive external ophthalmoplegia, the muscles including the levators of the eyelids become paralyzed almost symmetrically over a period of years. This disorder has been shown in most cases to be a form of mitochondrial myopathy at times coupled with the Kearns-Sayre syndrome noted further on. Oculopharyngeal dystrophy involves primarily the levators of the eyelids and, to a somewhat lesser extent, other eye muscles and pharyngeal-upper esophageal striated muscles. It begins in middle or late adult life and later, and—like progressive external ophthalmoplegia—tends later to involve girdle and proximal limb muscles.

There are several other less common chronic myopathies in which external ophthalmoplegia is associated with involvement of other muscles or organs, namely, the congenital ophthalmoplegia of the Goldenhar-Gorlin syndrome (see Aleksic et al); the Kearns-Sayre syndrome (retinitis pigmentosa, heart block, short stature, generalized weakness, and ovarian hypoplasia); other congenital myotubular and mitochondrial myopathies; nuclear ophthalmoplegia with bifacial weakness (Möbius syndrome); and the myotonic dystrophy of Steinert. Rarely, eye muscle weakness may occur at a late stage in other dystrophies, such as the facioscapulohumeral type. Although not a regular feature of the disease, ophthalmoparesis can occur in the “reverse myasthenic” syndrome of Lambert-Eaton.

Acute bilateral ophthalmoplegia raises an entirely different set of diagnostic considerations. It may be an expression of the Fisher syndrome that consists of ophthalmoplegia, areflexia, and ataxia and of other variants of the Guillain-Barré syndrome, or of botulism, diphtheria, rarely tick paralysis, and of occlusion of the basilar artery or its branches.

Ptosis is variable in all of these conditions. When present in infantile myopathic disease, it is frequently a marker of the congenital myasthenic syndromes. Trichinosis is a rare cause, associated also with periorbital edema.

2. *Bifacial palsy presenting as an inability to smile, to expose the teeth, and to close the eyes.* Varying degrees of bifacial weakness are observed in myasthenia gravis, usually conjoined with ptosis and ocular palsies. However, weakness of facial muscles may on occasion be combined with myasthenic weakness of the masseters and other bulbar muscles without involvement of ocular muscles. Facial weakness and ptosis are features of myotonic dystrophy. More severe or complete facial palsy occurs in facioscapulohumeral dystrophy, sometimes presenting several years before weakness of the shoulder girdle muscles. Bifacial weakness is also a feature of certain congenital myopathies (centronuclear, nemaline, carnitine deficiency), Kennedy type of degenerative bulbospinal atrophy (prominent facial fasciculations), and the Möbius syndrome (in combination with abducens palsies).

More *acute and subacute bifacial palsies* are usually attributable to the Guillain-Barré syndrome, sarcoidosis, Lyme disease, tick paralysis, Melkersson-Rosenthal syndrome, AIDS, polymyositis (rare), neoplastic infiltration, or are part of a cranial polyneuritis of unknown cause, all of which have been discussed in preceding chapters. Rarely, “idiopathic” Bell’s palsy is simultaneously bilateral (it is more often sequential). Advanced scleroderma, Parkinson disease, or a pseudobulbar state can immobilize the face to the point of simulating myopathic or neuropathic paralysis, but always in a context that makes the cause obvious.

3. *Bulbar (oropharyngeal) palsy presenting as dysphonia, dysarthria, and dysphagia with or without weakness of jaw or facial muscles.* Myasthenia gravis is the most frequent cause of this syndrome and must also be considered whenever a patient presents with the solitary finding of a hanging jaw or fatigue of the jaw while eating or talking; usually, however, ptosis and ocular palsies are conjoined. Dysphagia and dysphonia may be early and prominent signs of polymyositis as well as inclusion body myositis and may appear in patients with myotonic dystrophy, due to upper esophageal atonia.

Combinations of these palsies are also observed as an *acute syndrome* in botulism, in brainstem stroke, and at the outset of the Guillain-Barré syndrome. Diphtheria and bulbar poliomyelitis are now rare diseases that may present in this way. Progressive bulbar palsy (motor neuron disease) may be the basis of this syndrome (page 940); the diagnosis is most obvious when the tongue is withered and twitching. Syringobulbia, basilar invagination of the skull, and certain types of Chiari malformation may reproduce some of the findings of bulbar palsy by involving the lower cranial nerves. Rare cases of hereditary progressive aphonia include the earlier mentioned X-linked Kennedy syndrome of bulbospinal atrophy (page 947).

Spastic bulbar paralysis, or pseudobulbar palsy, is readily distinguished by the presence of hyperactive facial and gag reflexes, lack of muscle atrophy, and the associated clinical findings (pages 426 and 450). One must also keep in mind restricted extrapyramidal diseases, such as Wilson disease and dystonias, that cause the mouth to be kept open and the face and bulbar musculature to appear immobile. The mechanism of swallowing and the ways in which it is disturbed are discussed in Chap 26.

4. *Cervical palsy presenting with inability to hold the head*

erect or to lift the head from the pillow ("hanging, or dropped, head" syndrome, "campocormia"). This is due to weakness of the posterior neck muscles and of the sternocleidomastoids and other anterior neck muscles. In advanced forms of this syndrome the head may hang with chin on chest unless the patient holds it up with his hands. There may be difficulty differentiating the condition from a dystonic anterocollis; in the latter there is palpable tonic spasm of the sternomastoid and posterior neck muscles.

This topographic pattern occurs most often in idiopathic polymyositis and inclusion body myositis in which case it is often combined with mild dysphagia, dysphonia, and weakness of girdle muscles. The same symptom may be a feature of motor neuron disease and is infrequently the presenting feature. Myasthenic patients commonly complain of an inability to hold up their heads late in the day; both flexors and extensors of the neck are found to be weak. Occasionally this pattern is observed in patients with nemaline rod myopathy.

There is in addition, a poorly defined local myopathic process of the cervical paraspinal muscles that has no distinguishing histopathologic or histochemical features and has accounted for many of the cases of neck extensor weakness that we have encountered. The latter condition is observed in elderly persons, mainly men. There is severe but relatively nonprogressive weakness of the neck extensors and only mild weakness of shoulder girdle and proximal arm muscles. Katz and colleagues suggest the designation "isolated neck extensor myopathy" in preference to dropped head syndrome. What has been referred to as a "bent spine" syndrome (for which the term *campocormia* has also been used) is probably the same entity and may follow after years of the condition affecting the neck, or it may surface independently. These conditions of cervical weakness are reviewed by Umapathi and colleagues.

The major types of progressive muscular dystrophy, when advanced, usually affect the anterior neck muscles severely. Syringomyelia, spinal accessory neuropathy, some form of meningoradiculitis, and loss of anterior horn cells in conjunction with systemic lymphoma or carcinoma may differentially paralyze the various neck muscles.

5. *Weakness of respiratory and trunk muscles.* Usually the diaphragm, chest, and trunk muscles are affected in association with shoulder and proximal limb muscles, but occasionally weakness of the respiratory muscles is the initial or the dominant manifestation of muscle disease. Selective involvement of the intercostal muscles and diaphragm, giving rise to dyspnea and diminished vital capacity usually first brings the patient to the pulmonary clinic. The main causes are motor neuron disease, polymyositis, myasthenia, and, far less often because of their rarity, glycogen storage disease (acid maltase deficiency) and congenital nemaline myopathy. Unilateral paralysis of the diaphragm may result from compression of the phrenic nerve in the thorax by tumor or aortic aneurysm; an idiopathic or postinfectious variety may be related to brachial plexitis (page 1165). The paravertebral muscles may be severely affected in some types of muscular dystrophy, but usually in association with pelvicrural and shoulder muscle weakness. Nocturnal dyspnea, sleep apnea, and respiratory arrest may occur, particularly in myasthenics and patients with glycogen storage my-

opathies. And, of course, respiratory failure may threaten life in severe myasthenia gravis and Guillain-Barré syndrome, as it can in poliomyelitis.

As a general rule, in the acute neuromuscular paralyses, the cervical and shoulder muscles and the diaphragm, all of which share a common innervation, show a similar degree of weakness. Asking the patient to count aloud a consecutive series of numbers on one maximal breath can help to detect this pattern of muscle weakness (less than 20 equates with a vital capacity at or below about 2 L). Paradoxical inward movement of the abdomen with inspiration is another sign of diaphragmatic weakness. Disorders of breathing and ventilation are discussed in Chap. 26 and in Chap. 46 in relation to Guillain-Barré syndrome.

6. *Bibrachial palsy and the dangling-arm syndrome.* Weakness, atrophy, and fasciculations of the hands, arms, and shoulders characterize the common form of motor neuron disease, namely, amyotrophic lateral sclerosis. Primary diseases of muscle hardly ever weaken these parts disproportionately. Rarely, a diffuse weakness of both arms and the shoulder muscles may occur in the early stages of Guillain-Barré syndrome, paraneoplastic disease, and amyloid polyneuropathy, in special forms of IgM-related paraproteinemic, or in inflammatory polyneuropathy (e.g., brachial neuritis), and in porphyric polyneuropathy. A lesion affecting the central portion of the spinal cord in the cervical region produces this same pattern, but then in association with loss of pain and thermal sensation in the upper limbs and shoulders, a problem that excludes disease of muscle. Trauma and infarction of the cord are the usual causes of this type of myopathy (we have seen two cases attributable to multiple sclerosis but this is most uncommon).
7. *Proximal limb-girdle palsies presenting as inability to raise the arms or to arise from a squatting, kneeling, or sitting position.* Polymyositis, inclusion body myositis, dermatomyositis, and the progressive muscular dystrophies most often manifest themselves in this fashion. The endocrine and the acquired metabolic myopathies (e.g., Cushing disease, hyperthyroidism, and steroid or statin administration) are also common causes. Proximal limb weakness is a common feature of myasthenia but almost always after the development of ocular or pharyngeal involvement. The childhood Duchenne, Becker, and limb-girdle types of dystrophy tend first to affect the muscles of the pelvic girdle, gluteal region, and thighs, resulting in a lumbar lordosis and protuberant abdomen, a waddling gait, and difficulty in arising from the floor and climbing stairs without the assistance of the arms. Facioscapulohumeral dystrophy affects the muscles of the face and shoulder girdles foremost and is manifest by incomplete eye closure, inability to whistle and to raise the arms above the head, winging of the scapulae, and thinness of the upper arms with preserved forearm bulk ("Popeye" effect). Certain early or mild forms of dystrophy may selectively involve only the peroneal and scapular muscles (scapuloperoneal dystrophy). In the milder forms of polymyositis, weakness may be limited to the neck muscles or those of the shoulder or pelvic girdles.

A number of other diseases of muscle may express themselves by a disproportionate weakness of girdle and proximal limb musculature. An intrinsic metabolic myopathy, such as the adult form of acid maltase deficiency and

- the familial (hypokalemic) type of periodic paralysis, may affect only the pelvic and thigh muscles. In a number of the congenital polymyopathies (central core, nemaline, myotubular, etc.), a relatively nonprogressive weakness affects girdle muscles more than distal ones. These are discussed in Chap. 52. Proximal muscles are occasionally implicated in progressive spinal muscular atrophy, as in the syndrome first described by Wohlfart and coworkers and by Kugelberg and Welander, which unfortunately adds to confusion in diagnosis.
8. *Bicrural palsy presenting as lower leg weakness with inability to walk on the heels and toes, or as paralysis of all leg muscles.* With the exception of rare but distinctive distal types of muscular dystrophy, this pattern is not due to myopathy. Symmetrical weakness of the lower legs is usually due to polyneuropathy, although peroneal, anterior tibial, and thigh muscles are often weakened in muscular dystrophy. Diabetic polyneuropathy or carcinomatous or lymphomatous radiculopathy may cause asymmetrical weakness of thigh and pelvic muscles, often with pain and little sensory change. Chronic inflammatory demyelinating polyneuropathy (CIDP) may do the same. In total leg and thigh weakness, one, of course, considers a spinal cord disease, in which case there is usually impaired sphincteric function of the bladder and bowel as well as loss of sensory perception below a certain level on the trunk. Motor system disease may begin in the legs, asymmetrically and distally as a rule, and affect them out of proportion to other parts. Thus the differential diagnosis of distal or generalized leg weakness involves more diseases than are involved in the restricted paralyses of other parts of the body.
- A pure quadriceps femoris weakness may be the expression of several diseases. If bilateral, it usually indicates a polymyositis, an early stage of inclusion body myositis (where it may also be unilateral or asymmetrical), or a restricted dystrophy. In thyrotoxic and steroid myopathies, the major effects are on the quadriceps muscles. If unilateral or bilateral with loss of patellar reflex and sensation over the inner leg, this condition is due most often to a femoral neuropathy, as occurs from diabetes, or to an upper lumbosacral plexus lesion. Injuries to the hip and knee cause rapid disuse atrophy of the quadriceps muscles. A painful condition of infarction of this muscle is seen in diabetic patients.
9. *Distal bilateral limb palsies presenting usually as foot drop with steppage gait (with or without pes cavus), weakness of all lower leg muscles, and later wrist drop and weakness of hands.* The principal cause of this syndrome is a familial polyneuropathy, mainly the group of peroneal muscular atrophies of Charcot-Marie-Tooth type or the hypertrophic polyneuropathy of Déjerine and Sottas (see Chap. 46). Chronic nonfamilial polyneuropathies, particularly paraproteinemic and inflammatory ones with motor conduction block and exceptionally some forms of familial progressive muscular atrophy and distal types of progressive muscular dystrophy (Gowers, Milhorat, Welander, and Miyoshi types) may also present in this way. In myotonic dystrophy, there may be weakness of the leg muscles as well as the forearms, sternocleidomastoids, face, and eyes. With these exceptions, the generalization that *girdle weakness without sensory changes is indicative of myopathy and that distal weakness is indicative of neuropathy* is clinically useful.
10. *Generalized or universal paralysis: limb (but usually not cranial) muscles, involved either in attacks or as part of a chronic persistent, progressive deterioration.* When acute in onset and *episodic*, this syndrome is usually a manifestation of familial hypokalemic or hyperkalemic periodic paralysis. One variety of the hypokalemic type is associated with hyperthyroidism, another with hyperaldosteronism (Chap. 54). Attacks of porphyric neuropathy and of Refsum disease have an episodic nature. Generalized paresis (rather than paralysis) that has an acute onset and lasts many weeks is at times a feature of a severe form of idiopathic or parasitic (trichinosis) polymyositis and rarely of the toxic effects of certain pharmaceutical agents, particularly those used to treat hypercholesterolemia. Idiopathic polymyositis and rarely inclusion body myositis may involve all limb and trunk muscles but usually spare the facial and ocular muscles, whereas the weakness in trichinosis is mainly in the ocular and lingual muscles. In infants and young children, a chronic and persistent generalized weakness of all muscles except those of the eyes always raises the question of Werdnig-Hoffman spinal muscular atrophy or, if mild in degree and relatively nonprogressive, of congenital myopathy or polyneuropathy. In these diseases of infancy, paucity of movement, hypotonia, and retardation of motor development may be more obvious than weakness. Arthrogryposis may be present at birth. As a rule, universal weakness of muscle does not occur in the muscular dystrophies.
- Widespread *ascending paralysis* (progressing from the arms to the legs), developing over a few days, with involvement of cranial (including ocular) muscles, is usually due to an inflammatory demyelinating or axonal polyneuritis (Guillain-Barré syndrome) and occasionally to porphyric or diphtheric polyneuropathy, tick paralysis, or severe hypophosphatemia. In a setting of a critical illness with multiple organ failure or sepsis, generalized weakness of variable degree may occur from either a neuropathy ("critical illness" neuropathy) or a severe and widespread myopathy that is thought to be caused by the use of high doses of corticosteroids, especially if there has been concomitant use of neuromuscular blocking agents. Certain generalized neuropathies evolve subacutely, and this may also be true in patients undergoing peritoneal dialysis for end-stage renal failure or with toxic exposure to certain heavy metals. An even more insidious onset and slow (months to years) progression of paralysis, atrophy, and fasciculation of limb and trunk muscles without sensory loss characterize motor system disease. Here the eye muscles are always spared. The Lambert-Eaton syndrome may cause a similar picture.
11. *Paralysis of single muscles or a group of muscles.* This is usually neuropathic, less often spinal or myopathic. Muscle disease does not need to be considered except possibly in certain instances of pressure-ischemic necrosis of muscle due to local pressure or infarction, as in so-called monoplegic alcoholic myopathy or in diabetic muscle infarction. Also, the weakness of inclusion body myositis has a preference for certain sites, specifically parts of the quadriceps, or of the forearm muscles, particularly the long finger flexors (flexor digitorum profundus).

From this exposition of the topographic aspects of weakness, one can appreciate that each neuromuscular disease exhibits a pred-

ilection for particular groups of muscles. Apart from these topographic patterns that suggest certain possibilities of disease and exclude others, diagnosis depends on additional features—the age of the patient at the time of onset and tempo of progression, the coexistence of medical disorders, and certain laboratory findings (serum concentrations of muscle enzymes, EMG, and biopsy findings) and genetic determinants also figure prominently in the delineation of muscle diseases.

Muscle Fatigue, Lack of Endurance, and Exercise Intolerance

As stated earlier in this chapter and in Chap. 24, fatigue is an abstruse symptom, always requiring analysis and interpretation. When not attended by manifest reduction in muscle power, it is usually nonmuscular in origin. It may, on medical investigation, prove to be a systemic manifestation of infection, metabolic or endocrine disorder, severe anemia, reduced cardiopulmonary function, or neoplasia. More often, when expressed as a feeling of poor endurance, weariness, and disinclination to undertake or sustain mental and physical activity, it is indicative of neurasthenia, a psychiatric manifestation common to states of chronic anxiety and depression or simply to boredom and lack of purpose. An elusive syndrome of lifelong exercise intolerance, often accompanied by muscle cramps during exercise, has been traced in a limited number of cases to mutations in the cytochrome b gene of the mitochondrial DNA (Andreu et al), and similar syndromes have been attributed to a deficiency of myoadenylate—but these are both rare. The subject of fatigue as a physiologic phenomenon and as a clinical feature of many psychiatric and medical diseases, including those that are predominantly myopathic, is considered fully in Chap. 24.

Muscle Tone

All normal muscles display a slight resistance to stretch even when fully relaxed. When stretched to their limit and released, they recoil, mainly because of the elasticity of the fibers and their connective tissue sheaths. In addition, the trunk and proximal limb musculature is intermittently or constantly activated in the maintenance of attitudes and postures. To relax—i.e., to completely disengage a muscle from all its natural activities—requires practice and seems increasingly difficult in the elderly, in whom it merges with oppositional, or paratonic, rigidity (“gegenhalten,” page 63).

A reduced innervation of muscle, atrophy, or loss of contracting fibers are causes of “hypotonia.” In infants this state has come to be accepted as a mark of neuromuscular disease; the infant is said to be “floppy.” For this reason, the assessment of muscle tone is of special importance in infants (the floppy baby), but the testing of strength at this age is difficult. Tone can be assessed by lifting the infant in a prone position; if the child is hypotonic, the head and legs cannot be supported against gravity and, therefore, dangle. Or, when held under the arms, the hypotonic infant slips through the examiner’s hands. André-Thomas and colleagues introduced the terms *passivité*, to refer to the amplitude of the flapping movement of the hand or foot when the limb is shaken, and *extensibilité*, to denote the reduced resistance of a relaxed muscle to slow passive stretch. In our opinion, these are but different ways of testing muscle tone. Diminution in tone is observed in infants suffering from Werdnig-Hoffman disease or the congenital myopathies as well as in those with a benign type of hypotonia; diminished tone may also be seen in sickly infants with a variety of systemic diseases. In

adults, hypotonia is a feature of many of the myopathies and neuropathies, all of which reduce the number of contracting motor units.

The finding of generalized excessive tone, apart from that observed as a consequence of extrapyramidal rigidity, is rare in infants. A purely myopathic form of hypertonia is difficult to substantiate (the exception being hypocalcemic tetany). Various types of disease may lead to fibrous contracture and arthrogryposis, as stated earlier. An axial myopathy is the basis of the rigid spine syndrome, as mentioned earlier. For the most part, the muscle stiffness syndromes are due to continuous overactivity of motor units, the extreme forms being the stiff-man and the Isaacs syndromes and several related conditions (Chap. 55).

Changes in Muscle Volume

Diminution or increase in muscle bulk stands as another feature of disease that can be observed in all except the most obese patients. There are, of course, innate differences in muscle development, a greater salience of muscle in the male than in the female, and differences due to use and disuse. In general, the relative size of muscles is a genetic trait; in some families, muscles, like the skeleton, are large and in others, small. Greatly increased size and strength of muscles (*hypertrophia musculorum vera*) is an inherited trait caused by a mutation in the myostatin gene. It also is observed in cultists devoted to bodybuilding (although, as a rule, they are exercising muscles that are large from birth); in congenital myotonia (circus freaks with phenomenal muscular development often have this condition); in instances of a rare pathologic cramp syndrome; in the Bruck-DeLange syndrome of congenital hypertrophy of muscle, athetosis, and mental retardation; and in some patients destined to develop muscular dystrophy. In some of the latter patients, the muscle enlargement is in reality a *pseudohypertrophy*, in which the increase in size is accompanied by weakness. Here large and small fibers are mixed with fat cells, which have replaced many of the degenerated muscle fibers; other muscles in the same patient are atrophied. Other dystrophies (Becker, Emery-Dreifuss) may also cause *pseudohypertrophy*. Rarely, we have seen it in amyloidosis, sarcoidosis, eosinophilic myositis, and certain of the congenital myopathies. Hypothyroidism is often accompanied by an increase in volume of certain muscles, at times pronounced enough to simulate the *hypertrophia musculorum vera*. Enlargement of muscles in only one limb may be due to an arteriovenous malformation, neurofibroma, or the Klippel-Trénaunay-Weber syndrome involving the nerve root. A single muscle may become hypertrophied after partial injury to its nerve root (see Mielke et al); this is seen most often in relation to disc compression or surgical injury of the S1 nerve root.

Denervation is almost invariably attended by atrophy. Lesions of the peripheral nerve or anterior horn cells, if complete, lead to a loss of bulk of up to 85 percent of the original volume within 3 to 4 months, although some shrinkage of muscle becomes evident before that time. The most severe degrees of atrophy are observed in the chronic polyneuropathies, motor system diseases, and muscular dystrophies. The distribution of the atrophy corresponds to the paresis. (There are rare and unexplained instances where muscle hypertrophy follows denervation.) Cachexia, malnutrition, male hypogonadism, panhypopituitarism, and lipodystrophy tend to reduce muscle bulk without a proportionate reduction in the power of contraction (*pseudoatrophy*). Of interest is the fact that a number of myopathic diseases result in severe weakness with little or no

atrophy; these are polymyositis, myasthenia gravis, periodic paralyses, steroid myopathy, hypothyroidism, and Addison disease.

Twitches, Spasms, and Cramps

Fascicular twitches of muscle at rest (fasciculations), if pronounced and combined with muscular weakness and atrophy, usually signify motor neuron disease (amyotrophic lateral sclerosis, progressive muscular atrophy, or progressive bulbar palsy); but they may be seen in other diseases that involve the gray matter of the spinal cord (e.g., syringomyelia or tumor) as well as in lesions of the anterior roots (e.g., protruded intervertebral disc) and in certain peripheral neuropathies. Widespread fasciculations may occur acutely with severe dehydration and electrolyte imbalance after an overdose of neostigmine or with organophosphate poisoning. Slow and persistent fasciculations, spreading in a wave-like pattern along the entire length of a muscle and associated with slight reduction in the speed of contraction and relaxation, are part of the syndrome of continuous muscular activity (page 1278). Fasciculations that occur with muscular contraction, in contrast to those at rest, indicate a state of heightened irritability of muscle; this may occur for no discernible reason or as a sequela of denervation that leaves muscle with some paralyzed motor units, so that during contraction small and increasingly larger units are not enlisted smoothly. Fasciculations of the facial muscles are typical of the Kennedy type of bulbospinal atrophy.

Benign fasciculations, a common finding in otherwise normal individuals, can be identified by the lack of muscular weakness and atrophy and by the smallness of the muscle fascicle involved and repetitive appearance in only one or two regions. The recurrent twitches of the eyelid or muscles of the thumb experienced by most normal persons are often referred to as “live flesh” or myokymia but are benign fasciculations of this type. Individuals with truly benign fasciculations have normal EMGs (i.e., they have no fibrillations) as demonstrated in a large series of such patients studied and followed for many years by Blexrud and colleagues.

Myokymia is a less common condition, alluded to earlier, in which repeated twitchings impart a rippling appearance to the muscle. Another form of rippling is familial and associated with an unspecified type of myopathy (Chap. 55).

Muscle cramps, despite their common occurrence, are a poorly understood phenomenon. They occur at rest or with movement (action cramps) and are frequently reported in motor system disease, tetany, dehydration after excessive sweating and salt loss, metabolic disorders (uremia and hemodialysis, hypocalcemia, hypothyroidism, and hypomagnesemia), and certain muscle diseases (e.g., rare cases of Becker muscular dystrophy and congenital myopathies). Gospe and colleagues have reported a familial (X-linked recessive) type of myalgia and cramps associated with a deletion of the first third of the dystrophin gene, which is implicated in Duchenne dystrophy; strangely, there was no weakness or evidence of dystrophy. Lifelong, severe cramping of undetermined type has also been seen in a few families. The dramatic Satoyoshi syndrome is characterized by continuous painful leg cramps and alopecia universalis.

Far more frequent than all these types of cramping, and experienced at one time or another by most normal persons, is the benign form (*idiopathic cramp syndrome*) in which no other neuromuscular disturbance can be found. Most often benign cramps occur at night and affect the muscles of the calf and foot, but they may occur at any time and involve any muscle group. Some pa-

tients state that cramps are more frequent when the legs are cold and daytime activity has been excessive. In others, the cramps are provoked by the abrupt stretching of muscles, are very painful, and tend to wax and wane before they disappear. The EMG counterpart is a high-frequency discharge. Although of no pathologic significance, the cramps in extreme cases are so persistent and so readily provoked by innocuous movements as to be disabling. Cramps of all types need to be distinguished from *sensations of cramp* without muscle spasm. The latter is a dysesthetic phenomenon in certain polyneuropathies.

Contrasted to cramp is the physiologic contracture, observed in McArdle disease and carnitine palmitoyl transferase deficiency, in which increasing muscle shortening and pain gradually develop during muscular activity. Unlike cramping, it does not occur at rest, the pain is less intense, and the EMG of the contracted muscle at the time is relatively silent.

Cramps are also to be distinguished from the disabling and progressive form of painful spasm of the axial and proximal muscles known as the already mentioned *stiff-man syndrome*; this appears to be a disease of the spinal interneurons (page 1279). Continuous spasm intensified by the action of muscles and with no demonstrable disorder at a neuromuscular level is a common manifestation of localized tetanus and also follows the bite of the black widow spider. These disorders must be differentiated from a rare but distinctive type of encephalomyelitis of unknown cause (“spinal neuronitis”), characterized by intense rigidity and myoclonic jerking of trunk and limbs and painful spasms evoked by tactile and other stimuli. The damage in this disease is thought to be mainly to spinal internuncial neurons, with disinhibition of anterior horn cells (Howell et al; see also page 1067). There may also be difficulty distinguishing cramps and spasms from the early stages of a dystonic illness and from tetanus.

All the aforementioned phenomena of cramping and pathologic activity of muscle fibers are elaborated in Chap. 55.

Palpable Abnormalities of Muscle

Altered structure and function of muscle are not accurately revealed by palpation. Of course, the difference between the firm, hypertrophied muscle of a well-conditioned athlete and the slack muscle of a sedentary person is as apparent to the palpating fingers as to the eye, as is also the persistent contraction in tetanus, cramp, contracture, fibrosis, and extrapyramidal rigidity. The muscles in dystrophy are said to have a “doughy” or “elastic” feel, but we find this difficult to judge. In the Pompe type of glycogen storage disease, attention may be attracted to the musculature by an unnatural firmness and increase in bulk. The swollen, edematous, weak muscles in acute rhabdomyolysis with myoglobinuria or severe polymyositis may feel taut and firm but are usually not tender. Areas of tenderness in muscles that otherwise function normally, a state called myogelosis, have been attributed to fibrositis or fibromyositis, but their nature has not been divulged by biopsy.

A tumorous or granulomatous mass may develop in part of a muscle or throughout a muscle, posing a series of special clinical problems discussed on page 1282.

Muscle Pain

Notably, few of the primary muscle diseases are painful. When pain is prominent and continuous during rest and activity, there will usually be evidence of disease of the peripheral nerves, as in al-

coeliac-nutritional neuropathy, or of adjacent joints and ligaments (rheumatoid arthritis, polymyalgia rheumatica). Pain localized to a group of muscles is a feature of torticollis and other dystonias. Pain tends not to be prominent in polymyositis and dermatomyositis but there are exceptions, as commented below.

Other familiar painful disorders are acute brachial neuritis (neuralgic amyotrophy), radiculitis, and Bornholm disease, or pleurodynia, but actually little is known of the cause of the pain in any of them. The same is true of the muscular discomfort that characterizes the early stages of Guillain-Barré syndrome and of paralytic poliomyelitis. Intense pain is a prominent complaint in most of the muscle spasm and cramp syndromes mentioned earlier. Pain tends to be more definite in polyneuritis, poliomyelitis, and polyarteritis nodosa than it is in polymyositis, various forms of dystrophy, and other myopathies. If pain is present in polymyositis, it usually indicates coincident involvement of connective tissues and joint structures. Hypothyroidism, hypophosphatemia, and hyperparathyroidism are other sources of a myalgic myopathy. Certain drugs produce muscle aches in susceptible individuals. They include the "statin" lipid-lowering drugs, clofibrate, captopril, lithium, colchicine, beta-adrenergic blocking drugs, penicillamine, cimetidine, suxamethonium, and numerous others (see the table in the review by Mastaglia and Laing). These myalgic states are considered further in Chap. 55.

There are probably a limited number of mechanisms of muscle pain. Prolonged and sustained contraction gives rise to a deep aching sensation. Contraction under ischemic conditions—as when the circulation is occluded by a tourniquet or from atherosclerotic vascular disease—induces pain; the pain of intermittent claudication is presumably of this type and is not accompanied by cramp. It is postulated that lactic acid or some other metabolite accumulates in muscles and activates pain receptors, but this is unproven. The delayed pain, swelling, and tenderness that occur after sustained exercise of unconditioned muscles are evidently due to fiber necrosis (Armstrong).

Having listed all these causes of proximal pains, all physicians are aware that arthritic and mundane musculoskeletal complaints are more common causes of discomfort in practice.

Nonmuscular Abnormalities in Muscular Diseases

Clinical studies have divulged the involvement of many organs in certain diseases formerly thought to be purely myopathic. Some of the nonmuscular abnormalities, such as dislocation of the hips in several of the congenital myopathies, are secondary to the inadequate action of immature muscles. More important is the evidence that an abnormal gene and a depletion or other abnormality of the gene product may affect many systems to such a degree that they assume diagnostic importance. For example, in congenital dystrophy of the Fukuyama type and in Duchenne and myotonic dystrophies, cerebral development may be impaired with resulting mental retardation. In congenital muscular dystrophy of the Walker-Warburg and the Santavuori types, there is maldevelopment of both eye and brain.

The cardiac musculature or conducting system is often damaged in Duchenne dystrophy, myotonic dystrophy, Emery-Dreifuss dystrophy, Friedreich ataxia, Kearns-Sayre disease, and other mitochondrial disorders; in carnitine deficiency; and in some other adult dystrophies. In addition, a myocarditis may be quite prominent in polymyositis.

The retinas, eighth nerves, and ovaries are simultaneously involved in fully developed cases of Kearns-Sayre disease, and the cerebellum and other parts of the CNS show pathologic signs in some of the other mitochondrial myopathies. In several of the mitochondrial diseases there are mild dysmorphic features of the cranium and face and there may be endocrine abnormalities (mainly diabetes). Highly arched palate, long face, protruding jaw, and dental malocclusion are features of nemaline myopathy and myotonic dystrophy. Testicular atrophy with azospermia and gynecomastia accompany the X-linked bulbospinal muscular atrophy described by Kennedy. Many other associations of myopathy with markers of systemic changes can be named and several are highly diagnostic.

DIAGNOSIS OF MUSCLE DISEASE

As already stated, the symptoms and signs of muscle disease are most helpful when considered in connection with the age of the patient at the time of onset, their mode of evolution and course, and the presence or absence of familial occurrence. Since many of these diseases are hereditary, a careful family history is important. Stated differently, the familial occurrence of a muscle disease practically always indicates a genetic causation. The pattern of inheritance has diagnostic significance, and, if genetic counseling or prenatal diagnosis is a consideration, a detailed genealogic tree becomes essential. Historical data may be insufficient; it is often necessary to examine siblings and parents of the proband. The molecular genetics and other genetic aspects of the heritable muscle diseases—subjects of intense interest in recent years—are discussed at appropriate points in the chapters that follow.

As also stated earlier, of importance from a diagnostic standpoint is the principle that primary diseases of muscle seldom if ever are the cause of acute, widespread paralysis. Paralytic states evolving over the period of a few days are usually due to the Guillain-Barré syndrome, less frequently to other neuropathies, and now very rarely to poliomyelitis; one must also consider certain spinal cord diseases (Chaps. 44 and 46). Nevertheless, there are exceptions, the most notable being disorders of neuromuscular transmission and myopathy in critically ill patients who have been exposed to high doses of corticosteroids. Botulinum toxin can paralyze muscles within a few hours by blocking ACh release, and rarely myasthenia gravis or a myasthenic syndrome related to aminoglycoside antibiotic therapy may develop over days or less. Also, in the rare disorder known as "thyroid storm," there may be the rapid evolution of widespread muscle weakness, the defect evidently in the contractile mechanism of the muscle fibers. Hypokalemic paralysis, as in hyperaldosteronism, and an attack of familial periodic paralysis—due to either hypo- or hyperkalemia—may come on within a few hours. Severe cases of toxic myopathy, especially those due to alcohol or to "statin" drugs can be at times quite severe and occasionally abrupt in onset. Finally, a paroxysm of myoglobinuria, due to an infection or a metabolic myopathy, especially if there has been unusually strenuous exertion, may be followed within hours by a rapidly developing paresis of limb muscles, usually in association with severe pain.

Thus the occurrence of acute paralysis raises the consideration more of neurologic than of myologic disease. In the relatively rare instances of acute generalized myopathy, diagnostic suspicions are confirmed by measurements of electrolytes, muscle enzymes (CK and aldolase), the appearance of myoglobin in the urine and by nerve conduction studies and needle electrode examination of mus-

cles. These are summarized in the review by Mastaglia and Laing and have been described in Chap 45.

In summary, the clinical recognition of myopathic diseases is facilitated by a prior knowledge of a few syndromes, of the age of the patient at the onset of the illness, of a familial occurrence of the same or similar illnesses, and of the medical setting in

which weakness evolves. A description of these syndromes and the diseases of which they are manifestations forms the content of the chapters that follow. Diagnostic accuracy is aided by the intelligent use of the laboratory examinations discussed in Chap. 45, particularly the muscle enzymes, electromyogram, and muscle biopsy.

CHAPTER 49

THE INFLAMMATORY MYOPATHIES

The discovery that striated skeletal muscle and cardiac muscle could be the sole targets of a number of infectious diseases came about during the era of the development of microbiology and occupied the attention of many prominent clinicians, including Osler. As these diseases were being characterized, however, a number of other inflammatory states affecting muscle were found for which there was no infectious cause. Later, an autoimmune mechanism was postulated, but even today this is not securely established. This group of idiopathic inflammatory myopathies figures so prominently in clinical myology that the authors feel justified in devoting a chapter to the subject. But first, the infections of muscle are described.

THE INFECTIVE FORMS OF POLYMYOSITIS

Included here are trichinosis, toxoplasmosis, parasitic and fungal infections, and a number of viral infections. The related but unclassifiable entity of sarcoid myopathy is addressed at the end of the chapter.

Trichinosis

This parasitic disease is caused by the nematode *Trichinella spiralis*. Its general features have been discussed in Chap. 32 (page 625). With respect to the myopathic aspect of the illness, the authors have been most impressed with the ocular muscle weakness, which results in strabismus and diplopia; with weakness of the tongue, resulting in dysarthria; and with weakness of the masseter and pharyngeal muscles, which interferes with chewing and swallowing. Any weakness of limb muscles is usually mild and more severe proximally than distally. However, the diaphragm may be involved, as well as the myocardium. The affected muscles are slightly swollen and tender in the acute stage of the disease. Often, there is conjunctival, orbital, and facial edema, sometimes accompanied by subconjunctival and subungual splinter hemorrhages. As the trichinae become encysted over a period of a few weeks, the symptoms subside and recovery is complete. Many, perhaps the majority, of infected patients are asymptomatic throughout the invasive period, and as much as 1 to 3 percent of the population in certain regions of the country will be found at autopsy to have calcified trichinella cysts in their muscles with no history of parasitic illness. Heavy infestations have been known to end fatally, usually from cardiac and diaphragmatic involvement. In these more massive infections, the brain also may be involved, probably by emboli that arise in the heart from an associated myocarditis.

Diagnosis Clinically, one should suspect the disease in a patient who presents with a puffy face and tender muscles. Eosinophilia is practically always present in the peripheral blood (>700 cells per cubic millimeter), although the sedimentation rate is often normal. The creatine kinase (CK) level is moderately elevated. A skin test

using *Trichinella* antigen is available but it is unreliable. The enzyme-linked immunosorbent assay (ELISA) blood test is more accurate but it becomes positive only after 1 or 2 weeks of illness. Biopsy of almost any muscle (usually the deltoid or gastrocnemius), regardless of whether it is painful or tender, is probably the most reliable confirmatory test. More than 500 mg of muscle may be required to demonstrate larvae, but smaller specimens will almost invariably show an inflammatory myopathy. Muscle fibers undergo segmental necrosis, and the interstitial infiltrates contain a predominance of eosinophils. This accounts for the edema, pain, and tenderness of heavily infested muscles. The capsules of the larvae gradually thicken in the first month of the infection, and then calcify. The electromyogram (EMG) may exhibit profuse fibrillation potentials, a phenomenon attributed on theoretical grounds to the disconnection of segments of muscle fibers from their motor end plates (Gross and Ochoa).

Treatment No treatment is required in most cases. In patients with severe weakness and pain, a combination of thiabendazole 25 to 50 mg/kg daily in divided doses for 5 to 10 days and prednisone 40 to 60 mg/day is recommended. Albendazole, in a single oral dose of 400 mg daily, is equally effective but is not available in the United States except by special request (from Smith Kline Beecham).

Recovery, as mentioned, is complete as a rule except in rare patients with cerebral infarcts. Other aspects of this infestation are discussed in Chap. 32.

Toxoplasmosis

This is an acute to subacute systemic infection due to the encephalitozoon *Toxoplasma gondii*. Most *Toxoplasma* infections in immunocompetent patients, which occur in up to 10 to 30 percent of the population, are asymptomatic, but there may be fever and varying degrees of involvement of the skin, lymph nodes, retina, myocardium, liver, brain, and muscle. In one such case, *Toxoplasma* organisms and pseudocysts were detected in skeletal muscle (Kass and Adams); wherever a parasitic pseudocyst had ruptured, there was focal inflammation. Some muscle fibers had undergone segmental necrosis, but this was not prominent (one contained the organism), accounting for the relative paucity of muscle symptoms. With the introduction of acquired immunodeficiency syndrome (AIDS), many more toxoplasmic infections, including those of skeletal muscle, are seen (Gherardi et al). However, physicians who see many cases of AIDS have indicated to us that a primary AIDS myopathy and treatment-related muscle diseases are more common (see later). Also in this population, brain infestation with *Toxoplasma* is many times more common than myositis.

The myopathy, which occurs in the context of fever, lymphopenia, and failure of other organs, consists of weakness, wasting, myalgias, and elevated CK levels. Presumably, the immunocompromised patient is unable to respond to protozoan infections, and

latent infections are reactivated. Sulfadiazine in combination with pyrimethamine or trisulfapyrimidine, which act synergistically against the toxoplasmic trophozoites, improves the muscle symptoms and reduces serum CK. Folic acid must be given in addition. The subject of AIDS and toxoplasmic infection is discussed more fully further on pages 623 and 644.

Other Parasitic and Fungal Infections of Muscle

Echinococcosis, cysticercosis, trypanosomiasis (Chagas disease), sparganosis, toxocariasis, and actinomycosis have all been known to affect skeletal muscle on occasion, but the major symptoms relate more to involvement of other organs. Only cysticercosis may first claim the attention of the clinical myologist because of a dramatic pseudohypertrophy of thigh and calf muscles. Hydatids infest the paravertebral and lumbar girdle muscles in 5 percent of cases and may lead to their enlargement. Coenurosis and sparganosis are causes of movable lumps in the rectus abdominis, thigh, calf, and pectoralis muscles. Protozoan infections of muscle—microsporidiosis, African and American trypanosomiasis—which occurred only rarely until a decade ago, are now being observed in immunodeficient (HIV-infected) individuals in endemic areas. The reader who seeks more details may refer to the chapter on parasitic myositis by Bunker.

Viral Infections of Muscle

HIV and HTLV-I Myositis Human immunodeficiency virus (HIV) and human T-lymphotropic virus type I (HTLV-I) have become increasingly common causes of viral myositis (Engel and Emslie-Smith). Moreover, it is widely believed that zidovudine (ZVD), a drug included in most regimens to treat HIV infections, may itself induce an inflammatory myopathy with myalgia and weakness (Dalakas et al). The frequency of this particular drug-induced myopathy is not altogether certain; in a one large multicenter trial of antiretroviral drugs there was no increase in myopathy in patients who were treated with ZVD or any other drug in its class (Simpson et al).

An inflammatory, and presumed infectious, myopathy (a polymyositis) can develop early in the course of HIV infection and may rarely be the initial manifestation. The pattern is like that of idiopathic polymyositis with painless weakness of the girdle and proximal limb muscles. Reflexes are diminished in most cases, but this is difficult to interpret in view of the high incidence of concomitant polyneuropathy. Serum CK is elevated and the EMG shows an active myopathy with fibrillations, brief polyphasic motor units, and complex repetitive discharges.

The myopathologic changes in AIDS are also like those of idiopathic polymyositis. Additionally, in some cases, electron microscopy discloses the presence of nemaline (rod) bodies within type 1 fibers, similar to those observed in the congenital form of nemaline of polymyopathy (page 1247). As implied earlier, the pathogenesis of the AIDS myopathy has not been firmly established since there is as yet scant evidence of a direct viral infection of the muscle fibers. An immune basis has been suggested in view of a response to corticosteroids, plasma exchange, and gamma globulin, comparable to the beneficial effects in the idiopathic variety of polymyositis. Corticosteroids in doses similar to those used in the treatment of idiopathic polymyositis are said to be effective in ame-

liorating the weakness but they entail special risks in immunocompromised patients.

The clinical and pathologic features of the ZVD-induced myopathy are much the same as those of HIV myopathy except that moderate pain is said to be characteristic of the drug-induced variety. The myopathy has been attributed to the mitochondrial toxicity of the drug, which may account for the presence of “ragged red” fibers in biopsy specimens. The onset of symptoms appears to be related to the sustained administration of high doses of the drug (1200 mg daily for a year or longer). Cessation or reduction in dosage of the drug diminishes the muscular discomfort within weeks, but strength recovers more slowly.

A myopathy due to human T-cell leukemia virus (HTLV-I) infection also simulates polymyositis in its clinical and histologic features. The illness occurs most often in endemic areas but is less common than the myopathy that is associated with the virus (page 1059).

To be distinguished from the HIV- and ZVD-related inflammatory myopathies is the severe generalized muscle wasting that characterizes advanced AIDS. Muscle enzymes are normal and strength is little affected, considering the loss of muscle bulk. Histologically, there is atrophy of type 2 fibers. The pathogenesis of this cachectic syndrome is uncertain; it has been attributed to a multiplicity of systemic factors, including circulating catabolic cytokines.

Other Viral Myopathies In most patients with pleurodynia (epidemic myalgia, Bornholm disease), muscle biopsies disclose no abnormalities and there is no clear explanation of the pain. However, group B Coxsackie virus has been isolated from striated muscle of patients with this disorder. Also, a necrotizing myositis has been suspected in a number of patients with influenza; under the electron microscope some muscle fibers have been reported to contain structures with the features of influenza virions. Malaise, myalgia, and slight weakness and stiffness were the clinical manifestations. Because of the myalgia, it is difficult to know how much of the weakness is only apparent. Recovery has been complete within a few weeks. In one patient with generalized myalgia and myoglobinuria, the influenza virus was isolated from muscle (Gamboa et al). These observations suggest that the intense muscle pain in certain viral illnesses might be due to a direct viral infection of muscle. However, there are many cases of influenza myalgia, mainly of the calves and thighs, such as those reported by Lundberg and by Antony and coworkers, in which it was not possible to establish that there was a muscular disorder at all. In the condition described as *epidemic neuromyasthenia* (benign myalgic encephalomyelitis, Icelandic disease)—in which influenza-like symptoms were combined with severe pain and weakness of muscles—a viral cause was postulated but an organism has never been isolated. The illness has been absorbed into the large and indistinct category of chronic fatigue syndrome (page 435).

Despite these ambiguities, viral myositis is an established entity in myopathology. Echo 9, adenovirus 21, herpes simplex, Epstein-Barr virus, and *Mycoplasma pneumoniae* have all been cited by Mastaglia and Ojeda and by others as causes of sporadic myositis with rhabdomyolysis in humans. In these infections the non-myopathic aspects of the disease usually predominate; in some of them, the evidence of invasion of muscle has not been fully substantiated since, in many instances, a nonspecific (Zenker-type) degeneration could have explained the muscle findings. The existence of a true postinfectious polymyositis is also unsettled.

IDIOPATHIC POLYMYOSITIS AND DERMATOMYOSITIS

These are relatively common diseases that affect primarily the striated muscle and skin and sometimes connective tissues as well. The term used reflects the tissues involved. If the inflammatory changes are restricted clinically to the striated muscles, the disease is called *polymyositis* (PM); if, in addition, the skin is involved, it is called *dermatomyositis* (DM), although the two diseases are now understood to be immunopathologically quite distinct. Either may be associated with a connective tissue disorder, in which case the designation called on is PM or DM with rheumatoid arthritis, rheumatic fever, lupus erythematosus, scleroderma, Sjögren syndrome, or mixed connective tissue disease, as the case may be. There is also an inconsistent relationship of these two diseases and systemic carcinoma, as discussed further on.

Both diseases have been known since the nineteenth century. Polymyositis was first described by Wagner in 1863 and 1887, and DM was established as an entity by Unverricht in a series of articles written from 1887 to 1891. A modern classification introduced in the monograph of Walton and Adams included categories associated with neoplasia and with connective tissue diseases. References to the original articles and a survey of the literature since that time can be found in the monograph of Kakulas and Adams and in the chapters on the PM and DM syndromes by Engel and colleagues.

It is mentioned here and emphasized further on that there is currently disagreement regarding the frequency of PM as an independent idiopathic entity. Amato and Griggs are of the opinion that most cases so classified are due to DM, inclusion body myopathy (IBM; also called inclusion body myositis), or related to a connective tissue disease. The current authors are not in agreement with this point of view and continue to see well-studied and convincingly documented cases of classic PM.

Polymyositis

This is an idiopathic *subacute or chronic and symmetrical weakness of proximal limb and trunk muscles without dermatitis*. The onset is usually insidious and the course progressive over a period of several weeks or months. It may develop at almost any age and in either sex; however, a majority of patients are 30 to 60 years of age, and a smaller group shows a peak incidence at 15 years. Females predominate in all age groups. A febrile illness or benign infection may precede the weakness, but in most patients the first symptoms develop in the absence of these or other apparent initiating events.

The usual mode of onset is with a mainly painless weakness of the proximal limb muscles, especially of the hips and thighs and to a lesser extent the shoulder girdle and neck muscles. Often, the patient cannot easily determine the time of onset of weakness. Certain actions—such as arising from a deep chair or from a squatting or kneeling position, climbing or descending stairs, walking, putting an object on a high shelf, or combing the hair—become increasingly difficult. Pain of an aching variety in the buttocks, calves, or shoulders is experienced by only about 15 percent of patients and often indicates a combination of PM and rheumatoid arthritis, tendonitis, or other connective tissue disorder.

When the patient is first seen, many of the muscles of the trunk, shoulders, hips, upper arms, and thighs are usually involved. The posterior and anterior neck muscles (the head may loll) and the pharyngeal, striated esophageal, and laryngeal muscles (dys-

phagia and dysphonia) may be involved as well. In restricted forms of the disease, only the neck muscles or quadriceps may be implicated. Ocular muscles are not affected except in the rare (but well-described) instances of both PM and myasthenia gravis. The facial, tongue, and jaw muscles are only occasionally affected, and the distal muscles, namely the forearm, hand, leg, and foot are spared in 75 percent of cases. The respiratory muscles are weakened to a minor degree, and in an exceptional case there may be dyspnea, the cause of which is revealed only by an intercostal muscle biopsy (Thomas and Lancaster). Occasionally the early symptoms predominate in one proximal limb before becoming generalized.

The muscles are usually not tender, and atrophy and reduction in tendon reflexes, though sometimes present, are initially less pronounced than they are in patients with chronic denervation atrophy or with inclusion body myopathy (see further on). When reflexes are disproportionately reduced, one must think of an additional process such as systemic cancer with PM and polyneuritis, or IBM (see further on), Eaton-Lambert syndrome, or other more obscure forms of neuromyositis. As the weeks and months pass, the weakness and muscle atrophy progress unless treatment is initiated. Without physical therapy, fibrous contracture of muscles eventually develops. Some elderly individuals with a particularly chronic form of the disease may present with severe atrophy and fibrosis of muscles; the response to treatment in such cases is poor.

In both PM and DM, there may be involvement of organs other than muscle. In a surprising number of our cases of PM (and DM), cardiac abnormalities have been observed and, in a small proportion of these, unexpected sudden death has occurred. The cardiac manifestations have taken the form of relatively minor electrocardiographic changes, but several patients have had arrhythmias with clinical consequences. Among the fatal cases, about half have shown necrosis of myocardial fibers at autopsy, usually with only modest inflammatory changes. Interstitial lung disease is another known association in a few cases. Its frequency ranges from 5 to 47 percent in different series (see further on, under "Laboratory Findings in PM and DM"), but the lower figure is probably correct. Exceptionally, there is a low-grade fever, especially if joint pain coexists, but, as often, fever is due to unrecognized aspiration pneumonia.

Dermatomyositis

The presentation of muscle weakness is similar to that of polymyositis but the denominative feature is a rash. Most often, the skin changes precede the muscle syndrome and take the form of a localized or diffuse erythema, maculopapular eruption, scaling eczematoid dermatitis, or an exfoliative dermatitis. Sometimes, skin and muscle changes evolve together over a period of 2 or 3 weeks or less. A characteristic form of the skin lesions are patches of a scaly roughness over the extensor surfaces of joints (elbows, knuckles, and knees) with varying degrees of pink-purple coloration. Also highly typical is a lilac-colored (heliotrope) change in the skin over the eyelids, on the bridge of the nose, on the cheeks, and over the forehead; it may include a scaly component. Itching may be a troublesome symptom in regions of the other skin eruptions. This distribution suggests that the skin changes reflect heightened photosensitivity: a predominance of rash over the neck and upper shoulders has been termed the *V sign*, while rash over the shoulders and upper arms, the *shawl sign*. Periorbital and perioral edema are additional common findings but mainly in more fulminant cases. Red, raised papules may be present over exposed sur-

faces such as the elbows, knuckles, and distal and proximal interphalangeal joints (Gottron's papules); these are particularly prominent in DM of childhood. Skin changes may be transient and in some instances are restricted to one or more patches of dermatitis. These sometimes evanescent and restricted skin manifestations are emphasized because they are frequently overlooked but provide the clues to distinguishing DM from PM. In the healing stage, the skin lesions leave whitened atrophic scars with a flat, scaly base.

In contrast to PM, DM affects children and adults about equally. Among adults, DM is more frequent in females whereas in childhood, males and females are affected equally.

Other signs of interest include periarticular and subcutaneous calcifications that are common in the childhood form. Signs of associated connective tissue disease are more frequent than in pure PM (see further on). The Raynaud phenomenon has been reported in nearly one-third of the patients and a similar number have dilated or thrombosed nailfold capillaries as commented later. Whether this signifies the presence of a concurrent connective tissue disease has never been clarified, but we consider that it does so. Others subsequently develop a mild form of scleroderma and an associated esophageal weakness may be demonstrated by fluoroscopy in up to 30 percent of all patients. The superior constrictors of the pharynx are then involved, but cineradiography may be necessary to demonstrate the abnormality.

Dermatomyositis of Childhood Idiopathic PM occurs in children, but less frequently than it does in adults. Indeed, some of the myositic illnesses in children tend to be relatively benign but otherwise do not differ from those in adults. Far more frequently, however, there is a distinctive syndrome, described by Bunker and Victor, which is also designated as dermatomyositis but differs in some respects from the usual adult form of the disease. In these children and adolescents there is a greater involvement of blood vessels in the connective tissue of multiple organs as well as in skin and muscle. As mentioned earlier, this childhood form of DM is equally distributed between the sexes. It begins, as a rule, with rather typical skin changes, accompanied by anorexia and fatigue. Erythematous discoloration of the upper eyelids (the previously described heliotrope rash), frequently occurring with edema, is another characteristic early sign. The erythema spreads to involve the periorbital regions, nose, malar areas, and upper lip as well as the skin over the knuckles, elbows, and knees. Cuticular overgrowth, subungual telangiectasia, and ulceration of the fingertips may be found. Capillary prominence in the nail beds and avascular regions in the cuticle are said to be characteristic (as mentioned earlier) and need to be sought with a magnifying lens or ophthalmoscope [these signs are also seen in the form of scleroderma termed *CREST* (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia)]. Symptoms of weakness, stiffness, and pain in the muscles usually follow but may be concomitant with or rarely precede the skin manifestations. The muscular weakness is generalized but always more severe in the muscles of the shoulders and hips and proximal portions of the limbs. A tiptoe gait, the result of fibrous contractures of flexors of the ankles, is a common later abnormality. Tendon reflexes are depressed or abolished, commensurate with the degree of muscle weakness. Intermittent low-grade fever, substernal and abdominal pain (like that of peptic ulcer), melena, and hematemesis from bowel infarction occur, the result of an accompanying systemic vasculitis.

The mode of progression of DM of childhood, like that of the adult form, is variable. In some cases, the weakness advances rap-

idly, involving all the muscles—including those of chewing, swallowing, talking, and breathing—and leading to total incapacitation. Perforation of the gastrointestinal tract from bowel infarction is often the immediate cause of death. In other patients there is slow progression or arrest of the disease process, and in a small number there may be a remission of muscle weakness. Flexion contractures at the elbows, hips, knees, and ankles and subcutaneous calcification and ulceration of the overlying skin, with extrusion of calcific debris, are common manifestations in the later stages of the disease.

Connective Tissue Diseases with Polymyositis and Dermatomyositis In both PM and DM, the inflammatory changes are often not confined to muscle but are associated with connective tissue diseases, such as rheumatoid arthritis, scleroderma, lupus erythematosus, or combinations thereof (mixed connective tissue disease); the same muscle changes are associated less often with the Sjögren syndrome (keratoconjunctivitis sicca, xerostomia). Conversely, in the aforementioned diseases, inflammatory muscle changes are frequently found, but in a small proportion of muscles and often asymptotically. The incidence of these relationships cannot be stated with precision. A true necrotizing-inflammatory myopathy has been reported in up to 8 percent of cases of lupus erythematosus (higher than in our experience) and an even smaller proportion of cases of systemic sclerosis, rheumatoid arthritis, and Sjögren syndrome. The treatment of rheumatoid arthritis with D-penicillamine is believed to increase the incidence of, or perhaps independently precipitate, PM and DM.

Also notable is the sporadic co-occurrence of myositis with other putative autoimmune diseases such as myasthenia gravis and Hashimoto thyroiditis, and, less often, with a monoclonal paraprotein in the blood.

In the so-called overlap syndromes that incorporate connective tissue disease and myositis, there is usually greater muscular weakness and atrophy than can be accounted for by the muscle changes alone. Inasmuch as arthritis or periarticular inflammation may limit motion because of pain, result in disuse atrophy, and also at times cause a vasculitic mono- or polyneuritis, the interpretation of diminished strength in these autoimmune diseases is not easy. Malaise, aches, and pains are common and attributable mostly to the systemic disease. Sometimes the diagnosis must depend on muscle biopsy, EMG findings, and measurements of muscle enzymes in the serum as later described. In these complicated cases, the myositis may accompany the connective tissue disease or occur many years later.

It is worth commenting that PM may occur during pregnancy and that rarely the fetus is affected (most often the fetus and neonate are normal) with elevated CK levels for months postpartum (Messina et al).

Carcinoma with Polymyositis or Dermatomyositis At one time this was a controversial subject and, in some respects, it remains so. The reported incidence of systemic malignancy with PM and DM has varied considerably from one series to another (see Engel et al and Buchbinder and Hill). In the large series of Sigurgeirsson et al, 9 percent of 396 patients with PM were found to have carcinoma, either at the time of diagnosis of the muscle disease or within 5 years of it. DeVere and Bradley reported that 29 percent of the overall group of DM patients had an associated carcinoma; this figure rose to 40 percent if the patient was over 40 years of age and to 66 percent if the patient was both male and over 40. This, however, is much higher than that reported in all other series,

including that from our own experience. The relationship between myositis and malignancy is not understood but nonetheless the connection appears valid, even if infrequent.

The neoplastic processes linked most often with myositis is lung and colon cancer in men and breast and ovarian cancer in women, however, tumors have been reported in nearly every organ of the body. In about half the cases, the PM or DM antedates the clinical manifestations of the malignancy, sometimes by 1 to 2 or more years, a duration that brings the association into question. The morbidity and mortality of patients with this combination is usually determined by the nature of the underlying tumor and its response to therapy. Occasionally, excision of the tumor is attended by remission of the myositis.

Laboratory Findings in PM and DM In the majority of patients with PM and DM, regardless of any clinical associations, serum levels of CK and other muscle enzymes such as aldolase, are elevated. Serum CK levels tend to be higher in PM than in DM because of the widespread single-fiber necrosis in the former (as described in the following section on pathologic changes). However, in DM, if there are infarcts in muscle or acute perifascicular degeneration, CK levels will be moderately elevated as well. The sedimentation rate may be normal or mildly elevated in both diseases.

It has been appreciated that many cases of PM and DM are associated with autoantibodies in the blood. Some of these are undoubtedly nonspecific markers of an autoimmune or inflammatory state but others may be of pathogenic significance. Tests for circulating rheumatoid factor or antinuclear antibody are positive in fewer than half of cases. A high titer of antinuclear antibody (ANA), in conjunction with elevated antiribonuclear antibodies, suggests the coexistence of systemic lupus or mixed connective tissue disease. It must be emphasized, however, that absent or low-titer ANA and a normal sedimentation rate do not exclude the diagnosis of PM—a fact that limits their diagnostic usefulness.

Of greater interest are the findings that almost one-half of patients with PM and DM in some series have antibodies against various cellular components of muscle, in particular, antibodies directed against cytoplasmic transfer ribonucleic acid (tRNA) synthetases (called anti-Jo1) or against the tRNA itself. These are fairly specific to PM and, to a lesser extent, to DM. The clinical disorders associated with these antibodies usually combine myositis and some combination of (1) interstitial lung disease, (2) arthritis, (3) Raynaud syndrome, and (4) thickening of the skin of the hands (“mechanic’s hands”). Following from the designation of the main type of antibody, these have been termed *synthetase syndromes*. Furthermore, an unexpectedly high proportion of cases of PM and DM show myositis-specific antibodies that are directed against a cytoplasmic ribonucleoprotein complex (the signal recognition particle, or SRP) or against a protein complex that is a nuclear helicase (Mi-2). The former is found in about 5 percent of cases of PM, DM, or IBM and in some series has carried a heightened risk of cardiac involvement. Other probably less specific antibodies are directed against constituents of a nucleolar protein complex (PM-Scl) and ribonucleoproteins (Ro/SS-A and La/SS-B). In our view, these various autoantibodies, with the possible exception of anti-Jo1, are not especially useful as primary diagnostic tools but they have a role in refining diagnosis. For example, a positive Jo-1 antibody precludes the diagnosis of inclusion body myopathy. As discussed later, the presence of these antibodies also underscores the role for the humoral immune system in the pathogenesis of PM and raises opportunities for investigation.

Myoglobinuria can be detected in the majority of patients with an acute necrotizing form of the disease provided that a sensitive immunoassay procedure is used.

The EMG is quite helpful in diagnosis but has been normal in about 10 percent of our cases even when many muscles are sampled. It discloses a typical “myopathic pattern,” i.e., many abnormally brief action potentials of low voltage, in addition to numerous fibrillation potentials, trains of positive sharp waves, occasional polyphasic units, and myotonic activity—all but the brief potentials actually reflecting minor degrees of denervation from damage to the terminal axons (see Chap. 45). These findings are most apparent in weak muscles and are almost always seen when proximal weakness is well developed, but they may be observed in clinically unaffected areas as well. Indolent and chronic cases in which fibrosis of muscle and wasting have supervened may show polyphasic units that simulate denervation-reinnervation changes, alongside myopathic motor units. The EMG is also helpful in choosing a muscle for biopsy sampling but care must be taken not to obtain tissue from precisely the same site as a recent EMG needle insertion.

As stated earlier, the electrocardiogram has been abnormal in many of our cases and this finding may suggest the need for vigilance regarding cardiac symptoms and arrhythmias.

The muscle biopsy, if taken from an affected muscle, usually demonstrates the typical pathologic changes, with the limitations described below. It remains the essential diagnostic test. MRI may also be helpful in the assessment of myositis. Abnormalities in T1 and T2 signal intensity define regions of increased water content and inflammation in muscle, and spectroscopic studies demonstrate regional deficits in energy production. While MRI techniques cannot at this time replace a biopsy for diagnosis, they can define the distribution of lesion and thereby aid in targeting the muscle biopsy as well as provide a useful index the efficacy of drug therapy and, in some cases, distinguish IBM from either PM or metabolic muscle disease (see Lodi et al and also Dion et al).

Pathologic Changes in PM and DM Because of the scattered distribution of inflammatory lesions, and destructive changes, only part (or none) of the complex of pathologic changes may be divulged in any one biopsy specimen. Because of this limitation, more than one site of biopsy is advisable in some cases.

The principal changes in idiopathic PM consist of widespread destruction of segments of muscle fibers with an inflammatory reaction, i.e., phagocytosis of muscle fibers by mononuclear cells and infiltration with a varying number of lymphocytes and lesser numbers of other mononuclear and plasma cells. Evidence of regenerative activity of muscle, mainly in the form of proliferating sarcolemmal nuclei, basophilic (RNA-rich) sarcoplasm, and new myofibrils, is evident in damaged regions. Many of the residual muscle fibers are small, with increased numbers of sarcolemmal nuclei. Some of the small fibers are found in clusters, the result of splitting of regenerating fibers. Either the degeneration of muscle fibers or an infiltration of inflammatory cells may predominate in any given biopsy specimen, though both types of change are in evidence at autopsy.

In a single section from a biopsy sample, there may be only necrosis and phagocytosis of individual muscle fibers without infiltrates of inflammatory cells, or the reverse may be observed. However, in serial sections, muscle necrosis is always shown to be near inflammatory infiltrates. Repeated attacks of a necrotizing myositis appear to exhaust the regenerative potential of the muscles,

so that fiber loss, fibrosis, and residual thin and large fibers in haphazard arrangement may eventually impart a dystrophic aspect to the lesions. For all these reasons the pathologic picture can be correctly interpreted only in relation to the clinical and other laboratory data. Guidelines for the interpretation of the muscle biopsy reflecting these comments, a critical step in correct diagnosis of the inflammatory myopathies, are given in the review by Dalakas and Hohlfeld.

In DM, there are several additional and distinctive histopathologic changes. In contrast to the evident necrosis of single-fibers of PM, DM is characterized instead by perifascicular muscle fiber atrophy (referring to changes at the periphery of a fascicle, for reasons noted below). Moreover, the inflammatory infiltrates in DM predominate in the perimysial connective tissue, whereas in PM they are scattered throughout the muscle and are most prominent in relation to the muscle fiber membrane and the endomysium. The muscle lesions in dermatomyositis of childhood are similar to those of the adult form, only greatly accentuated. In a biopsy sample, the diagnosis can be inferred from the perifascicular degeneration and atrophy of muscle fibers.

Even more distinctive in DM are changes of a vasculitic nature in the small intramuscular blood vessels. Endothelial alterations (tubular aggregates in the endothelial cytoplasm) and occlusion of vessels by fibrin thrombi are the main abnormalities. Occlusion of small vessels also involves the intrafascicular nerves, so that the affected muscle may show both zones of infarction and denervation atrophy. The same vascular changes underlie the lesions in the connective tissue of skin, subcutaneous tissue, and gastrointestinal tract. This small vessel vasculitis is not seen in PM. The perifascicular muscle fiber atrophy is probably a result of an ischemic process set up by capillary occlusion.

Etiology and Pathogenesis The cause of *idiopathic* PM and DM, as the term indicates, is unknown. All attempts to isolate an infective agent have been unsuccessful. Several electron microscopists have observed virus-like particles in muscle fibers, but their causative role has not been proved. A polymyositic illness has not been induced in animals by injections of affected muscle. Nevertheless, the notion that an autoimmune mechanism is operative in PM and DM is supported by the association of these disorders with a number of the more clearly established autoimmune diseases (myasthenia gravis, Hashimoto thyroiditis, scleroderma, Sjögren disease, rheumatoid arthritis, Waldenstrom macroglobulinemia, agammaglobulinemia, and the other connective tissue diseases mentioned earlier). Further evidence of an autoimmune nature is the presence of specific autoantibodies in nearly half of cases as described earlier.

Immunopathologic studies have partially substantiated an autoimmune mechanisms and suggested, in addition, that PM and DM can be distinguished from one another on the basis of their immunopathologic characteristics. In DM, immune complexes, IgG, IgM, complement (C3), and membrane-attack complexes are deposited in the walls of venules and arterioles, indicating that the immune response is directed primarily against intramuscular blood vessels (Whitaker and Engel; Kissel et al). Such a response is entirely lacking in PM (and in IBM, discussed further on). Engel and Arahata have demonstrated a difference between the two disorders on the basis of the subsets and locations of lymphocytes that make up the intramuscular inflammatory aggregates. In PM, there are a large number of activated T cells, mainly of the CD8 class, whereas B cells are sparse. Moreover, T cells, accompanied by macrophages enclose and invade nonnecrotic muscle fibers. In DM, very few

fibers are affected in this manner, and the percentage of B cells at all sites is significantly higher than it is in PM. Engel and Arahata interpreted these differences as indicating that the effector response in DM is predominantly humoral, whereas in PM the response is composed of cytotoxic T cells, clones of which have been sensitized to a yet undefined surface antigen on the muscle fiber.

Diagnosis This is secure if there is a subacutely evolving proximal weakness, typical changes in the muscle biopsy, EMG abnormalities of myopathic type with scattered fibrillation potentials, and elevated serum levels of CK. For DM, the finding of one of the typical dermato features is of great value. However, all these criteria have been satisfied in only half of our cases, even in those who are later shown to be responsive to corticosteroids (see later). One must, therefore, often accept the diagnosis when most of the criteria are met. Fever, pain beyond that attributable to arthritic involvement, or a greatly elevated sedimentation rate ($> 100 \text{ mm/h}$) suggest an alternative diagnosis. The distinction from IBM, discussed further on, can be difficult and depends to a large degree on the muscle biopsy. As mentioned earlier, there has been considerable discussion regarding the diagnostic criteria for the inflammatory myopathies; some of these issues and reservations about the frequency with which the diagnosis is made are articulated by Amato and Griggs. The main point of controversy has been the proposal that true PM is rare and greatly overdiagnosed (see van der Muelen et al), a notion with which we do not fully agree. In contrast, inflammatory myopathy coexists with numerous systemic diseases as discussed, and some authors consider it to be a syndrome rather than a disease.

The problem of determining which patients should have an extensive evaluation for a systemic malignancy and for connective tissue disease is a difficult one. Opinions vary on this point but we have adopted the practice of careful inspection of the chest x-ray on all patients and of undertaking a more extensive evaluation in patients over age 55 or in smokers of any age. The evaluation in the latter group includes chest and abdominal computed tomography scans, stool guaiac CA-125, CEA, etc. In patients with recent weight loss, anorexia, or other symptoms suggestive of malignancy we have included upper and lower endoscopy and even occasionally resorted to a body positron emission tomography scan.

The anti-Jo1 antibody test can be obtained in patients with interstitial lung disease or rheumatoid arthritis (it is not referable to an underlying cancer). A routine evaluation for the conventional connective tissue diseases is only necessary if there is clinical evidence to support such a diagnosis.

In addition to these issues we call attention to the following problems that have arisen repeatedly in connection with the *diagnosis of PM*:

1. *The patient with proximal muscle weakness incorrectly diagnosed as having progressive muscular dystrophy.* Points in favor of PM are (a) lack of family history; (b) older age at onset; (c) more rapid evolution of weakness; (d) evidence, past or present, of other connective tissue diseases; (e) high serum CK and aldolase values; (f) many fibrillation potentials on EMG; (g) marked degeneration and regeneration in muscle biopsy; and finally, if there is still doubt, (h) unmistakable improvement with corticosteroid therapy.
2. *The patient with a connective tissue disease (rheumatoid arthritis, scleroderma, lupus erythematosus, Sjögren syndrome) suspected of having PM in addition.* Pain in these conditions

- prevents strong exertion (algesic pseudoparesis). Points against the coexistence of myositis are (*a*) the inability to document weakness out of proportion to muscle atrophy, (*b*) normal EMG, (*c*) normal serum CK and aldolase, and (*d*) normal muscle biopsy except possibly for areas of infiltration of chronic inflammatory cells in the endomysial and perimysial connective tissue (interstitial myositis).
3. *When muscle pain is a prominent feature, polymyalgia rheumatica must be differentiated.* This syndrome is characterized by pain, stiffness, and tenderness in the muscles of the neck, shoulders, and arms and sometimes of the hips and thighs; even passive motion of the limbs causes pain because of the periarticular locus of this disease. A high sedimentation rate, usually above 65 mm/h, is a diagnostic feature but more typically the value is close to 100 m/h, levels higher than they are in myositis. Biopsy of the temporal artery frequently discloses a giant-cell arteritis. CK levels—and of course muscle biopsy—are normal. Rapid disappearance of pain with administration of small doses of prednisone is also diagnostic of polymyalgia rheumatica (see page 1281).
 4. *The patient with restricted muscle weakness.* Weakness or paralysis of the posterior neck muscles, with inability to hold up the head, restricted bilateral quadriceps weakness, and other limited pelvicrural palsies are examples. Most often, the head-hanging or head-lolling syndrome proves to be due to PM and the other syndromes to restricted forms of dystrophy or to motor neuron disease. Inclusion body myositis is the main alternative consideration in cases of neck or quadriceps weakness, particularly if the latter weakness is asymmetric; muscle enzymes in the serum are normal or slightly elevated. Electromyography and biopsy are helpful in diagnosis.
 5. *The patient with diffuse myalgia and fatigability.* Most such patients with diffuse myalgia and fatigability have proved to be neurasthenic or depressed and rarely myopathic. A few cases will be found to be due to a toxic myopathy, particularly from one of the statin class of drugs. Hypothyroidism, McArdle disease, hyperparathyroidism, steroid myopathy, adrenal insufficiency, hyperinsulinemia, and early rheumatoid arthritis must be ruled out by appropriate studies (these toxic and metabolic myopathies are discussed in Chap. 51). Features that virtually exclude a PM are (*a*) lack of reduced peak power of contraction and (*b*) normal EMG, serum enzymes, and muscle biopsy.
 6. *The muscle biopsy of the patient with a clinical picture of PM discloses a noncaseating granulomatous reaction consistent with sarcoid (see further on).*

Treatment Most clinicians agree that corticosteroids (prednisone, 1 mg/kg, as a single daily dose orally, or intravenously) are the first line of therapy for both PM and DM. The response to corticosteroids is monitored by careful testing of strength and measurement of CK (not by following the ESR). In patients who respond, the serum CK decreases before the weakness subsides; with relapse, the serum CK rises before weakness returns. Once recovery has begun, typically several weeks or longer, and the dosage may be reduced gradually toward 20 mg daily. It is then appropriate to attempt to control the disease with an alternate-day schedule with double this amount (i.e., prednisone, 40 mg every other day) in order to reduce the side effects of the drug. After cautious reduction of prednisone over a period of 6 months to a year or longer, the

patient can usually be maintained on doses of 7.5 to 20 mg daily, with the aim of eventual discontinuation of the drug. Corticosteroids should not be discontinued prematurely, for the relapse that may follow is often more difficult to treat than the original illness.

In acute and particularly severe cases, treatment may be facilitated by the use initially of high-dose “pulse” methylprednisolone (1 g infused over 2 h each day for 3 to 5 days). This form of treatment should be regarded as a temporary measure until oral prednisone becomes effective. Alternatively, or sometimes in tandem with this approach, intravenous immunoglobulin or plasma exchanges may be instituted. In *patients with DM* who respond poorly to corticosteroids and other immunosuppressants or are severely affected early on, the addition of intravenous immunoglobulin (IVIG) infusions often proves helpful—although several courses of treatment at monthly intervals may be required to achieve sustained improvement. In several controlled studies of small numbers of patients with DM, practically all showed improvement in muscle strength and in skin changes and a reduction in CK concentration, (see Dalakas; Mastaglia et al). PM has also been reported to respond favorably to treatment with IVIG, but the evidence is less firm. Further controlled studies are required to corroborate these reports and to establish, in both PM and DM, the optimal doses and modes of administration. It is noteworthy from our experience that IVIG has seldom been effective in PM or DM when used alone or as initial therapy.

Some patients who cannot tolerate, or are refractory to, prednisone may also respond favorably to oral *azathioprine* (150 to 300 mg/day), with care being taken to keep the white blood cell (WBC) level below about 3000 cells per cubic millimeter. Currently favored as an adjunct to steroids is *methotrexate* (5 to 10 mg/week in three divided oral doses, increased by 2.5 mg per week, to a total dose of 20 mg weekly). Methotrexate or azathioprine should generally be given along with the smallest effective doses (15 to 25 mg) of prednisone. Some clinicians favor, from the beginning, a combination of prednisone in low dosage and one of these immunosuppressant drugs, and this approach is generally necessary when systemic vasculitis or interstitial pneumonitis is coupled with DM. The steroid-sparing effects of azathioprine may also be useful in patients requiring long-term therapy. *Cyclophosphamide*, which is a useful drug in the treatment of Wegener granulomatosis, polyarteritis, and perhaps other vasculitides, is said to be of lesser value in PM, but several of our rheumatologist colleagues recommend it and we have seen good responses in adults. Mycophenolate mofetil has also been introduced and has allowed a reduction in steroid dose within several months in both PM and DM, according to a number of anecdotal reports. *Cyclosporine* has also been used in recalcitrant cases; it has few advantages over other immunosuppressive drugs and has a number of potentially serious side effects, including nephrotoxicity. Whole-body radiation is said to be helpful in a few drug-resistant cases, but the side effects should be considered.

Prognosis Except for patients with malignancy, the prognosis in adult PM and DM is favorable. Only a small proportion of patients with PM succumb to the disease, and then usually from a secondary pulmonary complication or from myocarditis as already mentioned. Several of our patients have had severe aspiration pneumonias as a result of their dysphagia. The period of activity of disease varies considerably but is usually around 2 years in both the child and adult. As indicated earlier, the majority improve with corticosteroid therapy, but many are left with varying degrees of weakness of the

shoulders and hips. Approximately 20 percent of our patients have recovered completely after association of steroid therapy, and long-term remissions have been achieved in about an equal number. The extent of recovery is roughly proportional to the acuteness and severity of the disease and the duration of symptoms prior to institution of therapy. Patients with acute or subacute PM in whom treatment is begun soon after the onset of symptoms have the best prognosis. In the series of DeVere and Bradley, in which patients were treated early, there was remission in over 50 percent of cases, whereas in the series of Riddoch and Morgan-Hughes, in which patients were treated more than 2 years after onset of the disease, the rate was considerably lower. These patients who have come to our attention after a long period of proximal weakness and with substantial muscle atrophy have not recovered well, although some improvement can be expected over years.

Even in patients with a coexistent malignancy, muscle weakness may lessen and serum enzyme levels decline in response to corticosteroid therapy, but weakness returns after a few months and may then be resistant to further treatment. As already stated, if the tumor is successfully removed, the muscle symptoms may remit but even this experience has not been uniform.

The overall mortality after several years ranges around 15 percent, being higher in childhood DM, in PM with connective tissue diseases, and, of course, with malignancy.

INCLUSION BODY MYOPATHY

Inclusion body myositis, or myopathy, is the third major form of idiopathic inflammatory myopathy and, depending on the care taken with histologic diagnosis, is found to be as common as PM and DM. Its defining features, the intracytoplasmic and intranuclear inclusions, were first described in 1965 by Adams and colleagues, who also drew attention to a number of clinical attributes now considered characteristic. By 1994, more than 240 sporadic cases and 59 familial ones had been recorded in the medical literature (Mikol and Engel), but the diagnosis is now made so frequently that this low number almost certainly reflects the misidentification of IBM as PM in the past. Garlepp and Mastaglia concluded that over one-third of cases of inflammatory myopathy, especially in men, are of this type. A set of clinical and pathologic diagnostic criteria for the disease has been proposed by Griggs and coworkers and are useful for research purposes.

The disease predominates in males (in a ratio of 3:1) and has its onset in middle or late adult life. Practically all instances occur sporadically but an unrelated inherited form, either autosomal recessive or dominant, is well known (Cole et al, Neville et al). Many, but not all of these forms of autosomal recessive IBM are caused by a mutation on chromosome 9p1-q1 (Argov et al, Eisenberg et al). An autosomal recessive distal myopathy with rimmed vacuoles (a central feature of IBM; see later) has also been described in Japan. The process has been shown to be allelic to the same 9p chromosomal abnormality which in turn gives rise to most cases of hereditary IBM. The mutation involves an unusual bifunctional protein that is both a kinase and an epimerase, defects of which reduce the number of sugar and sialic acid residues on muscle proteins. These chemical changes increase the susceptibility of the muscle membrane to injury, similar in a general way to the circumstances in the muscular dystrophies. One must express some skepticism about the validity of linking sporadic and familial cases on the basis of a single histopathologic finding (the inclusions).

Diabetes, any one of a variety of autoimmune diseases, and a

relatively mild polyneuropathy are associated in about 20 percent of the sporadic cases of IBM, but an association with malignancy or connective tissue disease has not been established.

Clinical Manifestations The illness is characterized by a steadily progressive, painless muscular weakness and atrophy, which may be generalized or affect the limbs selectively and often asymmetrically. Either the proximal or distal muscles may be affected, or the limbs may be involved more or less evenly. In about 20 percent of cases the disease begins with focal weakness of the quadriceps, finger or wrist flexors, or lower leg muscles on one or both sides and spreads to other muscle groups only after many months or years. Selective weakness of the flexor pollicis longus is a particularly characteristic pattern of involvement, and isolated quadriceps weakness or neck extensor weakness are other patterns that should bring the diagnosis to mind. The tendon reflexes are normal initially but diminish in about half the patients as the disease progresses. Interestingly, the knee jerks may be depressed or lost even without much in the way of quadriceps weakness; the opposite is true in PM, i.e., as a rule, the reflexes are spared until the quadriceps is extremely weak. Dysphagia is common (Wintzen et al), and some type of cardiovascular abnormality has been seen in a few cases but not with the frequency of changes in PM. The selective or asymmetric involvement of distal muscles may suggest the erroneous diagnosis of motor neuron disease.

The muscle weakness in familial IBM begins in early childhood and usually spares the quadriceps. Also, in the familial form, unlike in sporadic cases, the muscles lack inflammatory changes—for which reason the designation *familial IBM* is more appropriate.

Laboratory and Muscle Biopsy Features The CK is normal or slightly elevated, generally showing lower levels than in cases of PM with comparable amounts of weakness. EMG abnormalities are much like those found in PM as discussed earlier. In addition, a small proportion of IBM patients display a more frankly neuropathic EMG pattern, mainly with very numerous fibrillation potentials, particularly in the distal limb muscles.

The diagnosis ultimately depends on virtually diagnostic features in the muscle biopsy. There are structural abnormalities of muscle fibers and inflammatory changes. The latter are identical to but usually of lesser severity than those observed in idiopathic PM. (The infiltrating cells are mainly T cells of the CD8 type.) However, the denominative finding is of intracytoplasmic subsarcolemmal vacuoles and eosinophilic inclusions in both the cytoplasm and nuclei of degenerating muscle fibers. The vacuoles contain, and are rimmed by, basophilic granular material ("rimmed vacuoles"), a point of difference from the vacuoles seen inconsistently in PM. Special stains, notably Gomori trichrome, and extensive inspection of biopsy specimens are required to disclose these inclusions, for they are infrequent, widely dispersed, and easily overlooked. The inclusions are also congophilic, i.e., they stain positively for β -amyloid protein, the detection of which is enhanced by the use of fluorescence illumination (Askanas et al). As noted in subsequent chapters, similar inclusions are found in a number of other muscle diseases and are not in and of themselves diagnostic, especially without the destructive and mildly inflammatory changes. Also, the clinical context in which these other diseases occur usually cause little difficulty in identifying the inclusions as an ancillary and minor abnormality.

Ultrastructural studies show that the protein inclusion accumulates at or near foci of abnormal tubulofilamentous structures in

both the nuclei and cytoplasm. The nature of these diverse changes is obscure. The tubulofilamentous inclusions have suggested a viral origin, but one has never been isolated and serologic studies have failed to substantiate a viral causation except perhaps for one patient in whom adenovirus type 2 was isolated from a biopsy specimen (Mikol and Engel). No evidence has emerged to date to suggest an autoimmune mechanism, and the inflammatory component, although similar to PM, is thought to be possibly a secondary phenomenon as noted later.

Treatment Inclusion body myositis has not responded in any consistent fashion to treatment with corticosteroids or other immunosuppressive drugs. Indeed, the disease should be suspected in recalcitrant cases of apparent PM. Despite this, because a few patients improve slightly or cease worsening with steroids, a several-month trial is often recommended (Lotz et al). The level of CK and the degree of leukocyte infiltration of muscle often diminish with corticosteroid treatment despite a lack of clinical improvement. On this basis, Barohn and coworkers have suggested, as alluded to earlier, that the inflammatory response is not a primary cause of muscle destruction. Sayres and colleagues concluded in a review of 32 patients that low-dose methotrexate and corticosteroids may slow the progression of disease, but this regimen has not been widely adopted. In a few cases there has been brief improvement in response to IVIG, especially in the weakened muscles involved in swallowing, but the gains have been unsustained and serial histopathologic examinations have detected no change. Plasma exchange and leukocytapheresis have been tried, also with generally discouraging results. The disease in most patients is relentlessly progressive over many years, sometimes very slowly, and no method of treatment has altered the long-term prognosis. Sometimes, the process remains fairly restricted for up to a decade, thereby creating less disability than in cases that generalize.

OTHER INFLAMMATORY MYOPATHIES

Included under this heading are a large number of unrelated myositides and certain rare forms of focal myositis and relatively minor changes in muscle that occur in the course of inflammatory diseases of blood vessels or disseminated or systemic infections or curiously, with thymoma. Most of them do not warrant extensive consideration here but are described in detail in monographs devoted to muscle disease (see Banker). We are uncertain how to place the newly described and undoubtedly rare entity of myositis with abundant macrophage infiltration and aluminum hydroxide crystalline deposits. A type of fasciitis that is also characterized by pronounced infiltration of macrophages has been related to vaccinations that contain the aluminum compound, but the myositis is not related to this aforementioned entity (see Bassez et al).

Three inflammatory myopathic diseases, however, are quite distinctive and of interest to neurologists; (1) the eosinophilic myositis, fasciitis and myalgia syndrome, (2) orbital myositis, and (3) sarcoidosis of muscle.

Eosinophilic Myositis and Fasciitis This term has been applied to four separate and probably overlapping clinical entities: (1) eosinophilic fasciitis, (2) eosinophilic monomyositis (sometimes multiplex), (3) eosinophilic PM, and (4) the eosinophilia-myalgia syndrome.

Eosinophilic Fasciitis This condition, mistakable for PM, was originally reported by Shulman in 1974. He described two men

with a scleroderma-like appearance of the skin and flexion contractures at the knees and elbows associated with hyperglobulinemia, elevated sedimentation rate, and eosinophilia. Biopsy revealed greatly thickened fascia, extending from the subcutaneous tissue to the muscle and infiltrated with plasma cells, lymphocytes, and many eosinophils; the muscle itself appeared normal and the skin lacked the characteristic histologic changes of scleroderma. One of Shulman's patients recovered in response to prednisone.

The many reports that followed have fully substantiated and amplified Shulman's original description. The disease predominates in men, in a ratio of 2:1. Symptoms appear between the ages of 30 and 60 years in most cases and are often precipitated by heavy exercise (Michet et al). Initially there may be low-grade fever and myalgia, followed by the subacute development of diffuse cutaneous thickening and limitation of movement of small and large joints. In some patients, proximal muscle weakness and eosinophilic infiltration of muscle can be demonstrated (Michet et al). Repeated examinations of the blood disclose an eosinophilia in most but not all patients.

Usually, the disease remits spontaneously or responds well to corticosteroids. A small number relapse and do not respond to treatment, and some have developed aplastic anemia and a form of lympho- or myeloproliferative disease.

Eosinophilic Monomyositis Painful swelling of a calf muscle or, less frequently, some other muscle has been the chief characteristic of this disorder. A painful mass forms within the muscle. Biopsy discloses inflammatory necrosis and edema of the interstitial tissues; the infiltrates contain variable numbers of eosinophils. This disorder is typified by one of our patients—a young woman who developed such an inflammatory mass first in one calf and then, 3 months later, in the other. The response to prednisone in this patient was dramatic; the swelling and pain subsided in 2 to 3 weeks, and power of contraction was then found to be normal. When the connective tissue and muscle are both damaged, a chaotic regeneration of fibroblasts and myoblasts may occur, forming a pseudotumor mass that may persist indefinitely.

Eosinophilic Polymyositis Layzer and associates described a third form of eosinophilic disorder, which they classified as a true subacute PM. Their patients were adults in whom predominantly proximal weakness evolved over several weeks. The other features of the muscle disorder were also typical of PM except that the inflammatory infiltration was predominantly eosinophilic and the muscles were swollen and painful. Moreover, in each case the muscle disorder was part of a severe and widespread systemic illness typical of the *hypereosinophilic syndrome*. The systemic manifestations included a striking eosinophilia of the blood (20 to 55 percent of the white blood cells), cardiac involvement (conduction disturbances and congestive failure), vascular disorder (Raynaud phenomenon, subungual hemorrhages), pulmonary infiltrates, strokes, anemia, neuropathy, and hypergammaglobulinemia. There was a favorable response to corticosteroids in two patients, but in a third the outcome was fatal within 9 months. Layzer and coworkers noted that a lack of necrotizing arteritis distinguished this process from polyarteritis nodosa and Churg-Strauss disease. No infective agent could be isolated. An allergic mechanism seems a likely cause of the lesions, and in the present authors' view one cannot exclude an angitis as a cause of all of the lesions.

The last two of these previously mentioned syndromes (eosinophilic monomyositis and PM) have overlapping features, as shown by Stark's cases, in which a monomyositis was accompanied by several of the systemic features described by Layzer et al.

Eosinophilia-Myalgia Syndrome Beginning in 1980, a number of sporadic reports documented a lingering systemic illness characterized by severe generalized myalgia and eosinophilia of the peripheral blood following the ingestion of L-tryptophan. In late 1989 and early 1990, there occurred a massive outbreak of this eosinophilia-myalgia syndrome, as the illness came to be called. Over 1200 cases were reported to the Centers for Disease Control (Medsger), and we examined several of them. The outbreak was ultimately traced to the use of nonprescription L-tryptophan tablets supplied by a single manufacturer and contaminated by a ditryptophan-aminal of acetaldehyde (Mayeno et al).

The onset was relatively acute, with fatigue, low-grade fever, and eosinophilia (>1000 cells per cubic millimeter). Muscle pain and tenderness, cramps, weakness, paresthesias of the extremities, and induration of the skin were the main clinical features. A severe axonal neuropathy with slow and incomplete recovery was associated in some cases. Biopsies of the skin fascia, muscle, and peripheral nerve disclosed a microangiopathy and an inflammatory reaction in connective tissue structures—changes like those observed in scleroderma, eosinophilic fasciitis, and the *toxic oil syndrome*. The latter syndrome, caused by the ingestion of contaminated rapeseed oil (in Spain, 1981), gave rise to a constellation of clinical and pathologic changes that were similar if not identical to those caused by contaminated L-tryptophan (Ricoy et al; page 1134). The two toxins are also closely linked chemically.

The cutaneous lesions and eosinophilia of this syndrome responded to treatment with prednisone and other immunosuppressive drugs, but other symptoms did not. The severe axonal neuropathy in our patients has improved incompletely over several years, leaving one of our patients chairbound with severe distal atrophic weakness.

Acute Orbital Myositis Among the many cases of orbital inflammatory disease (pseudotumor of the orbit, page 234), there is a small group in whom the inflammatory process appears to be localized to the extraocular muscles. To this latter group the term *acute orbital myositis* has been applied. The abrupt onset of orbital pain that is made worse by eye motion, redness of the conjunctiva adjacent to the muscle insertions, diplopia caused by restrictions of ocular movements, lid edema, and mild proptosis are the main clinical features. It may spread from one orbit to the other. The erythrocyte sedimentation rate is usually elevated and the patient may feel generally unwell, but only rarely can the ocular disorder be related to a connective tissue disease or any other specific sys-

temic disease. Computed tomography and MRI have proved to be particularly useful in demonstrating the swollen ocular muscles or muscle and separating orbital myositis from the many other remitting inflammatory orbital and retro-orbital conditions (Dua et al). As a rule, acute orbital myositis resolves spontaneously in a matter of a few weeks or a month or two, although it may recur in the same or the opposite eye. Administration of steroids appears to hasten recovery.

Sarcoid Myopathy, Granulomatous Myositis, and Localized Nodular Myositis

Although there are undoubtedly examples of muscle involvement in patients with sarcoidosis, they seem to be less frequent and less certain than would appear from the medical literature. In some cases, sarcoid myopathy becomes evident as a slowly progressive, occasionally fulminant, painless proximal weakness. The CK and angiotensin-converting enzyme levels are elevated. Muscle biopsy discloses the presence of numerous noncaseating granulomas. It is important to note that such lesions may also be found in patients with sarcoidosis who have no weakness. Treatment with moderate doses of corticosteroids (prednisone, 25 to 50 mg daily) is usually effective in symptomatic cases, but an immunosuppressive agent such as cyclosporine may have to be given in addition if improvement is not evident in several weeks.

Much more puzzling have been cases of myopathy with the clinical features of idiopathic PM and the presence of noncaseating granulomas in the muscle biopsy but with no evidence of sarcoidosis of the nervous system, lungs, bone, skin, or lymph nodes. Such cases call into question the validity of a muscle granuloma as a criterion of sarcoidosis, but the matter cannot be settled until we have better laboratory tests than are now available. These cases are presently classified as *granulomatous myositis* and, if limited to one or a small group of muscles, *localized nodular myositis* (Cumming et al). We suspect that such lesions have several clinical associations. In one syndrome, described by Namba and colleagues, this type of myositis was combined with myasthenia gravis, myocarditis, and thyroiditis. The process has, on a few occasions, been associated with Crohn disease. Electron microscopy in some instances has disclosed muscle fiber invasion by lymphocytes, suggesting a cell-mediated immune reaction. Very rarely, a granulomatous myositis may complicate tuberculosis or syphilis.

CHAPTER 50

THE MUSCULAR DYSTROPHIES

The muscular dystrophies are a group of progressive hereditary degenerative diseases of skeletal muscles. The innervation of the affected muscles, in contrast to that of the neuropathic and spinal atrophies, is unaffected. Indeed, confirmation that these disorders originated in muscle came from the demonstration of intact spinal motor neurons, muscular nerves, and nerve endings in the presence of severe degenerative changes in the muscle fibers. In the last several decades final proof of this concept has come from the observations that genetic defects in the muscular dystrophies often involve genes that are expressed only in muscle. The symmetrical distribution of muscular weakness and atrophy, intact sensations, preservation of cutaneous reflexes, and a strong heredofamilial incidence are the characteristic features of this group and serve to set them apart on clinical grounds alone. The intensity of the degenerative changes in muscle and the cellular response and the vigor of the regenerative changes distinguish the dystrophies histologically and also have implications regarding their pathogenesis. The term *dystrophy* should, therefore, be reserved for the purely degenerative muscular disease of hereditary type and all other progressive diseases of muscle should be referred to as myopathies or polymyopathies. The latter category of more benign and relatively nonprogressive myopathies—each named largely on its special histopathologic appearance such as central core, nemaline, mitochondrial, and centronuclear diseases—present a greater difficulty in classification. Like the dystrophies, they are primarily diseases of muscle and are heredofamilial in nature; but they are placed in a separate category because of nonprogressive or slowly progressive course and their distinctive histochemistry and ultrastructure (Chap. 52).

The current clinical classification of the muscular dystrophies is based mainly on the distribution of the dominant muscle weakness, however, several of the classical types have retained their eponymic designations; hence: Duchenne-Becker, Emery-Dreifuss, and facioscapulohumeral, limb-girdle, oculopharyngeal, and distal types. To these are added myotonic dystrophy and a group of so-called congenital muscular dystrophies, usually severe in degree. The extraordinary depth of information regarding the molecular nature of the dystrophies is one of the most gratifying developments of modern neuroscience. The majority of the dystrophies are due to changes in structural elements of the muscle cell, mainly in its membrane, but other important categories are being identified, such as mutated messenger RNA. In keeping with the outlook expressed throughout the book, we adhere to a clinical orientation in describing the muscular dystrophies but make clear the idea that treatment in the future will be dominated by understanding of molecular mechanisms. A modern classification still separates the muscular dystrophies according to the traditional clinical types and their patterns of mendelian inheritance but also incorporates the nature and locus of the abnormal gene and the defective gene product. Each of the muscular dystrophies is subsequently described in accordance with this scheme.

Historical Background The differentiation of dystrophic diseases of muscle from those secondary to neuronal degeneration was an achievement of neurologists of the second half of the nineteenth century. Isolated cases of muscular dystrophy had been described earlier, but no distinction was made between neuropathic and myopathic disease. Thus, Little had described what appears to be Duchenne muscular dystrophy in lectures given at the Royal Orthopedic Hospital in 1843 and 1844. Meryon in 1852 gave the first clear description of progressive weakness and atrophy of muscle in young boys who, at autopsy, had an intact spinal cord and nerves—a fact that led him to postulate an “idiopathic disease of muscles, dependent perhaps on defective nutrition.” In 1855, the French neurologist Duchenne described the progressive muscular atrophy of childhood that now bears his name. However, it was not until the second edition of his famous monograph in 1861 that the “hypertrophic paraplegia of infancy” was recognized as a distinct syndrome. By 1868 he was able to write a comprehensive description of 13 cases and recognized that the disease was muscular in origin and restricted to males. Gowers in 1879 gave a masterful account of 21 personally observed cases and called attention to the characteristic way in which such patients arose from the floor (Gowers sign).

Leyden in 1876 and Möbius 1879 reported a nonhypertrophic form of disease that began in the pelvic girdle muscles and could affect both sexes. Erb, in 1891, crystallized the clinical and histologic concept of a group of diseases due to primary degeneration of muscle, which he called *muscular dystrophies*. The first descriptions of facioscapulohumeral dystrophy were published by Landouzy and Déjerine in 1894; of progressive ocular myopathy, by Fuchs in 1890; of myotonic dystrophy, by Steinert and by Batten and Gibb in 1909; of distal dystrophy, by Gowers in 1888, Milhorat and Wolff in 1943, Welander in 1951, and Miyoshi et al in 1986; and of oculopharyngeal dystrophy, by Victor, Hayes, and Adams in 1962.

In addition to these classic forms of dystrophy, a number of variant syndromes have come to light. Bramwell in 1922 described hereditary quadriceps myopathy; Dreifuss in 1961 and Emery in 1966 placed on record a sex-linked humeroperoneal dystrophy; and Seitz in 1957 distinguished a form of scapuloperoneal dystrophy with cardiomyopathy from the larger group of scapuloperoneal syndromes. References to these and other writings of historical importance can be found in the works of Kakulas and Adams, of Walton et al., and of Engel and Franzini-Armstrong (see References).

In the more recent history of the dystrophies, the most notable event has been the discovery by Kunkel, in 1986, of the dystrophin gene and its protein product. Since then there has been an extraordinary accumulation of molecular-genetic, ultrastructural, and biochemical information about the muscular dystrophies, which has greatly broadened our understanding of their mechanisms and causation. It has also clarified a number of uncertainties as to their

clinical presentations and has necessitated a revision of the older conventional classification.

Duchenne Muscular Dystrophy (Severe Generalized Muscular Dystrophy of Childhood) (See Table 50-1)

This is the most frequent and best known of the muscular dystrophies. It begins in early childhood and runs a relatively rapid, progressive course. The incidence rate is in the range of 13 to 33 per 100,000 yearly or about one in 3300 live male births in every part of the world. There is a strong familial liability since the disease is transmitted as an X-linked recessive trait, occurring predominantly in males. However, careful examination of their mothers will show slight involvement in as many as half of the so-called mutant cases, as pointed out by Roses and coworkers. Approximately 30 percent of patients have no family history of the disease and represent spontaneous mutations.

Very occasionally, a severe proximal muscular dystrophy occurs in young girls. This may have several explanations: The female may have only one X chromosome, as occurs in the Turner (XO) syndrome and that chromosome carries the Duchenne gene, or the so-called Lyon principle may be operative; i.e., there is inactivation of the unaffected paternal X chromosome allowing expression of the mutated Duchenne protein from the maternal chromosome in a large proportion of embryonic cells. It so happens that most childhood dystrophies in girls prove to be of an entirely different type that is not X-linked and is instead due to an auto-

somal recessive mutation causing a limb-girdle dystrophy as discussed further on.

Clinical Features Duchenne muscular dystrophy is usually recognized by the third year of life and almost always before the sixth year. Nearly half of the patients show evidence of disease before beginning to walk. Many of them are slightly backward in other ways (psychomotor retardation), and the muscle weakness may at first be overlooked. A greatly elevated creatine kinase (CK) may be the first clue. In another group of young children, an indisposition to walk or run normally at the expected time brings them to medical attention; or, having achieved these motor milestones, they appear to be less active than usual and are prone to falls. Increasing difficulty in walking, running, and climbing stairs, swayback, and waddling gait become ever more obvious as time passes. The iliopsoas, quadriceps, and gluteal muscles are involved initially; then the pretibial muscles weaken (foot drop and toe walking). Muscles of the pectoral girdle and upper limbs are affected after the pelvic-crural ones; the serrati, lower parts of pectorals, latissimus dorsi, biceps, and brachioradialis muscles are affected, more or less in the order mentioned.

Enlargement of the calves and certain other muscles is progressive in the early stages of the disease, but most of the muscles, even the ones that are originally enlarged, eventually decrease in size; only the gastrocnemii, and to a lesser extent the lateral vasti and deltoids, are consistently large, and this peculiarity may attract attention before the weakness becomes evident. The enlarged muscles have a firm, resilient ("rubbery") feel and as a rule are slightly

Table 50-1

Duchenne/Becker, Emery-Dreifuss, limb-girdle, and related major muscular dystrophies

INHERITANCE TYPE	GENE OR CHROMOSOME	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
<i>X-linked recessive</i>				
Duchenne/Becker	Dystrophin	1st	10–50 x	Proximal, then distal muscles Cardiac muscle
Emery-Dreifuss	Emerin	2nd–3rd	5 x	Proximal muscles, joint contractures Life-threatening cardiac arrhythmias
<i>Autosomal dominant</i>				
LGMD 1A	Myotilin	3rd–4th	2 x	Distal greater than proximal weakness, vocal cords, pharynx
LGMD 1B	Lamin A/C	1st–2nd	3–5 x	Resembles Emery-Dreifuss disease Proximal muscles and heart, joint contractures
LGMD 1C	Caveolin-3	1st decade	4–25 x	Proximal muscles
LGMD 1D	6p	3rd–5th	2–4 x	Proximal muscles; cardiomyopathy
LGMD 1E	7q	1st	Nl	Proximal muscles
<i>Autosomal recessive</i>				
LGMD 2A	Calpain-3	1st–2nd	3–15 x	Proximal and distal muscles
LGMD 2B	Dysferlin	2nd–3rd	10–50 x	Proximal and distal muscles Allelic to Miyoshi myopathy
LGMD 2C–F	α , β , γ , δ -sarcoglycans	1st–3rd	5–40 x	Phenotype of Becker dystrophy
LGMD 2G	Telethonin	2nd	3–17 x	Proximal greater than distal muscles
LGMD 2H	TRIM32	1st–3rd	2–25 x	Proximal greater than distal muscles
LGMD 2I	Fukutin-related protein (FKRP)	1st–3rd	10–30 x	Proximal greater than distal muscles FKRP defects also cause CMD
LGMD 2J	Titin	1st–3rd	2 x	Proximal and sometimes distal muscles

CMD: childhood muscular dystrophy.

LGMD: limb-girdle muscular dystrophy.

N: normal.

less strong and more hypotonic than healthy ones (pseudohypertrophy). Rarely, all muscles are at first large and strong, even the facial muscles, as in one of Duchenne's cases ("Farnese Hercules"); histologically, this is a true muscle hypertrophy.

Muscles of the pelvic girdle, lumbosacral spine, and shoulders become weak and wasted, accounting for certain clinical peculiarities. Weakness of abdominal and paravertebral muscles accounts for a lordotic posture and protuberant abdomen when standing and the rounded back when sitting. Bilateral weakness of the extensors of the knees and hips interferes with equilibrium and with activities such as climbing stairs or rising from a chair or from a stooped posture. In standing and walking, the patient places his feet wide apart in order to increase his base of support. To rise from a sitting position, he first flexes his trunk at the hips, puts his hands on his knees, and pushes the trunk upward by working the hands up the thighs. In rising from the ground, the child first assumes a four-point position by extending the arms and legs to the fullest possible extent and then works each hand alternately up the corresponding thigh (the sign traditionally attached to Gowers' name). In getting up from a recumbent position, the patient turns his head and trunk and pushes himself sideways to a sitting position S. A. K. Wilson used an alliterative phrase to describe the characteristic abnormalities of stance and gait—the patient "straddles as he stands and waddles as he walks." The waddle is due to bilateral weakness of the gluteus medius. Many affected boys have a tendency to walk on their toes as a consequence of contractures in the gastrocnemii muscles. Calf pain is not infrequent. Weakening of the muscles that fix the scapulae to the thorax (serratus anterior, lower trapezius, rhomboids) causes a winging of the scapulae, and the scapular angles can sometimes be seen above the shoulders when one is facing the patient.

Later, weakness and atrophy spread to the muscles of the legs and forearms. The muscles that are selectively affected include the neck flexors, wrist extensors, brachioradialis, costal part of the pectoralis major, latissimus dorsi, biceps, triceps, anterior tibial, and peroneal muscles. The ocular, facial, bulbar, and hand muscles are usually spared, although weakness of the facial and sternocleidomastoid muscles and of the diaphragm occurs in the late stages of the disease. As the trunk muscles atrophy, the bones stand out like those of a skeleton. The space between the lower ribs and iliac crests diminishes with affection of the abdominal muscles.

The limbs are usually loose and slack, but as the disability progresses, fibrous contractures appear as a result of the limbs remaining in one position and the imbalance between agonists and antagonists. Early in the ambulatory phase of the disease, the feet assume an equinovarus position due to shortening of the posterior calf muscles, which act without the normal opposition of the pretibial and peroneal muscles. Later, the hamstring muscles become permanently shortened because of a lack of counteraction of the weaker quadriceps muscles. Similarly, contractures occur in the hip flexors because of the relatively greater weakness of hip extensors and abdominal muscles. This leads to a pelvic tilt and compensatory lordosis to maintain standing equilibrium. The consequences of these contractures account for the habitual posture of the patient with Duchenne dystrophy: lumbar lordosis, hip flexion and abduction, knee flexion, and plantar flexion. As they become severe, these contractures contribute importantly to the eventual loss of ambulation. Scoliosis, due to unequal weakening of the paravertebral muscles, and flexion contractures of the forearms appear, usually after walking is no longer possible.

The tendon reflexes are diminished and then lost as muscle

fibers disappear, the ankle reflexes being the last to go. The bones are thin and demineralized, and the appearance of ossification centers is delayed. Smooth muscles are spared, but the heart is usually affected. Various types of arrhythmia may appear. The electrocardiogram (ECG) shows prominent R waves in the right precordial leads and deep Q waves in the left precordial and limb leads, the result of cardiac fiber loss and replacement fibrosis of the basal part of the left ventricular wall (Perloff et al).

Death is usually the result of pulmonary infections and respiratory failure and, sometimes, of cardiac decompensation. These patients usually survive until late adolescence, and not more than 20 to 25 percent of patients live beyond the twenty-fifth year. The last years of life are spent in a wheelchair; finally the patient becomes bedfast.

Mild degrees of mental retardation, which is nonprogressive, are observed in many cases. The average IQ is 85 but the range has been 40 to 130. Approximately one-quarter have an IQ below 70.

As mentioned earlier, Roses and colleagues have studied the female carriers of the disease (i.e., the mothers of affected boys) and report a slight weakness and enlargement of the calves as well as elevated CK values and abnormalities of the electromyogram (EMG) and muscle biopsy—all slight in degree—in over 80 percent. A small number of female carriers manifest a moderate degree of myopathy that may mimic limb-girdle dystrophy (see further on). The muscle fibers of such patients (referred to as *manifesting* or *symptomatic* carriers) show a unique mosaic immunostaining pattern—some fibers containing dystrophin and others lacking it (Hoffman et al). This diagnostic information is particularly helpful in genetic counseling.

The serum CK values are 25 to 200 times normal, which, with the EMG and muscle biopsy findings, help to exclude a hereditary spinal muscular atrophy. The EMG shows fibrillations, positive waves, low-amplitude and brief polyphasic motor unit potentials, and, sometimes, high-frequency discharges. The female carrier may occasionally display the same abnormalities, but to a much milder degree.

The molecular and genetic bases of the disease are discussed further on.

Becker-Type Muscular Dystrophy

This well-characterized dystrophy is closely related to the Duchenne type. It had long been noted that mixed with the Duchenne group of cases were certain relatively benign ones. In 1955, Becker and Keiner proposed that the latter be separated as a distinct entity, now called Becker muscular dystrophy. Its incidence is difficult to ascertain, probably 3 to 6 per 100,000 male births. Like the Duchenne form, it is an X-linked disorder, practically limited to males and transmitted by females. It causes weakness and hypertrophy in the same muscles as the Duchenne dystrophy, but the onset is much later (mean age, 12 years; range, 5 to 45 years). While boys with Duchenne dystrophy are usually dependent on a wheelchair by early in the second decade, it is not uncommon for those with Becker dystrophy to walk well into adult life. We have for example encountered patients who served in the military with the disease undetected. If maternal uncles are affected by the disease and are still walking, the diagnosis is relatively easy. Mentation is usually normal. Cardiac involvement is also less frequent than in Duchenne dystrophy but there are cases that present with a cardiomyopathy, and we have been made aware of two brothers who had cardiac

transplantation before the disease was detected. Kuhn and associates have reported a genealogy in which early myocardial disease and cramping myalgia were prominent features.

Pathology of Duchenne and Becker Dystrophies In the early stages of Duchenne dystrophy, the most distinctive features are prominent segmental degeneration and phagocytosis of single fibers or groups of fibers and evidence of regenerative activity (basophilia of sarcoplasm, hyperplasia and nucleolation of sarcolemmal nuclei, and the presence of myotubes and myocytes). The necrosis excites a regenerative or restorative process, which explains the forking of fibers and clustering of small fibers with prominent nuclei. The necrotic sarcoplasm and sarcolemma are removed by mononuclear phagocytic (macrophage) cells. There may also be a few T lymphocytes in the region suggesting inflammation. The blood vessels are normal. There is a hyalinization of the sarcoplasm of many degenerating and nondegenerating fibers. In longitudinal sections, these are seen as "contraction bands," expressive of the irritability of dystrophic muscle. This phenomenon may be present before there is any significant degree of degeneration and is more extensive in Duchenne than in any of the other dystrophies. Eventually there are histologic changes that are common to all types of advanced muscular dystrophies: loss of muscle fibers, residual fibers of larger and smaller size than normal—all in haphazard arrangement, and the secondary reaction of an increase in lipocytes and fibrosis.

Hypertrophy of muscle is believed to be a result of work-induced enlargement of the remaining sound fibers in the face of adjacent fiber injury. But examples of true hypertrophy of entire muscles prior to the first sign of weakness may also occur and are difficult to explain. In these cases, large fibers may be present when at most there are only a few degenerating fibers. Pseudohypertrophy is due to lipocytic replacement of degenerated muscle fibers, but in its earlier stages the presence of many enlarged fibers contributes importantly to the enlargement of muscle, all secondary changes. Thus a true hypertrophy appears to give way to pseudohypertrophy. Smallness of residual fibers (possibly atrophy) is a prominent histologic feature. It is uncertain if this represents a gradual failure of cell metabolism and reduction in volume of all sarcoplasmic constituents or a stage in the regeneration of the damaged muscle fiber. The fibers do eventually degenerate and disappear, owing presumably to an exhaustion of regenerative capacity after repeated injuries or more and more extensive necrosis. In the late stage of the dystrophic process, only a few scattered muscle fibers remain, almost lost in a sea of fat cells. It is notable that the late or burned-out stage of chronic polymyositis resembles muscular dystrophy in that the fiber population is depleted, the residual fibers are of variable size, and fat cells and endomysial fibrous tissue are increased; lacking only are the hypertrophied fibers of dystrophy. This resemblance confirms that many of the typical changes of muscular dystrophy are nonspecific, reflecting only the chronicity of the myopathic process.

Etiology of Duchenne and Becker Dystrophies The most important development in our understanding of the Duchenne and Becker muscular dystrophies was the discovery by Kunkel of the abnormal gene on the X chromosome and of its gene product, *dystrophin* (Hoffman et al). The protein is expressed in skeletal, cardiac, and smooth muscle as well as in brain. The *dystrophin* gene is to date the largest one known, spanning more than 2 Mb of genomic DNA. This is the likely explanation for the observation

that one third of affected boys have a spontaneous mutation in the gene that is not inherited from their mother. The biochemical assay of dystrophin and its histochemical demonstration near the sarcolemma have made possible the accurate diagnosis of the Duchenne and Becker phenotypes and have clarified the relationship between these two disorders. Whereas dystrophin is absent in patients with the Duchenne phenotype, it is present but structurally abnormal in the Becker type. Moreover, phenotypes that fall between the classic Duchenne and Becker forms (intermediate or "outlier" cases) are characterized by a lower than normal amount of dystrophin. The Duchenne and Becker dystrophies and their intermediate forms are spoken of as *dystrophinopathies*.

A slightly different form of dystrophin, originating in a different part of the gene, is found in neurons of the cerebrum and brainstem and in astrocytes, Purkinje cells, and Schwann cells, at nodes of Ranvier (Harris and Cullen). A deficiency of the cerebral dystrophin may in some yet unexplained way account for the mild mental retardation. It will be interesting to learn how such a deficiency might impair brain development and whether there is any connection to some cases of mental deficiency without muscular dystrophy.

Figure 50-1 is useful in understanding the pathogenesis of the dystrophinopathies and certain of the limb-girdle and congenital dystrophies described further on. In normal skeletal and cardiac muscle, dystrophin is localized to the cytoplasmic surface of the sarcolemma, where it interacts with F-actin of the cytoskeleton (the filamentous reinforcing structure of the muscle cell). Dystrophin is also tightly bound to a complex of sarcolemmal proteins, known as dystrophin-associated proteins (DAPs), and glycoproteins (DAGs). Of special biologic importance in this complex are these two proteins and a 156-kDa glycoprotein called *dystroglycan*. The latter actually lies just outside the muscle cell and links the sarcolemmal membrane to the extracellular matrix (the inner portion of the basement membrane) by binding with merosin, a subunit of laminin. The dystrophin-glycoprotein complex functions in this scheme as a transsarcolemmal structural link between the subsarcolemmal cytoskeleton and the extracellular matrix. Moreover, all the associated membrane-binding proteins (adhalin, merosin, laminin) are implicated in specific muscular dystrophies, as discussed later in the chapter.

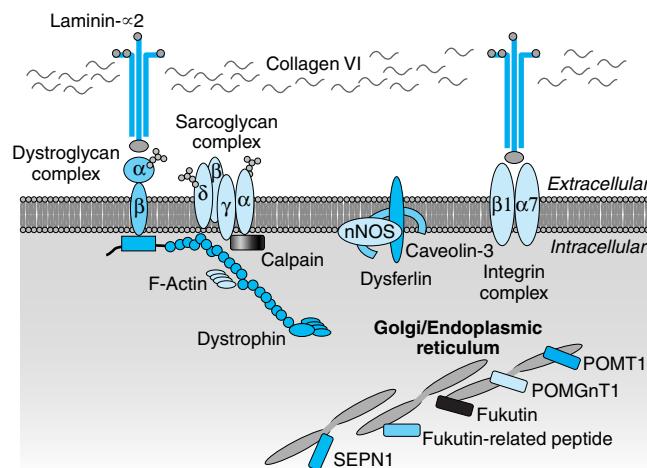

Figure 50-1. The molecular organization of the dystrophin-glycoprotein complex in the membrane and sarcolemma and endoplasmic reticulum-Golgi apparatus. These proteins are related to Duchenne, limb-girdle, Miyoshi, and certain congenital dystrophies. Details in text.

The loss of dystrophin leads to a parallel loss of DAPs and to disruption of the dystroglycan-protein complex. This change renders the sarcolemma susceptible to breaks and tears during muscle contraction—a hypothesis proposed first by Mokri and Engel and entirely consistent with the ultrastructural abnormalities that characterize Duchenne dystrophy. These authors demonstrated defects of the plasma membrane (sarcolemma) in a large proportion of nonnecrotic hyalinized muscle fibers, allowing ingress of extracellular fluid and calcium. The entrance of calcium is speculated to activate proteases and to increase protein degradation. The membrane defects and the associated alterations in the underlying region of the fiber represent the earliest and most basic pathologic change in Duchenne dystrophy and account for the leakage into the serum of CK and other enzymes of muscle.

Diagnosis The identification of dystrophin has made possible a number of highly refined tests for the diagnosis of Duchenne and Becker dystrophies, as well as for the carrier state. For example, analysis of the dystrophin gene in DNA obtained from white blood cells or from 50 mg of skeletal muscle can demonstrate the gene mutations in Duchenne and Becker patients and discriminate between these diseases with great accuracy. Also, immunostaining of muscle for dystrophies makes possible the differentiation of Duchenne, Becker, the carrier state, and other muscle disorders. An alternative method, developed by Byers and colleagues, employs an enzyme-linked immunosorbent assay (ELISA) to measure the dystrophin levels in muscle biopsy samples. This testing is a rapid and relatively inexpensive tool for establishing the diagnosis of Duchenne and Becker muscular dystrophies and distinguishing them from unrelated disorders.

Other Dystrophinopathies Refined testing for the dystrophin protein has also brought to light several much rarer types of dystrophin abnormalities. One, described by Gospe and coworkers, takes the form of a familial X-linked *myalgic-cramp-myoglobinuric syndrome*, resulting from the deletion of the first third of the dystrophin gene. The muscle changes are mild and relatively nonprogressive. Another dystrophinopathy takes the form of an *X-linked cardiomyopathy*, characterized by progressive heart failure in young persons without clinical evidence of skeletal muscle weakness; biopsy of skeletal muscle reveals reduced immunoreactivity to dystrophin (Jones and de la Monte). In yet another type, a glyceral-kinase deficiency is associated with varying degrees of adrenal hypoplasia, mental retardation, and myopathy.

Emery-Dreifuss Muscular Dystrophy

(See Table 50-1)

This is another X-linked muscular dystrophy, characterized by the special feature of muscle contractures, but relatively benign in comparison with the Duchenne type. It was described originally by Emery and Dreifuss and subsequently by Hopkins and by Merlini and their colleagues. The primary gene defect is a deficiency of the protein emerin, encoded by a gene on the X chromosome. Emerin is a constituent of the nuclear membrane (Fig. 50-2).

The age of onset varies from childhood to late adolescence or adulthood. Weakness affects first the upper arm and pectoral girdle musculature and later the pelvic girdle and the distal muscles in the lower extremities. A consistent and distinguishing feature of the disease is the early appearance of contractures in the flexors of the elbow, extensors of the neck, and posterior calf muscles. Facial

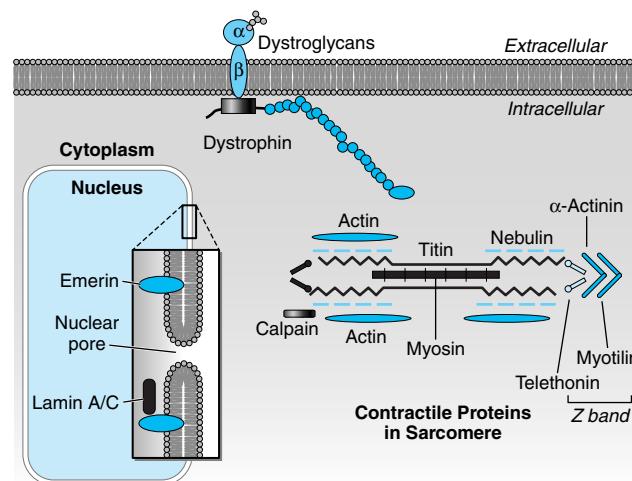

Figure 50-2. Expanded schematic of the nuclear and contractile proteins of the muscle. These proteins are referable to Emery-Dreifuss dystrophy and a number of the distal and the congenital dystrophies, as well as several of the limb-girdle dystrophies. Details in text.

muscles are affected occasionally. There is no hypertrophy or pseudohypertrophy, and mentation is unaffected. A severe cardiomyopathy with variable sinoatrial and atrioventricular conduction defects is a common accompaniment. The course of the myopathy is generally benign, more like that of Becker dystrophy, but weakness and contractures are severe in some cases, and sudden cardiac death is a not infrequent occurrence. For this reason, close monitoring by a cardiologist and the prophylactic insertion of a pacemaker at the appropriate time may be life-saving.

It has been proposed, but not proven, that the X-linked *scapuloperoneal muscular atrophy with cardiopathy* (Mawatari and Katayama) and the *X-linked scapuloperoneal syndrome* described by Thomas and coworkers (1972) are variants of Emery-Dreifuss dystrophy. The latter disorder, like Emery-Dreifuss dystrophy, is due to an abnormality of emerin. A *humeroperoneal myopathy* described by Gilchrist and Leshner is phenotypically much the same as the Emery-Dreifuss syndrome, though it is genetically distinct, being inherited as an autosomal dominant trait.

Facioscapulohumeral (FSH) Muscular Dystrophy (Landouzy-Déjerine Muscular Dystrophy) (See Table 50-2)

This is a slowly progressive dystrophy involving primarily the musculature of the face and shoulders, often with long periods of nearly complete arrest. The pattern of inheritance is usually autosomal dominant.

While less common than the Duchenne and myotonic dystrophies, this disease is not rare (an estimated yearly incidence rate of 5:100,000) and we see one or more new cases yearly. The age of onset is usually between 6 and 20 years but cases beginning in early adult life are occasionally encountered. As a rule, the first manifestations are difficulty in raising the arms above the head and winging of the scapulae, although in many cases bifacial weakness may have initially attracted attention, even in early childhood. There is involvement especially of the orbicularis oculi, the zygomaticus, and the orbicularis oris, whereas the masseters as well as the temporalis, extraocular, pharyngeal, and respiratory muscles

Table 50-2

Selected muscular dystrophies*

TYPE	GENE OR CHROMOSOME	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
Myotonic dystrophy	Expanded intronic CTG repeat in myotonin kinase	1st–2nd	1–2 x	Distal weakness, myotonia, cataracts Testicular atrophy, balding, cardiac arrhythmias
Proximal myotonic myopathy	Expanded intronic CCTG repeat in zinc finger protein	1st–2nd	1–2 x	Resembles myotonic dystrophy with prominent proximal muscle weakness but no infancy onset; less facial weakness
Facioscapulohumeral dystrophy	Multigene dysregulation at 4q telomere	1st–4th	1–2 x	Facial, scapular, anterior tibial muscles
Oculopharyngeal dystrophy	Exonic GCG expansion (alanine) in poly-A binding protein	6th–7th	1–2 x	Hearing loss, ocular telangiectasias
Bethlem myopathy	Collagen VI, subunits α 1-3	1st–3rd	1–4 x	Oculopharyngeal and levator palpebrae muscles Proximal weakness Contractures in fingers, elbows, knees May present as CMD

* All inherited in an autosomal dominant pattern.

CMD: childhood muscular dystrophy.

CCTG: cytosine, cytosine, thymine, guanidine.

CTG: cytosine, thymine, guanidine.

GCG: guanidine, cytosine, guanidine.

are spared. Weakness and atrophy of the involved muscles are the major physical findings; pseudohypertrophy occurs only rarely and is slight. There is an inability to close the eyes firmly, to purse the lips, and to whistle; the lips have a peculiar looseness and tendency to protrude. The lower parts of the trapezius muscles and the sternal parts of the pectorals are almost invariably affected. By contrast, the deltoids may seem to be unusually large and strong, an appearance that may be mistaken for pseudohypertrophy. The advancing atrophic process involves the sternocleidomastoid, serratus magnus, rhomboid, erector spinae, latissimus dorsi, and eventually the deltoid muscles. The bones of the shoulders become prominent; the scapulae are winged and elevated (“angel-wing” appearance), and the clavicles stand out. The anterior axillary folds slope down and out as a result of wasting of the pectoral muscles. Usually the biceps waste less than the triceps, and the brachioradialis muscles even less, so that the upper arm may be thinner than the forearm (“Popeye” effect). Pelvic muscles are involved later and to a milder degree, giving rise to a slight lordosis and pelvic instability. The pretibial muscles weaken, and foot drop is added to the waddling gait. Beevor’s sign, an upward movement of the umbilicus on flexing the neck due to weakness of the lower abdominal muscles, is reportedly common (Awerbuch et al) but we have not seen it in early cases.

Early in the disease, the muscular weakness may be asymmetrical (winging of only one scapula). Many of the patients with milder degrees of this form of dystrophy are unaware that they have the disease. This was true of nearly half of the very large series of patients described by Tyler and Stephens in the Utah Mormon population. At any point, the disease may become virtually arrested. Nevertheless, 15 to 20 percent of patients eventually require a wheelchair (Tawil et al).

An occasional feature of this group of diseases is the congenital absence of a muscle (one pectoral, brachioradialis, or biceps femoris) or part of a muscle in patients who later develop the typical features of FSH. Also, the external ocular muscles are known to occasionally become affected late in the illness. Cardiac involvement is rare, but in a few of the cases tachycardia, cardiomegaly,

and arrhythmias (ventricular and atrial extrasystoles) have occurred. Mental function is normal. Serum CK values are normal or slightly elevated.

At a molecular level, facioscapulohumeral dystrophy has been found to have a consistent association with deletions of variable size on the tip of chromosome 4q. This disorder is a consequence of alterations of a noncoding portion of DNA. It has been postulated that the deletions interfere with the expression of a gene or genes located proximal to the deletions (see Tawil et al) or that they alter the conformation of chromosome 4 within the nucleus, thereby affecting gene expression.

A variant in which only the shoulder and arm muscles are affected, sparing the face, and a form with bilateral foot drop are known (Krasnianski et al). In some cases, usually with severe deletions at the FSH locus on chromosome 4, there is an early onset and relatively rapid progression and an association with facial diplegia, sensorineural deafness, and, sometimes, exudative retinal detachment (Coats disease). Using fluorescein angiography, Fitzsimmons and others have found a variety of other retinal abnormalities—telangiectases, occlusion, leakage, and microaneurysms—in 56 of 75 persons with the usual form of facioscapulohumeral dystrophy, suggesting that these retinal abnormalities are an integral part of the disease. Other subtypes of FSH are linked to the same genetic site as the classic disease, including a face-sparing variant and a completely unexpected phenotype with progressive external ophthalmoplegia.

Scapuloperoneal Muscular Dystrophy

Beginning with Brossard in 1886, there were numerous reports of a distinctive pattern of progressive muscular weakness and wasting that typically involves the muscles of the neck, shoulders, and upper arms and anterior tibial and peroneal groups, causing foot drop. The nature of this disorder has been a matter of controversy, some writers claiming it to be a progressive muscular dystrophy and others, a muscular atrophy of spinal or neuropathic type. Probably both are correct in that either process can produce more or less the

same pattern of weakness. Davidenkow, who wrote extensively on this subject, described a form of familial scapuloperoneal weakness and atrophy associated with areflexia and distal sensory loss (a spinal-neuronopathic form), and others have confirmed these findings (see discussions of Thomas et al and of Munsat and Serratrice). Nevertheless, Thomas and colleagues (1975) firmly established the existence of a purely myopathic form. The onset of symptoms in their 6 patients was in early or middle adult life, with difficulty in walking due to bilateral foot drop; symptoms referable to scapulohumeral involvement came later. Progression was slow and none of the patients became severely incapacitated. Autosomal dominant inheritance seemed likely.

More recently, Wilhelmsen and associates have described a large family with autosomal dominant scapuloperoneal myopathy (14 affected persons in a 44-member pedigree). Onset was in early adult life with difficulty in walking and climbing stairs, due to foot drop, followed by weakness of the proximal arm muscles. In 3 individuals from this family, the disease was relentlessly progressive, but in the others it was relatively benign. In addition to the nonspecific histologic features of muscular dystrophy, some fibers contained eosinophilic hyaline inclusions and rimmed vacuoles. Linkage analysis has localized the gene to chromosome 12, proving that it is not simply an allelic variant of facioscapulohumeral or one of the other types of muscular dystrophy. It is now clear that there is some molecular heterogeneity in these cases, as other pedigrees link to chromosome 3.

Limb-Girdle Muscular Dystrophies (LGMD: Scapulohumeral and Pelvifemoral Muscular Dystrophies, Erb Dystrophy) (See Table 50-1)

There is a large group of patients with muscular dystrophy who do not fit into the Duchenne/Becker, facioscapulohumeral, or scapuloperoneal categories previously described. Children of both sexes in this group lack the hypertrophy of calves and other muscles; adults with late-onset forms have either pelvic or shoulder girdle involvement or both, and their facial muscles are spared. Insofar as Wilhelm Erb first called attention to these types of dystrophy, they were classified by Walton and Nattrass as the "limb-girdle dystrophies of Erb." This clinically based grouping has been problematic from the time it was proposed because, like the scapuloperoneal group, it is heterogeneous—the only unifying feature being the presence of limb-girdle weakness with sparing of the facial muscles. The inheritance has been variable, but the autosomal recessive forms are the most common. Either the shoulder girdle or pelvic girdle muscles may be first affected (traditionally these forms had been referred to as the Erb juvenile atrophic and Leyden-Möbius types, respectively). The weakness and atrophy may become evident during either late childhood or early adult life and spread from shoulders to hips or vice versa.

The later the onset of these disorders, the more likely that the course will be benign. In the latter group, while the EMG is myopathic, the CK values are only moderately elevated and may even be normal in the most chronic forms. Cardiac involvement is infrequent, and mental function is normal.

As indicated earlier, the status of this group of limb-girdle dystrophies as a clinical-genetic entity is being steadily eroded. The delineation of the progressive spinal muscular atrophies and the congenital and metabolic myopathies has considerably narrowed the category of limb-girdle dystrophies as originally described.

During the past decade, with the application of molecular genetic techniques, progress in this direction has accelerated greatly. At the time of this writing, at least 5 forms of autosomal recessive (LGMD type 2), 5 forms of autosomal dominant (LGMD type 1), and 10 forms of autosomal recessive (LGMD type 2) limb-girdle dystrophies have been defined—most with a distinct chromosomal locus and, 7 of them with an identifiable protein gene product that in most cases turns out to be a constituent of the muscle membrane (Bushby). This information is summarized in Table 50-1, and discussion of the better-characterized types follow.

Limb-Girdle Muscular Dystrophy 2I (Fukutin-Related Protein Mutation) The discovery of the "fukutin-related protein" initially came about because mutant forms cause a severe congenital muscular dystrophy. However, it became apparent that certain mutations also cause a common type of later-onset limb-girdle dystrophy. As the designation "2" indicates, it is transmitted in an autosomal recessive manner. In a series of 16 patients from 14 families, Poppe and colleagues have tried to characterize the main features. The onset of proximal girdle weakness occurs mainly in the second to fourth decades, but as early as age 2 years. The majority of patients eventually had respiratory failure and several had congestive heart failure, features that accompany some of the other limb-girdle dystrophies. In most other ways, this disease reflects the heterogeneity of clinical presentation of the other subtypes of limb-girdle disease. A period of stabilization or muscular power lasting several to 35 years is common, followed by a decade or more of progression that eventually involves the shoulder muscles. Most patients, particularly those with later onset, remained able to walk into their forties. Other features are variable, for example, dysphagia and ptosis; however, distal weakness is not seen and intelligence is normal.

The defective FKRP gene is located on chromosome 19q13.3. It is related in function to four other muscle genes including fukutin (hence its name). All five of these genes are glycosyl transferases that attach sugar groups to proteins such as alpha-dystroglycan. In all, the severity of the clinical phenotype is inversely related to the levels of glycosylation of alpha-dystroglycan. Defects in any of the five genes can cause developmental lesions in the brain in addition to muscle disease, although those associated with FKRP mutations are less common and less severe.

Severe Childhood Autosomal Recessive Muscular Dystrophy (SCARMD: Sarcoglycanopathy; LGMD 2C, D, E, and F; See Table 50-1) These entities comprise the best-defined group of limb-girdle dystrophy. Clinically they resemble severe Duchenne dystrophy in practically all respects, including the presence of calf hypertrophy, cardiomyopathy, and marked elevation of CK in the early stages of the illness. The obvious distinction from Duchenne dystrophy is the autosomal recessive pattern of inheritance (affecting of both girls and boys in the same sibship). The largest and best-studied group of this severe, recessive pelvic-pectoral dystrophy (99 children in 28 families), has come from Tunisia (Ben Hamida et al). It also occurs commonly in other Arab countries and has been observed repeatedly in Brazil and less so in Europe and North America.

The basic defect is in one of four dystrophin-associated glycoproteins (DAGs)— α -, β -, γ - and δ -sarcoglycan (see Fig. 50-1); α -sarcoglycan (designated 50 DAG) is also called adhalin, from the Arabic word *adhal*, meaning muscle. A primary deficiency of adhalin has been traced to a defective gene on chromosome 17q21 (Roberds et al). A primary defect in β -sarcoglycan (43 DAG) has

been mapped to chromosome 4q12, of γ -sarcoglycan (35 DAG) to the pericentromeric region of chromosome 13q, and of β -sarcoglycan (35 DAG) to chromosome 5q. Primary defects in 43 DAG or 25 DAG, may in addition lead to a deficiency of adhalin, but the latter is incomplete and represents a secondary effect, possibly explained by the proximity of the defective genes to the adhalin gene.

From a practical point of view, despite clinical similarities, there is usually no serious difficulty in distinguishing these dystrophies (formerly termed SCARMD) from a dystrophinopathy. In addition to the difference in inheritance, they can be readily diagnosed by showing a loss of sarcolemmal immunostaining for any of the dystrophin-associated glycoproteins but with preservation of staining for dystrophin itself. However, it is not possible on clinical grounds to distinguish one sarcoglycanopathy from another; this can be accomplished only by specific immunostaining.

Autosomal Recessive Muscular Dystrophy Linked to Chromosomes 15q and 2p (LGMD 2A and B; Calpain Mutation; See Table 50-1) These forms of limb-girdle dystrophy have been described in several large kindreds, in Indiana (among the Amish people), on the island of Réunion in the Indian Ocean, and in Brazil, affecting males and females equally. Both the shoulder and pelvic girdles are involved. The degree of weakness has varied considerably. In one form of the disease, called LGMD 2A, the abnormal gene codes for a calcium-activated neutral protease, or calpain. This “calpainopathy” is currently believed to account for about 40 percent of patients with LGMD. Frequently, and early in the course of disease, there are Achilles tendon contractures and very high serum CK levels (at least 10 times normal)—features that may permit distinction from the sarcoglycanopathies.

Yet another recessive limb-girdle dystrophy of slow progression has been identified in a Palestinian and Sicilian family and is due to a mutation in the gene for the protein dysferlin, which localizes to the muscle fiber membrane. Noteworthy is the fact that this same protein is involved in the distal form of Miyoshi muscular dystrophy described further on (page 1223). Early involvement of the gastrocnemius muscle (inability to walk on tiptoe) and extraordinarily high levels of CK, as in calpainopathy, are clues to the latter disease.

Autosomal Dominant Limb-Girdle Dystrophies (See Table 50-1) Several dystrophies with the LGMD phenotype are inherited as autosomal dominant traits. For example, LGMDA 1A is an autosomal dominant limb-girdle dystrophy of late onset that was described in a large North Carolina family (49 affected members in a pedigree of 218 persons). The mean age at onset was 27 years. Proximal leg weakness, with or without proximal arm weakness, and elevated CK values were the main clinical characteristics. Speer and colleagues have documented that the primary defect is in a gene encoding the protein *myotilin* (see Fig. 50-2).

LGMD 1B is a dominantly inherited disorder arising from mutations in the gene encoding the nuclear membrane protein *lamin A/C* (see Fig. 50-2). Mercuri and colleagues note that the phenotypes of these mutations vary widely. The muscle disorders range from severe cases that mimic congenital muscular dystrophy to milder ones with features of limb girdle dystrophy or Emery-Dreifuss muscular dystrophy. The diverse, nonmuscular manifestations of lamin A/C mutations include a cardiomyopathy, a form of lipodystrophy, a syndrome of accelerated aging (Hutchinson-Gilford progeria), and a recessively inherited axonal neuropathy.

Preceding these genetic findings, in 1976, Bethlem and van Wijngaarden described an autosomal dominant, early-onset limb-girdle dystrophy in 28 members of three unrelated Dutch families. Flexion contractures of the elbows, ankles, and interphalangeal joints of the fingers were present from the beginning stages of weakness but neither the weakness nor the contractures were disabling. Unlike Emery-Dreifuss dystrophy, contractures of the neck and spine were not present. Uniformity of clinical expression, slow progression with long periods of arrest, and normal longevity are other important features of the illness. Mohire and coworkers have proposed the designation *Bethlem myopathy*. A similar disease has now been reported from many parts of the world. Linkage analysis has assigned the gene locus of this myopathy to the subunits of a collagen gene on chromosomes 2 and 21. Another group of similarly affected Dutch families described by van der Kooi and coworkers also displayed an autosomal dominant pattern of inheritance. Clinically the latter dystrophy is much the same as described by Bethlem, except that more than half of the affected members develop abnormalities of cardiac rhythm in their later years necessitating pacemaker implantation. In contrast to the Bethlem cases, the gene abnormality is on chromosome 1q.

Progressive External Ophthalmoplegia (PEO: Ocular Myopathy of von Graefe-Fuchs, Kearns-Sayre Syndrome; See also page 843) This is a slowly progressive myopathy primarily involving and often limited to the extraocular muscles. Usually, the levators of the eyelids are the first to be affected, causing ptosis, followed by progressive balanced ophthalmoparesis. This disorder usually begins in childhood, sometimes in adolescence, and rarely in adult life (as late as 50 years).

Several variants of PEO have been described. The most common one arises from either deletions or point mutations in mitochondrial DNA; the deletions are associated with the Kearns-Sayre syndrome. This is a relatively uniform syndrome that comprises childhood ophthalmoplegia, pigmentary degeneration of the retina, varying degrees of heart block, short stature, and elevated CSF protein. However, it is clear that some cases of PEO are transmitted in a mendelian manner and thus are not of mitochondrial origin. Of these, some are mid- to late-adult onset and represent oculopharyngeal dystrophy (later). Another rare group are unusual cases of facioscapulohumeral dystrophy with extraocular muscle palsy.

However, when the foregoing PEO categories are eliminated there remains a distinctly different category of dominantly inherited PEO. Males and females are equally affected; the pattern of inheritance is autosomal dominant in some and recessive or uncertain in others. Once started, the disease progresses relentlessly until the eyes are motionless. Simultaneous involvement of all extraocular muscles permits the eyes to remain in a central position, so that strabismus and diplopia are uncommon (in rare instances one eye is affected before the other). The pupillary responses and accommodation are normal. As the patient attempts to raise his eyelids and to see under them, the head is thrown back and the frontalis muscle is contracted, wrinkling the forehead (hutchinsonian facies). The eyelids are abnormally thin because of atrophy of the levator muscles. The orbicularis oculi muscles are frequently involved in addition to the extraocular muscles. Thus, in progressive external ophthalmoplegia, as in myasthenia gravis and myotonic dystrophy, there can be a characteristic combination of weakness of eye closure and eye opening, a combination that is nearly always myopathic. Other facial muscles, masseters, sternocleidomastoids, deltoids, or peronei are variably weak and wasted in about 25 percent

of cases. The characteristic feature of progressive external ophthalmoplegia is that ptosis and ocular paralysis precede involvement of other muscles by many years.

Opinions had varied as to whether all cases of progressive external ophthalmoplegia should be assigned a myopathic origin. First, dystrophy and partial denervation of these muscles are difficult to distinguish on the basis of the biopsied eye muscle, as was pointed out by Ringel and associates. (Denervation of eye muscles does not result in a clearly visible grouped atrophy pattern.) The myopathic origin of some cases is proven by intactness of neurons in the brainstem nuclei and normality of the cranial nerves. Genetic studies have defined the molecular basis for some cases of the dominantly inherited PEO. Given that there is considerable clinical overlap between Kearns-Sayre syndrome and dominantly inherited PEO, it is not surprising that some of the dominantly inherited gene defects causing PEO result in disturbances in mitochondria DNA. Mutations in three nuclear genes have been implicated. (These are twinkle, a mitochondrial DNA binding protein; ANT1, an adenine nucleotide transporter in the intermembrane space in the mitochondrion; and POLG, a subunit of the mitochondrial DNA polymerase. There are also recessively inherited instances of familial PEO, one of which involves a nuclear gene.

Oculopharyngeal Dystrophy

(See Table 50-2)

Oculopharyngeal dystrophy is inherited as an autosomal dominant trait and is unique in respect to its late onset (usually after the 45th year) and the restricted muscular weakness, manifest mainly as a bilateral ptosis and dysphagia. E. W. Taylor first described the disease in 1915 and assumed that it was due to a nuclear atrophy (oculomotor-vagal complex). However, Victor and colleagues, in 1962, showed that the descendants of Taylor's cases had a late-life dystrophy (myopathic EMG and biopsy). One of the families described by Victor and Adams was subsequently traced by Barbeau through 10 generations to an early French-Canadian immigrant, who was the progenitor of 249 descendants with the disease. Other families showing a dominant (rarely recessive) pattern of inheritance and a number of sporadic cases have been observed in many parts of the world.

Associated with slowly progressive ptosis is difficulty in swallowing and change in voice. Swallowing becomes so difficult that food intake is limited, resulting in cachexia. The latter can be ameliorated by cutting the cricopharyngeus muscles and, failing this measure, by a gastrostomy or nasogastric tube. Later in the disease, in some families, the external ocular muscles and shoulder and pelvic muscles become weakened and atrophic to a varying extent. In the few autopsied cases, a loss of fibers of modest proportions was widespread in these and many other muscles. Rimmed vacuoles in the sarcoplasm and, by electron microscopy, intranuclear tubular filaments are characteristic but not specific histologic findings (these features are seen in several other myopathies, particularly in inclusion body myositis). The brainstem nuclei and cranial nerves are normal. As in the other mild and restricted muscular dystrophies, the serum CK and aldolase levels are normal, and the EMG is altered only in the affected muscles.

The gene product is a protein that binds to RNA (poly-A binding protein). The defect is an expansion of a string of alanines. Normally, there are six repeats; in dominantly inherited oculopharyngeal dystrophy, there are 8 to 13 glucagon repeats; in the recessively inherited form there are 7 repeats on each allele. Thus,

this represents one of the most subtle nucleotide expansion diseases yet discovered.

Myotonic Dystrophy (Dystrophia

Myotonica: See Table 50-2)

This is the most common adult form of muscular dystrophy. It was described in 1909 by Steinert, who considered it to be a variant of congenital myotonia (Thomsen disease; see Chap. 54), and, in the same year, by Batten and Gibb, who recognized it as a unique clinical entity. It is distinguished by an autosomal dominant pattern of inheritance with a high level of penetrance, special topography of the muscle atrophy, associated obvious myotonia, and occurrence of dystrophic changes in nonmuscular tissues (lens of eye, testicle and other endocrine glands, skin, esophagus, heart, and, in some cases, the cerebrum). Certain muscles—namely the levator palpebrae, facial, masseter, sternocleidomastoid, and forearm, hand, and pretibial muscles—are consistently involved in the dystrophic process. It is possible that Gowers' famous case of an 18-year-old youth with weakened and wasted anterior tibial and forearm muscles and sternocleidomastoids, in conjunction with paresis of the orbicularis and frontalis muscles, was an example of this disease, differing from the simple distal muscular dystrophy described later by Welander and others (see further on).

Despite some clinical variability of myotonic dystrophy, the defective gene has been the same in every population that has been studied. At this locus on chromosome 19q there is a specific molecular defect—an unstable trinucleotide sequence (CTG) that is longer in affected individuals than it is in healthy siblings or unaffected control subjects. Whereas healthy individuals will have 5 to 30 CTG repeats, patients with myotonic dystrophy have 50 to 2000. Longer sequences are associated with more severe disease, and increases in size through successive generations leads to earlier occurrence (genetic anticipation). The CTG repeats reside within the myotonin protein kinase gene. It is of considerable interest that these CTG repeating segments do not code for a protein (i.e., they are intronic), quite unlike conditions such as Huntington disease in which the triplet expansion codes for amino acid sequences within a protein. A critical element in the pathogenesis of this disease is the intranuclear accumulation of the expanded RNA sequences; these are believed to alter RNA binding proteins, thereby perturbing the expression of many genes.

Clinical Features In most instances of myotonic dystrophy the weakness and muscular wasting does not become evident until early adult life but it may present in childhood, usually with facial weakness and ptosis. Also, a severe, *neonatal (congenital)* form of the disease is well known and is described separately further on.

In the common early-adult form of the disease, the small muscles of the hands along with the extensor muscles of the forearms are often the first to become atrophied. In other cases, ptosis of the eyelids and thinness and slackness of the facial muscles may be the earliest signs, preceding other muscular involvement by many years. Atrophy of the masseters leads to narrowing of the lower half of the face, and the mandible is slender and malpositioned so that the teeth do not occlude properly. This—along with the ptosis, frontal baldness, and wrinkled forehead—imparts a distinctive physiognomy that, once seen, can be recognized at a glance (“hatchet” face). The sternocleidomastoids are almost invariably thin and weak and are associated with an exaggerated forward curvature of the neck (“swan neck”). Atrophy of the anterior tibial

muscle groups, leading to foot drop, is an early sign in some families.

Pharyngeal and laryngeal weakness results in a weak, monotonous, nasal voice. The uterine muscle may be weakened, interfering with normal parturition, and the esophagus is often dilated because of loss of muscle fibers in the striated as well as smooth muscle parts. Megacolon occurs in some patients. Diaphragmatic weakness and alveolar hypventilation, resulting in chronic bronchitis and bronchiectasis, are common late features, as are cardiac abnormalities; the latter are most often due to disease of the conducting apparatus, giving rise to bradycardia and a prolonged P-R interval. Patients with extreme bradycardia or high degrees of atrioventricular block may die suddenly; for such individuals, insertion of a pacemaker is often recommended (Moorman et al). Mitral valve prolapse and left ventricular dysfunction (cardiomyopathy) are less frequent abnormalities. In this disorder, as in Emery-Dreifuss dystrophy, careful assessment by a knowledgeable cardiologist is required.

The disease progresses slowly, with gradual involvement of the proximal muscles of the limbs and muscles of the trunk. Tendon reflexes are lost or much reduced. Contracture is rarely seen, and the thin, flattened hands are consequently soft and pliable. Most patients are confined to a wheelchair or bed within 15 to 20 years of the first signs, and death occurs before the normal age from pulmonary infection, heart block, or heart failure.

The phenomenon of *myotonia*, which expresses itself in prolonged idiomuscular contraction following brief percussion or electrical stimulation and in delay of relaxation after strong voluntary contraction, is the third striking attribute of the disease (the other two being the facial, ptotic and limb weakness, and the cardiac-autoimmune features). Not as widespread or severe as in myotonia congenita (Thomsen disease—see page 1265), it is, nonetheless, easily elicited in the hands and tongue in almost all cases and in the proximal limb muscles in half of the cases. Gentle movements do not evoke it (eye blinks, movements of facial expression, and the like are not impeded), whereas strong closure of the lids and clenching of the fist are followed by a long delay in relaxation.

Myotonia may precede weakness by several years. Indeed, Maas and Paterson have claimed that many cases diagnosed originally as myotonia congenita eventually proved to be examples of myotonic dystrophy. Of interest is the fact that in congenital or infantile cases of myotonic dystrophy, the myotonic phenomenon is not elicited until later in childhood, after the second or third year of life (see later). Moreover, the patient often becomes accustomed to the myotonia and does not complain about it. The relation of myotonia to the dystrophy is not direct. Certain muscles that show the myotonia best (tongue, flexors of fingers) are seldom weak and atrophic. Moreover, there may be little or no myotonia in certain families that show the other characteristic features of myotonic dystrophy. The muscle hypertrophy that is characteristic of myotonia congenita is not a feature of myotonic dystrophy.

The fourth major characteristic is the association of dystrophic changes in nonmuscular tissues. The most common of these are lenticular opacities, which are found by slit-lamp examination in 90 percent of patients. At first dust-like, they then form small, regular opacities in the posterior and anterior cortex of the lens just beneath the capsule; under the slit lamp they appear blue, blue-green, and yellow and are highly refractile. Microscopically, the crystalline material (probably lipids and cholesterol, which cause the iridescence) lies in vacuoles and lacunae among the lens fibers.

In older patients a stellate cataract slowly forms in the posterior cortex of the lens.

Mild to moderate degrees of mental retardation are not infrequent, and the brain weight in several of our patients was 200 g less than in normals of the same age. Late in adult life, some patients become suspicious, argumentative, and forgetful. In some families, a hereditary sensorimotor neuropathy may be added to the muscle disease (Cros et al).

Other nonspecific abnormalities, such as hyperostosis of the frontal bones and calcification of the basal ganglia, both readily discerned by CT scanning, seem to be more common in patients with myotonic dystrophy than they are in healthy persons.

Progressive frontal alopecia, beginning at an early age, is a characteristic feature in both men and women with this disease. Testicular atrophy with androgenic deficiency, reduced libido or impotence, and sterility are frequent manifestations. In some patients gynecomastia and elevated gonadotropin excretion are found. Testicular biopsy may show atrophy and hyalinization of tubular cells and hyperplasia of Leydig cells. Thus all the clinical characteristics of the Klinefelter syndrome may be present. However, the nuclei of skin or bone marrow cells only rarely show the "sex chromatin" mass (Barr body). The majority of patients have the usual sex chromatin constitution. Ovarian deficiency occasionally develops in the female patient but is seldom severe enough to interfere with menstruation or fertility. The prevalence of clinical or chemical diabetes mellitus is only slightly increased in patients with myotonic dystrophy, but an increased insulin response to a glucose load has proved to be a common abnormality. Numerous surveys of other endocrine functions have yielded rather little of significance.

In an extensive clinical experience with this form of dystrophy, we have been impressed with the variability of its clinical expression. In many patients, intelligence has been unimpaired and the myotonia and muscle weakness have been so mild that the patients were unaware of any difficulty. Pryse-Philips and associates emphasized these features in their description of a large Labrador kinship in which 27 of 133 patients had only a partial syndrome and only minor muscle symptoms at the time of examination.

Pathologic Features In addition to displaying most of the common findings of muscular dystrophy, there are several highly unusual myopathologic features. Peripherally placed sarcoplasmic masses and circular bundles of myofibrils (ringbinden) are common. Central nucleation may be marked. In many of the muscle spindles there is an excess of intrafusal fibers (particularly in the congenital form, see later). In addition, one observes necrosis of single muscle fibers and many atrophic fibers. Many of the terminal arborizations of the peripheral nerves are unusually elaborate and elongated. The spindle and nerve changes may be secondary to the myotonia or to an as yet poorly characterized associated terminal neuropathy.

Congenital Myotonic Dystrophy Brief reference was made earlier to this distinctive and potentially lethal form of myotonic dystrophy. Its not infrequent occurrence is evident from Harper's (1975) study of 70 personally observed patients and 56 others gathered from the medical literature. Profound hypotonia and facial diplegia at birth are the most prominent clinical features; myotonia, however, is notable for its absence. The drooping of the eyelids, the tented upper lip ("carp" mouth), and the open jaw impart a

characteristic appearance, which allows immediate recognition of the disease in the newborn infant and child. Difficulty in sucking and swallowing, bronchial aspiration (due to palatal and pharyngeal weakness), and respiratory distress (due to diaphragmatic and intercostal weakness and pulmonary immaturity) are present in varying degrees of severity; the latter disorders are responsible for a previously unrecognized group of neonatal deaths (24 such deaths among siblings of affected patients in Harper's study). In surviving infants, delayed motor and speech development, swallowing difficulty, mild to moderately severe mental retardation, and talipes or generalized arthrogryposis are common. Once adolescence is attained, the disease follows the same course as the later form. As stated earlier, clinical myotonia in the congenital form of the disease becomes evident only later in childhood, although EMG study may disclose myotonic discharges in early infancy. The diagnosis may be suspected by the simple test of eliciting myotonia in the mother. Electrocardiographic changes occur in one-third of the patients.

In the congenital form of this disease the affected parent is always the mother, in whom the disease need not be severe. Electrophysiologic testing will bring out the myotonia in the mother if it is evident on percussion of muscle. (In cases of adult onset, transmission is maternal or paternal.) These data suggest that in addition to inheriting the myotonic dystrophy gene, the congenital cases also receive some maternally transmitted factor, the nature of which is presently unknown. The prenatal diagnosis of myotonic dystrophy is readily accomplished by examination for CTG repeats in the amniotic fluid or in a biopsy of chorionic villi. However, it is not possible to predict whether a fetus with an expanded mutation will have congenital myotonic dystrophy or later onset myotonic dystrophy.

Proximal Myotonic Myopathy (PROMM; See Table 50-2) Under this name, Ricker and colleagues have described a myopathy characterized by autosomal dominant inheritance, proximal muscle weakness, myotonia, and cataracts. Seventeen families, containing 50 affected members, have been studied by these authors. Onset was between 20 and 40 years, with intermittent myotonic symptoms of the hands and proximal leg muscles, followed by a mild, slowly progressive weakness of the proximal limb muscles without significant atrophy. Cataracts developed in one half the patients and cardiac arrhythmias in only two. Onset in infancy; ptosis; weakness of facial, jaw, and distal limb muscles; and mental abnormalities were notably absent, thereby distinguishing PROMM from the conventional form of myotonic dystrophy.

Histologically the appearance was that of a nonspecific myopathy, without ringbinden or subsarcolemmal masses. Analysis of leukocyte and muscle DNA discloses no expansion of the CTG component of the myotonic dystrophy gene. Rather, the gene defect for this disease has been mapped to chromosome 3q where there is an expansion of a CCTG repeat. Like the expanded CTG repeat in myotonic dystrophy, the CCTG expansion in PROMM is associated with intranuclear accumulation of the expanded RNA transcript and like the CTG repeats of myotonic dystrophy, the CCTG segments do not code for a protein.

The Distal Muscular Dystrophies

(**Welander, Miyoshi Types**) (See Table 50-3)

Included in this group are several slowly progressive distal myopathies with onset principally in adult life. Weakness and wasting

of the muscles of the hands, forearms, and lower legs, especially the extensors, are the main clinical features. Although such cases had been reported by Gowers and others, their differentiation from myotonic dystrophy and peroneal muscular atrophy was unclear until relatively recently.

Several types of distal dystrophy are inherited as *autosomal dominant* traits. For example, Milhorat and Wolff studied 12 individuals from one family affected by "a progressive muscular dystrophy of atrophic distal type." The onset was between 26 and 43 years; within 5 to 15 years the patients had become disabled. There was one autopsy, confirming the dystrophic nature of the disease.

A different dominantly inherited distal dystrophy was described by Welander in a study of 249 patients from 72 Swedish pedigrees (not to be confused with the Kugelberg-Welander juvenile spinal muscular atrophy affecting proximal muscles—see page 946). Weakness developed first in the small hand muscles and then spread to the distal leg muscles, causing a steppage gait. Fasciculations, cramps, pain, sensory disturbances, and myotonia were notably absent. Some patients have a low-grade sensory neuropathy, suggesting that pathology in this disorder may not be exclusively in muscle. Senile cataracts appeared after the age of 70 in 3 patients and can be discounted as having special significance. No endocrine disorders were detected. Dystrophic changes were demonstrated in 3 autopsies and 22 biopsy specimens. The central nervous system and peripheral nerves were normal. Progression of the disease was very slow; after 10 years or so some wasting of proximal muscles was seen in a few of the patients. Welander dystrophy has been linked to chromosome 2p13, near the locus for the below described Miyoshi myopathy.

Markesberry and colleagues reported a late-onset distal myopathy in which weakness began in the distal leg muscles (tibialis anterior) and later spread to the hands; there was also cardiomyopathy and heart failure. Identical distal myopathies have been described in Finnish patients by Udd and colleagues and found to be caused by dominant mutations in the "titin" gene. A form beginning in childhood described by Laing and colleagues was shown to be due to a mutation in the gene for myosin heavy chain. The characteristic feature in all these cases is progressive bilateral foot drop.

Miyoshi Dystrophy A second type of distal dystrophy characterized by an *autosomal recessive* pattern of inheritance is particularly prevalent in Japan (Miyoshi et al, Nonaka et al), but numerous cases exist in all parts of the world. Onset of the disease is in early adult life, with weakness and atrophy of the leg muscles, most prominent in the peroneal or the gastrocnemius and soleus muscles. Over many years the weakness extends to the thighs, gluteal muscles, and arm muscles, including the proximal ones. Serum CK concentrations are greatly increased in the early stages of the disease. In this "Miyosh type" of dystrophy the mutation leads to an absence of the muscle protein *dysferlin*. Dysferlin is a membrane protein that does not interact with any of the dystrophin-binding elements. Whereas dystrophin and its binding partners are believed to confer tensile strength the muscle membrane, dysferlin and its associated proteins (e.g., the annexins) function in calcium-mediated membrane repair (Lennon). Of interest is the fact, mentioned earlier, that one of the limb-girdle dystrophies (2B) has been linked to the same chromosomal locus and also lacks the dysferlin protein. It is also striking that different family members with the same dysferlin mutation can have disease onset in either a proximal (LGMD) or distal (Miyoshi) pattern, suggesting that additional factors modify the pattern of weakness produced by dysferlin deficiency. We

Table 50-3
Distal muscular dystrophies

INHERITANCE DISORDER	GENE OR PROTEIN DEFICIENCY	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
<i>Autosomal recessive</i>				
Miyoshi myopathy	Dysferlin	2nd–3rd	10–50 x	Begins in gastrocnemius muscles, rarely, in anterior tibial muscles Identical genetic defects may cause LGMD-2B Involves multiple muscle groups, spares heart
Nonaka myopathy with rimmed vacuoles (familial IBM)	GNE kinase–epimerase UDP-N-acetylglucosamine-2-epimerase/N-mannosamine kinase	2nd–3rd	3–10 x	Distal more than proximal weakness Quadriceps sparing Spares heart
<i>Autosomal dominant</i>				
Welander distal dystrophy	Unknown	4th–5th	2–3 x	Weakness begins in hands Slow progression Spares cardiac muscle
Tibial muscular dystrophy	Titin	4th–8th	2–4 x	Onset in tibial distribution No cardiac involvement
Scapuloperoneal dystrophy	Chromosomes 12q, 3p22	3rd–6th	2–10 x	Scapuloperoneal weakness Hyaline bodies in muscle Early onset of foot drop
Desmin myopathy	Desmin	3rd–4th	2–3 x	Onset of distal weakness, slowly progressive Cardiac arrhythmias (sometimes fatal)
Gower-Laing	Myosin heavy chain	2nd–3rd	3 x	Anterior tibial (early foot drop)

IBM: inclusion body myopathy.

have encountered one family in which two individuals with dysferlin mutations had proximal weakness at onset while a sibling with the same lesion had anterior tibial weakness. The Miyoshi myopathy is the one we have encountered most often among the distal muscular dystrophies.

An apparently separate form of distal myopathy with autosomal dominant inheritance and onset before 2 years of age has been described by Magee and DeJong and by van der Does de Willebois and coworkers. Whether these infantile-onset cases represent a true muscular dystrophy has not been established beyond doubt. Several even rarer distal myopathies with linkage to specific genetic sites are summarized in the review by Illa but most are not well enough characterized to require elaboration here.

Congenital Muscular Dystrophy (Fukuyama, Walker-Warburg, Merosin Deficient, Rigid Spine, and Other Types) (See Table 50-4)

Early in the twentieth century there were scattered reports of congenital myopathy, but the status of this condition was difficult to evaluate, mainly because of a lack or incompleteness of pathologic examinations. Some cases may have represented congenital myotonic dystrophy, or one of the congenital myopathies described in Chap. 52. In 1957 Bunker, Victor, and Adams described two patients (siblings), one dying 1½ h after birth and the other at the age of 10 months of a congenital muscular dystrophy with arthrogryposis. The pathologic changes consisted of muscle fiber degeneration, variation in fiber size, fibrosis, and fat cell replacement. The

central and peripheral nervous systems were intact. The severity of the degenerative changes was such that a developmental disorder of muscle could be excluded. Pearson and Fowler, in 1963, reported a brother and sister with similar clinical and pathologic findings, and Walton et al described yet another patient, aged 4 years. By 1967 Vassella and colleagues were able to collect 27 cases from the medical literature and to add 8 cases of their own. The high incidence of sibling involvement pointed to an autosomal recessive inheritance.

Defined as a muscle dystrophy already present at birth, often with contractures of proximal muscles and trunk, the severity of the weakness and degree of progression have varied widely. Of the 8 cases reported by Rotthauwe and others, one had a benign course, but the others all had weakness and hypotonia at birth, and difficulty in sucking and swallowing had interfered with nutrition. Their oldest patients, aged 14 and 23 years, and several others had walked, but at a late age. In the Finnish series of Donner and associates, congenital dystrophy accounted for 9 percent of the 160 cases of neuromuscular disease seen at their hospital over a decade. The weakness and hypotonia were generalized, and 3 had ECG abnormalities. The CK values were elevated and the EMGs were myopathic.

This group of dystrophies began to come into focus in the 1960s with a series of articles from Japan relating the details in over 100 patients with congenital dystrophy (Fukuyama et al). It is the second most common muscular dystrophy in Japan but it is rare elsewhere. A feature of these cases was the coexistence of severe mental retardation and developmental anomalies of the cerebral cortex. Hyperlucency in the periventricular white matter (by

Table 50-4
Congenital muscular dystrophies

DISORDER	GENE OR PROTEIN DEFICIENCY	CK ELEVATION	REGIONS AFFECTED
Merosin deficiency	Merosin	5–35 x	Hypotonia, diffuse weakness, slow motor development Cognitive function largely spared
Fukutin CMD	Fukutin	10–50 x	Hypotonia, diffuse weakness, slow motor development Mental retardation, seizures common MRI: hypomyelination, hydrocephalus
FKRP CMD	FKRP	10–50 x	Hypotonia, diffuse weakness, slow motor development Cognitive function largely spared
Muscle-eye brain disease	<i>N</i> -acetyl-glucosaminyl-transferase POMGnT1	5–20 x	Hypotonia, diffuse weakness, slow motor development Mental retardation, seizures common Cataracts, retinal dysplasias, retinitis, glaucoma Hypoplasia of optic nerve MRI: hypomyelination, hydrocephalus, lissencephaly
Walker-Warburg disease	<i>O</i> -Mannosyl-transferase 1 POMT1	5–20 x	Hypotonia, diffuse weakness, slow motor development Mental retardation, seizures common Cataracts, retinal dysplasias, retinitis, glaucoma MRI: hypomyelination, hydrocephalus, lissencephaly
Rigid spine syndrome	Selenoprotein SEPN1	N1	Hypotonia, restricted flexion of the neck and spine Contractures at multiple joints, normal heart Cognitive function largely spared
Integrin CMD	Integrin α -7	1–2 x	Hypotonia, diffuse weakness, slow motor development Slowed motor development \pm mental retardation
LARGE CMD	LARGE	N1	Profound mental retardation, cerebral white matter changes

computed tomography) was frequently observed. In another group of cases, congenital muscular dystrophy was associated with lissencephaly as well as cerebellar and retinal malformations (Walker-Warburg syndrome; see Dobyns et al). In a series of 19 Finnish cases reported by Santavuori and coworkers, congenital muscular dystrophy was associated with retinal degeneration and optic atrophy, hydrocephalus, pachygyria-polymicrogyria, and hypoplastic or absent septum pellucidum and corpus callosum [“muscle-eye-brain”(MEB) disease]. Lebenthal and colleagues later described a large Arab pedigree with congenital muscular dystrophy and patent ductus arteriosus. Some patients had contractures at birth; in others contractures developed at a later age. The EMG disclosed a myopathic pattern, and CK levels were moderately elevated.

In recent years the classification and relationships of the congenital muscular dystrophies have been clarified to some extent by a number of molecular genetic studies (see Table 50-4). Remarkably, the major congenital muscular dystrophies share an important biological attribute: each involves either an abnormality of a protein that binds to the dystrophin complex (e.g., laminin α 2 or merosin) or an abnormality of a protein in the Golgi apparatus that is important in processing proteins (such as the dystroglycans and sarcoglycans) that are destined to interact with the dystrophin complex (see Fig. 50-1).

The most frequent congenital muscular dystrophy in the Caucasian population is the classic (Occidental) type, so called because it is characterized exclusively by muscle involvement. Occasionally there are abnormal white matter signals on magnetic resonance imaging. Tomé and others have shown that in approximately one half such patients, merosin is completely absent (“merosin-negative” cases). Merosin, the predominant isoform of α -laminin in the basement membrane of the muscle fiber, is closely bound to α -

dystroglycan, which in turn is bound to the dystrophin cytoskeleton (see Fig. 50-1). An absence of merosin interrupts this linkage and leads to muscle degeneration. The diagnosis of merosin deficiency can be made prenatally by immunostaining chorionic villi cells, and postnatally, by staining skeletal muscle biopsy material. In most cases that are merosin deficient, the disorder is genetically linked to the merosin (laminin α -2) gene. These mutations would be predicted to alter or prevent the expression of the protein.

An additional member of the group of merosin-positive congenital muscular dystrophies is one termed *rigid spine syndrome*. The term was first proposed by Dubowitz and the clinical syndrome, as outlined by Flanigan and coworkers, consists of (1) infantile hypotonia with early weakness of neck muscles and poor head control; (2) stabilization with only slight decrease of muscle strength but marked loss of muscle bulk; (3) prominent contractures of spinal muscles resulting in scoliosis and rigidity in flexion and, to a lesser extent, contractures of limb joints; (4) respiratory insufficiency with onset before adolescence; and (5) normality of intellectual and cardiac function. This unusual congenital muscular dystrophy with rigid spine syndrome (CMD-RSS) arises from mutations in a gene encoding a so-called selenoprotein.

In the Fukuyama type of congenital muscular dystrophy, the abnormal gene product fukutin has been identified. As noted above, fukutin is one of five genes whose mutations alter protein glycosylation, deranging function of both muscle and brain. Thus, the genes for MEB and the Walker-Warburg syndrome are also glycosyltransferases (respectively, POMGnT1 and POMT1) as is the aforementioned fukutin-related peptide. Most recently, it has been shown that another form of congenital muscular dystrophy follows mutations of another glycosylation gene (known as “LARGE”).

Problems in Diagnosis

The following are some of the common problems that arise in the diagnosis of muscular dystrophy:

1. *The diagnosis of muscular dystrophy in a child who has just begun to walk or in whom walking is delayed.* Tests of peak power on command cannot be used with reliability in small children. The most helpful points in identifying Duchenne dystrophy are (a) unusual difficulty in climbing stairs or arising from a crouch or from a recumbent position on the floor, showing greater weakness at the hips and knees than at the ankles; (b) unusually large, firm calves; (c) male sex; (d) high serum CK, aldolase, and myoglobin levels; (e) myopathic EMG; (f) biopsy findings; and (g) special methods of testing for dystrophin protein (see previous discussion).
2. *The adult patient with diffuse or proximal muscle weakness of several months' duration, raising the question of polymyositis versus dystrophy.* Even biopsy may be misleading in showing a few inflammatory foci in an otherwise dystrophic picture. The main points that help to distinguish polymyositis from adult dystrophy have been indicated in Chap. 49. As a rule, polymyositis evolves more rapidly than dystrophy and is associated with high CK and aldolase values (higher than most of the dystrophies except the Duchenne and distal Miyoshi types), and the EMG shows many fibrillation potentials (rare in adult forms of muscular dystrophy). With these points in mind, if immunostaining of a muscle biopsy fails to reveal the diagnosis of a dystrophy, there may still be uncertainty, in which instance a trial of prednisone may be indicated for a period of 6 months. Unmistakable improvement favors polymyositis; questionable improvement (physician's and patient's judgment not in accord) leaves the diagnosis unsettled but suggests inclusion of body myopathy or a dystrophy.
3. *An adult with a very slowly evolving proximal weakness.* In addition to facioscapular and limb-girdle dystrophies, myositis and inclusion body myopathy, several of the congenital polymyopathies discussed in Chap. 52 may begin to cause symptoms or to worsen in adult years. These include central core and nemaline myopathy. Examples have been reported in the adult of mild forms of acid maltase or debrancher enzyme deficiency with glycogenosis, progressive late-stage hypokalemic polymyopathy, mitochondrial myopathy, and carnitine polymyopathy. Muscle biopsy and histochemical staining of the muscle usually provide the correct diagnosis.
4. *The occurrence of subacute or chronic symmetrical proximal weakness in a child or adolescent that raises the question of spinal muscular atrophy (Kugelberg-Welander type—see page 946) as well as of polymyositis and muscular dystrophy.* Electromyography and muscle biopsy settle the matter by distinguishing neuropathic from myopathic changes. Some of the same problems arise in an adult with distal dystrophy.
5. *Weakness of a shoulder or one leg of some weeks' standing, with increasing atrophy.* This is usually due to a radiculopathy or mononeuritis, the beginning of motor system disease (progressive spinal muscular atrophy), but rarely may be the early stage of a muscular dystrophy. The first two may develop silently, in mild form, and attract notice only when wasting begins (denervation atrophy takes 3 to 4 months to

reach its peak). Points in favor of these acquired diseases are (a) acute or subacute onset and pain, (b) confinement of the disease to muscles originally affected and sparing of other muscles, and (c) an EMG showing denervation effects. Biopsy is seldom performed under such circumstances, for, by temporizing, the problem eventually settles itself. Invariably muscle dystrophy becomes bilateral and symmetrical; mononeuritis stabilizes or recovers; motor neuron disease declares itself by the presence of fasciculations and relatively rapid progression of weakness. Facioscapulohumeral dystrophy may begin with asymmetric shoulder weakness.

6. *The distinctions, in the child or adolescent, between dystrophy and one of the congenital or metabolic myopathies are considered in relation to these disorders (Chaps. 51 and 52).*

Treatment of the Muscular Dystrophies

There is no specific treatment for any of the muscular dystrophies. The physician is forced to stand by and witness the unrelenting progression of weakness and wasting. The various vitamins (including vitamin E), amino acids, testosterone, and drugs such as penicillamine, recommended in the past, have all proved to be ineffective. The administration of prednisone appears to slightly retard the tempo of progression of Duchenne dystrophy for a period of up to 3 years (Fenichel et al). The optimal dose is 0.75 mg/kg given daily, but it must often be reduced because of intolerable side effects (weight gain, behavioral and gastrointestinal disorders). Creatine may be of minor benefit as in the study by Walter and colleagues.

Quinine has a mild curare-like action at the motor end plate and thus relieves myotonia (see Chap. 54). Although symptomatic relief of the myotonia is usually achieved, the drug has no effect on progression of the muscle atrophy or other degenerative aspects of myotonic dystrophy. The usual dose is 0.3 to 0.6 g orally, repeated as needed about every 6 h. Mild toxic symptoms such as tinnitus may develop before enough quinine has been given to relieve myotonia. Some patients find the side effects more distressing than the myotonia and prefer not to take quinine except on occasions when the myotonia is troublesome in a particular activity. Also, procainamide (0.5 to 1.0 g 4 times daily) and phenytoin are sometimes useful in alleviating myotonia, but the former may be dangerous, even in patients with a pacemaker. (Quinine and procainamide slow conduction through the AV node, whereas phenytoin does not have this effect.) Testosterone has been found to increase muscle mass in patients with myotonic dystrophy but was of no value in preserving strength or lessening myotonia (Griggs et al).

Respiratory failure occurs in virtually all patients affected with Duchenne dystrophy after they become wheelchair-bound, as well as in some of the other dystrophic diseases. It may be so insidious as to become evident only as sleep apnea, as a retention of carbon dioxide that causes morning headache, or as progressive weight loss that reflects the excessive work of breathing. If there are frequent episodes of oxygen desaturation, some improvement in daytime strength and alertness can be attained by assisting ventilation at night. This may be accomplished in the early stages of disease by a negative-pressure cuirass-type of device that expands the chest wall periodically or, more conveniently, by nasal positive pressure (so-called NIPPV or BIPAP). Later, positive-pressure ventilation through a fenestrated tracheostomy is required that allows nighttime ventilation but leaves the patient free to speak and breathe

during the day. With regard to earlier, or anticipatory treatment, in patients free of respiratory failure with vital capacities between 20 and 50 percent of predicted values, a randomized trial of nasal mechanical ventilation failed to demonstrate improvement or prolonged survival (Raphael et al). There is a clinical impression that even more severely affected patients can be managed at home for prolonged periods with respiratory assistance. Needless to say, the common complications of muscular dystrophy—pulmonary infections and cardiac decompensation—must be treated symptomatically. Surgical management of cataracts is indicated when they become mature.

As noted earlier, a vital element in the care of patients with certain of the dystrophies is monitoring for early evidence cardiac arrhythmias. In disorders such as myotonic dystrophy, Emery-Dreifuss dystrophy, and some of the mitochondrial disorders it is imperative that cardiac status should be evaluated on a regular basis (typically yearly) with echocardiography and 24-h rhythm monitoring, preferably by a cardiologist who is familiar with these diseases. The timely use of cardiac pacemakers, implemented at the earliest sign of arrhythmia, is essential in this patient population.

Vignos, who reviewed the studies that evaluated muscle-strengthening exercises, has offered evidence that maximal resistance exercises, if begun early, can strengthen muscles in Duchenne, limb-girdle, and facioscapulohumeral dystrophies. In the study he conducted, none of the muscles were weaker at the end of a year than at the beginning. Cardiorespiratory function after endurance exercise was not significantly improved. Contractures were reduced by passive stretching of the muscles 20 to 30 times a day and by splinting at night. If contractures have already formed, fasciotomy and tendon lengthening are indicated in patients who

are still ambulating but this is not recommended early in the course of the disease. Maintenance of ambulation and upright posture will delay scoliosis. In general, preventive measures are more successful than restorative ones.

In recent years there has been interest in the injection of human myoblasts or muscle stem cells that contain a full complement of dystrophin and other structural elements into the muscles of patients with muscular dystrophy. There is an analogous effort to refine the technology of viral-mediated gene delivery to allow gene and protein replacement in the recessively inherited dystrophies. The difficulties of injecting every dystrophic muscle are obvious. Thus far, there is no convincing evidence of the efficacy of such injections, even for those into an individual muscle. Until such time as gene or stem cell therapy, or other novel approaches, become practical for muscular dystrophy, physicians must rely on physical methods of rehabilitation.

From such observations it may be concluded that two factors are of importance in the management of patients with muscular dystrophy: avoiding prolonged bed rest and encouraging the patient to maintain as full and normal a life as possible. These help to prevent the rapid worsening associated with inactivity and to conserve a healthy attitude of mind. Obesity should be avoided; this requires careful attention to diet. Swimming is a useful exercise. Massage and electrical stimulation are probably worthless. The education of children with muscular dystrophy should continue, with the aim of preparing them for a sedentary occupation.

Prevention by prenatal counseling is available for most dystrophies but proper diagnosis is essential. Special centers provide the genetic and psychological services necessary to carry this out properly.

CHAPTER 51

THE METABOLIC AND TOXIC MYOPATHIES

Three classes of metabolic disease of muscle are recognized—one of which is traceable to a primary, or hereditary, metabolic abnormality of the muscle itself; another in which the myopathy is secondary to a disorder of endocrine function, i.e., to disease of the thyroid, parathyroid, pituitary, or adrenal gland; and a third group, due to a large variety of myotoxic drugs and other chemical agents. The latter two groups are relatively common and more likely to come initially to the attention of the internist rather than the neurologist.

The hereditary metabolic myopathies are of special interest because they reveal certain aspects of the complex chemistry of muscle fibers. Indeed, each year brings to light some new genetically determined enzymopathy of muscle. As a consequence, a number of diseases formerly classified as dystrophic or degenerative, are consistently being added to the enlarging list of metabolic myopathies. There are now so many of them that only the most representative can be presented in a textbook of neurology. Complete accounts of this subject can be found in the section on metabolic disorders in Engel and Franzini-Armstrong (eds.), *Myology*, and in the chapter by DiMauro and colleagues in the *Handbook of Clinical Neurology*.

PRIMARY METABOLIC DISORDERS OF MUSCLE

The chemical energy for muscle contraction is provided by the hydrolysis of adenosine triphosphate (ATP) to adenosine diphosphate (ADP); ATP is restored by phosphocreatine and ADP acting in combination. These reactions are particularly important during brief, high-intensity exercise. During periods of prolonged muscle activity, rephosphorylation requires the availability of carbohydrates, fatty acids, and ketones, which are catabolized in mitochondria. Glycogen is the main sarcoplasmic source of carbohydrate, but blood glucose also moves freely in and out of muscle cells as needed during sustained exercise. The fatty acids in the blood, derived mainly from adipose tissue and intracellular lipid stores, constitute the other major source of energy. Carbohydrate is metabolized during aerobic and anaerobic phases of metabolism, the fatty acids, only aerobically.

Resting muscle derives approximately 70 percent of its energy from the oxidation of long-chain fatty acids. As stated earlier, the circumstances during exercise are somewhat different. During a short period of intense exercise, the muscle utilizes carbohydrate derived from glycogen stores; myophosphorylase is the enzyme that initiates the metabolism of glycogen. With longer aerobic exercise, blood flow to muscle and the availability of glucose and fatty acids is increased. At first, glucose is the main source of energy during exercise; later, with exhaustion of the glycogen stores, energy is provided by oxidation of fatty acids. Thus, muscle failure at a certain phase of exercise is predictive of the type of energy failure. A rising blood concentration of β -hydroxybutyrate reflects the increasing oxidation of fatty acids, and an increase in blood lactate reflects the anaerobic metabolism of glucose. The cytochrome oxidative mechanisms are essential in both aerobic and

anaerobic muscle metabolism; these mechanisms are considered in Chap. 37 in relation to the mitochondrial diseases, and are referred to here only briefly.

It follows from these observations that the efficiency and endurance of muscle depend on a constant supply of glycogen, glucose, and fatty acids and on the adequacy of the enzymes committed to their metabolism. Biochemical derangements in their metabolism give rise to a large number of muscle disorders, the most important of which are elaborated in the following pages.

Glycogen Storage Myopathies

An abnormal accumulation of glycogen in the liver and kidneys was described by von Gierke in 1929; shortly thereafter, Pompe (1932) reported a similar disorder involving cardiac and skeletal muscle. Major contributions to our understanding of glycogen metabolism were made by McArdle, by Cori and Cori, and by Hers, who discovered the deficiency of acid maltase in Pompe disease and enunciated the concept of inborn lysosomal diseases (see Chap. 37). Since then, many nonlysosomal enzyme deficiencies have been identified and have become the basis of the classification presented in Table 51-1. These enzymatic deficiencies alter the metabolism of many cells but most strikingly those of the liver, heart, and skeletal muscle. In about half of the affected individuals, a chronically progressive or intermittent myopathic syndrome is the major manifestation of the disease. It is a curious fact, that with the exception of the rare phosphoglycerate kinase deficiency (X-linked recessive inheritance), *all the glycogenoses are inherited as autosomal recessive traits*. The most impressive and common of these glycogen storage diseases from the standpoint of the clinical neurologist are 1,4-glucosidase (acid maltase) and myophosphorylase deficiencies.

Acid Maltase Deficiency (Glycogenosis Type II; Pompe Disease and Related Disorders) A deficiency of this enzyme takes three clinical forms, of which the first (Pompe disease) is the most malignant. Pompe disease develops in infancy, between 2 and 6 months; dyspnea and cyanosis call attention to enlargement of the heart, and the liver may be enlarged as well. The skeletal muscles are found to be weak and hypotonic, though their bulk may be increased. The tongue may be enlarged, giving the infant a cretinoid appearance. Hepatomegaly, while often present, is not pronounced. Exceptionally, the heart is relatively normal in size, and the central nervous system and muscles bear the brunt of the disorder. The clinical picture then resembles infantile spinal muscular atrophy (Werdnig-Hoffmann disease) and, to add to difficulty in differential diagnosis, there may be fasciculations. The disease is rapidly progressive and ends fatally in a few months. The electromyogram (EMG) shows myopathic changes, but there are, in addition, fibrillation potentials, heightened insertional activity, and pseudomyotonia. Large amounts of glycogen accumulate in muscle, heart, liver, and neurons of the spinal cord and brain. All tissues lack alpha glucosidase (acid maltase). The gene encoding acid maltase

has been mapped to the distal portion of the long arm of chromosome 17 (17q23).

In the second (childhood) form, onset is during the second year, with delay in walking and slowly progressive weakness of shoulder, pelvic girdle, and trunk muscles. The toe walking, waddling gait, enlargement of calf muscles, and lumbar lordosis resemble those of Duchenne dystrophy. Cardiomyopathy is exceptional, hepatomegaly is less frequent than in the infantile form, and mental retardation was present in only 2 of 18 cases reported by DiMauro et al. Death occurs between 3 and 24 years of age, usually from ventilatory insufficiency.

In the third, or adult, form there is a more benign truncal and proximal limb myopathy. The weakness is slowly progressive over many years, and death is usually the result of weakness of respiratory muscles. At times the only severe weakness is of the diaphragm, as in the case reported by Sivak and colleagues, making adult acid maltase deficiency part of a select group of neuromuscular disorders that may present in this way (along with motor neuron disease, nemaline rod myopathy, and myasthenia gravis). The liver and heart are not enlarged. Creatine kinase (CK) values are increased, as they are in all forms of the disease. The EMG discloses a number of abnormalities—brief motor unit potentials, fibrillation potentials, positive waves, bizarre high-frequency discharges, and occasional myotonic discharges (without clinical evidence of myotonia). The disease must be differentiated from other chronic adult polymyopathies, including polymyositis and the endocrine myopathies, and from motor neuron disease.

Aside from the elevation of the muscle-derived enzymes CK and aldolase, blood studies are normal. The diagnosis in all forms of acid maltase deficiency is readily confirmed by muscle biopsy. The sarcoplasm is vacuolated and most vacuoles contain periodic acid-Schiff (PAS)-positive diastase-digestible material; they stain intensely for acid phosphatase. The glycogen particles lie in aggregates; electron microscopy shows some of them to occupy lysosomal vesicles (i.e., this is a lysosomal storage disease) and others to lie free. The myofibrils are disrupted, and some muscle fibers degenerate. Glycogen accumulation is more pronounced in type 1 fibers. As indicated earlier, in the more severe infantile form of acid maltase deficiency, heart muscle and the large neurons of the spinal cord and brainstem may also accumulate glycogen and degenerate. The difference in severity between infant and adult forms may relate to the completeness of enzyme deficiency, but possibly other factors are also at work since more than one of the three types may occur in the same family.

Treatment The adult who is threatened by respiratory failure should be observed frequently with measurements of vital capacity and blood gases. Umpleby and coworkers reported that a low-carbohydrate, high-protein diet may be beneficial. A few of our patients died unexpectedly during sleep. Respiratory support (rocking bed, nasal positive pressure, and negative-pressure cuirass) may prolong life.

Enzyme replacement therapy is being investigated in the treatment of Pompe disease. Recombinant acid alpha-glucosidase is injected intravenously and the early results are promising.

Myophosphorylase Deficiency (Type V Glycogenosis; McArdle Disease) and Phosphofructokinase Deficiency (Type VII Glycogenosis; Tarui Disease) These disorders are considered together since they are clinically virtually identical and both express themselves by the development of muscle cramps (actually true physiologic contractures, page 1194) in response to exercise—a

feature that distinguishes them from other glycogenoses. In both these diseases an otherwise normal child, adolescent, or adult begins to complain of weakness and stiffness and sometimes pain on using the limbs. Muscle contraction and relaxation are normal when the patient is in repose, but strenuous exercise, either isometric (carrying heavy weights) or dynamic (climbing stairs or walking uphill), causes the muscles to shorten (contracture), since they are unable to relax. After vigorous exercise, episodes of myoglobinuria are common; these may result in renal failure. With mild sustained activity, the patient experiences progressive fatigue and weakness, which diminish following a brief pause. The patient can then resume his activities at the original pace ("second-wind" phenomenon). During the second-wind phase, the patient copes with his symptoms by increasing cardiac output and substituting free fatty acids and blood-borne glucose for muscle glycogen (Braakhekke et al).

The primary abnormality in McArdle disease is a deficiency of myophosphorylase, which prevents the conversion of glycogen to glucose-6-phosphate. Phosphofructokinase deficiency (*Tarui disease*) interferes with the conversion of glucose-6-phosphate to glucose-1-phosphate; the defect in the latter condition is also present in red blood cells (Layzer et al). The gene for myophosphorylase has been localized to the long arm of chromosome 11 (11q13), and analysis of DNA from the patient's leukocytes can be used for diagnosis. The muscle (M) subunit of the phosphofructokinase protein in Tarui disease localizes to a gene defect on chromosome 1. This defect predominates in Ashkenazi Jewish men.

Clinical variants of these disorders are well known. Some patients, with no previous symptoms of cramps or myoglobinuria, develop progressive weakness of limb muscles in the sixth or seventh decade. One of these older patients came to our attention because of chronically elevated levels of CK and mild muscle cramping after climbing stairs. In others, rapidly progressive weakness became evident in infancy, with early death from respiratory failure. These unusual forms are not directly related to severity of the enzyme deficiencies.

The contracted muscles in these disorders, unlike muscles in other involuntary spasms, no longer use energy, and they are more or less electrically silent (i.e., no electrical activity is recorded from maximally contracted muscle during the cramps induced by ischemic exercise); moreover, the muscle does not produce lactic acid. This shortened state is spoken of as *physiologic contracture*. Ischemia contributes to this condition by denying glucose to the muscle, which cannot function adequately on fatty acids and non-glucose substrates. These features are the basis of the *forearm ischemic exercise test*, which, while controversial in its use, may be helpful if performed carefully in the diagnosis of both McArdle and Tarui disease. An indwelling catheter is placed in the antecubital vein and a basal blood sample is obtained. Above the elbow, a sphygmomanometer cuff is inflated to exceed arterial pressure. After 1 min of vigorous hand exercise (30 hand closures against an ergometer), blood samples are obtained at 1 and 3 min. Normal individuals show a three- to fivefold increase in blood lactate. In patients with either McArdle or Tarui disease, the lactate fails to rise. This procedure has reportedly caused a localized rhabdomyolysis (Meinck et al), for which reason Griggs and associates recommend that the test be carried out *without* a blood pressure cuff. Problems with consistency in conducting the test and processing blood samples for lactate limit its validity unless it is performed by experienced individuals and laboratories.

Table 51-1The glycogenoses affecting skeletal muscle ^a

GLYCOGENOSIS TYPE (PROPER NAME)	DEFECTIVE ENZYME	ONSET OF DISEASE ^b	HYPO- TONIA	EXERCISE INTOLERANCE				SEVERE RESPI- RATORY MUSCLE WEAKNESS	CONTRAC- TURES

^a All types: elevated CK; myopathic EMG, with increased irritability and myotonia.^b I, infancy; C, childhood; Ad, adolescence; A, adult.

Additional features (not charted above): feeding difficulties, II Pompe; retarded growth, III; neurologic abnormalities, II Pompe, IX; seizures, VIII, IX; hypoglycemic seizures, III; jaundice, VII, IX; cirrhosis, IV; generalized scaling erythema, XI; firm consistency of muscle, II Pompe; elevated serum aspartate aminotransferase and lactic dehydrogenase, II; elevated serum bilirubin, VII, IX; failure of LDH to rise proportionally to elevation of CK, XI; fasting hypoglycemia, III; hemolytic anemia and reticulocytosis, VII, IX; hemoglobinuria, IX; excessive rise in serum pyruvate during ischemic exercise test, XI.

Definitive diagnosis depends upon the histochemical stains of biopsied muscle, which reveal an absence of phosphorylase activity (in McArdle disease) or of phosphofructokinase activity (in Tarui disease).

Treatment The main treatment is a planned reduction and intermittency in physical activity. Sucrose, taken as 75 g in a beverage, has been shown by Vissing and Haller to cause a short-lived improvement in exercises tolerance and they propose that exercise-induced rhabdomyolysis can be avoided by this well-timed drink. Fructose and creatine taken orally are also said to be helpful in some cases but the reported results are not as impressive as they are for sucrose. Improvement has also been described after the administration of glucagon (Kono et al) and after a high-protein diet (Slonim and Goans), but these effects are not consistent.

Other Forms of Glycogenosis (see Table 51-1) Of the remaining glycogen storage diseases, type III (*debranching enzyme deficiency; Cori-Forbes disease*) affects muscle, but not consistently. The childhood form is characterized mainly by a benign hepatopathy, sometimes accompanied by diminished muscle strength and tone. An adult form beginning in the third and fourth decades presents with proximal and distal myopathy. The course is slowly progressive and may be associated with wasting of the leg and hand muscles. In the series reported by DiMauro and colleagues, several patients who developed weakness during adult life complained of rapid fatigue and aching of muscles, occurring with exertion and first noticed at an early age. Serum CK values were elevated and the EMG showed a myopathic picture as well as increased insertion activity, pseudomyotonic discharges, and fibrillation potentials. Rarely in the adult form, glycogen also accumulates in the

peripheral nerves, giving rise to mild symptoms of polyneuropathy. The enzymatic defect is one of amylo-1,6-glucosidase deficiency.

Disturbance of skeletal muscle is even less prominent in type IV glycogenosis (*branching enzyme deficiency*, or *Andersen disease*). This is a rapidly progressive disease of infancy and early childhood, characterized by cirrhosis and chronic hepatic failure, usually with death in the second or third year. Hepatomegaly due to accumulation of an abnormal polysaccharide is a universal finding. Muscle weakness and atrophy, hypotonia, and contractures occur less regularly and are usually overshadowed by the liver disease. The diagnostic hallmark of this myopathy is the presence of basophilic, intensely PAS-positive polysaccharide granules in skin and muscle.

The remaining nonlysosomal glycogenoses (types VIII through XI) need only be mentioned briefly. They are all rare and clinically heterogeneous, and a myopathy—characterized by intolerance to exercise, cramps, myoglobinuria, elevated CK, and sometimes renal failure—has been observed in only a small proportion of them. Phosphoglycerate kinase deficiency (type IX glycogenosis) differs in that it is inherited as a sex-linked recessive trait localized to chromosome Xq13. Hemolytic anemia—becoming evi-

dent soon after birth—mental retardation, seizures, and tremor are other features that set this glycogenosis apart from the others. The myopathic features of the lysosomal and nonlysosomal glycogenoses are listed in Table 51-1 and detailed accounts can be found in the monographs of Griggs and associates and of Engel and Franzini-Armstrong (chapters by DiMauro and Tsujino and by Engel and Hirschhorn).

Disorders of Lipid Metabolism Affecting Muscle

Although it has long been known that lipids are an important source of energy in muscle metabolism (along with glucose), it was only in 1970 that W. K. Engel and others reported the abnormal storage of lipid in muscle fibers attributable to a defect in the oxidation of long-chain fatty acids. The subjects of their report were twin sisters who had experienced intermittent cramping of muscles associated with myoglobinuria after vigorous exercise. In 1973, A. G. Engel and Angelini described a young woman with progressive myopathy, lipid storage predominantly in type 1 muscle fibers, and a deficiency of muscle carnitine, a cofactor

required for the oxidation of fatty acids. Since that time, highly sophisticated biochemical techniques have greatly expanded the study of fatty acid metabolism and the identification of many of the primary defects.

Biochemistry of Fatty Acid Metabolism Carnitine (β -hydroxy-gamma-*N*-trimethylamino-butyrate), derived from lysine and methionine, plays a central role in the metabolism of fatty acids. About 75 percent of carnitine comes from dietary sources (red meat and dairy products); the remainder is synthesized in the liver and kidneys. Practically all of the body carnitine is stored in muscle, where it has two main functions: (1) transporting long-chain fatty acyl-CoAs from the cytosol compartment of the muscle fiber into the mitochondria, where they undergo β -oxidation, and (2) preventing the intramitochondrial accumulation of acyl-CoAs, thus protecting the muscle cell from the membrane-destabilizing effects of these substances.

In order to be oxidized, the long-chain fatty acids undergo a series of biochemical transformations. First they are activated to corresponding acyl-CoA esters by acyl-CoA synthetase, which is located on the outer mitochondrial membrane. Since the inner mitochondrial membrane is impermeable to acyl-CoA esters, they are transferred into the mitochondria as acylcarnitine esters. This is accomplished by carnitine palmitoyl transferase I (CPT I), also located on the outer mitochondrial membrane. A second carnitine palmitoyl transferase (CPT II), bound to the inner face of the inner mitochondrial membrane, reconverts the acylcarnitines to fatty acyl-CoAs, which undergo β -oxidation within the mitochondrial matrix. The steps in the transport of long-chain fatty acids into the mitochondrial matrix (the carnitine cycle) are described in detail in the reviews of DiMauro et al, DiDonato, and Roe and Coates. Isoforms of carnitine palmitoyltransferase are critically involved in this process at the inner and outer membranes of the mitochondria.

Clinical Features of Disordered Fatty Acid Metabolism Despite the many biochemical abnormalities that have been identified in the fatty acid metabolic pathways, there are essentially three clinical patterns by which these defects are expressed:

1. One constellation of symptoms referred to as the *encephalopathic* syndrome has its onset in infancy or early childhood. Its very first manifestation may be sudden death (sudden infant death syndrome, or SIDS), or there may be vomiting, lethargy and coma, hepatomegaly, cardiomegaly, muscular weakness, and hypoketotic hypoglycemia, with prominent hyperammonemia, i.e., a Reye-like syndrome. Undoubtedly, instances of this syndrome have not been recognized as abnormalities of fatty acid metabolism but have been designated incorrectly as the Reye syndrome or as SIDS. They are discussed in Chap. 37.
2. A second (*myopathic*) syndrome appears in late infancy, childhood, or adult life and takes the form of a progressive myopathy, with or without cardiomyopathy. The myopathy may follow episodes of hypoketotic hypoglycemia or may develop de novo.
3. The third syndrome is one that usually begins in the second decade of life. It is induced by a sustained period of physical activity or fasting and is characterized by repeated episodes of *rhabdomyolysis* with or without myoglobinuria.

Summarized below are the main disorders of fatty acid metabolism that affect skeletal muscle; these are all rare but interesting disorders:

Primary Systemic Carnitine Deficiency To date, this is the only form of carnitine deficiency that can be considered primary. Its main clinical features are progressive lipid storage myopathy and cardiomyopathy, sometimes associated with the signs of hypoketotic hypoglycemia. There is no dicarboxylic aciduria, in distinction to the secondary β -oxidation defects, in all of which dicarboxylic aciduria is present. The cardiomyopathy, which is fatal if untreated, responds dramatically to oral administration of L-carnitine, 2 to 6 g/day. This disorder is inherited as an autosomal recessive trait. In these families there is frequently a history of sudden unexplained death in siblings, so that early identification of affected children is essential.

Carnitine Palmitoyltransferase (CPT) Deficiency This disease is also inherited as an autosomal recessive trait. The gene encoding CPT has been mapped to chromosome 1q12. There are three types of CPT deficiency, referred to as types I, IIA, and IIB. Type I is the most common. It affects males predominantly, beginning in the second decade of life. Attacks of myalgia, cramps, and muscle weakness, "tightness," and stiffness are precipitated by sustained (though not necessarily intense) exercise and less often by a prolonged period of fasting. Fever, anesthesia, drugs, emotional stress, and cold are rare precipitating events. The attacks vary greatly in frequency. They are usually accompanied by myoglobinuria, and renal failure occurs in about one fourth of cases (DiMauro et al). The attacks are not aborted by rest and, once initiated, there is no second-wind phenomenon. There are no warning signs of an impending attack. Any muscle group may be affected. Persistence of weakness after an attack is uncommon. Serum CK rises to high levels not only during attacks of myoglobinuria but also after vigorous exercise without myoglobinuria. A mild form is more likely to occur in females.

In type I deficiency, necrosis of muscle fibers, particularly type I fibers, occurs during attacks, followed by regeneration. Between attacks, muscle is normal. In type IIA, lipid bodies accumulate in the liver, and in type IIB, excess lipid is detected in heart, liver, kidneys, and skeletal muscle.

During attacks, CPT is either undetectable or greatly reduced in muscle. Dicarboxylic aciduria is absent. Assays are available for the measurement of CPT I and II in circulating lymphocytes and cultured fibroblasts.

Treatment There is no specific therapy except that directed at the myoglobinuria and its renal complications. However, a high-carbohydrate, low-fat diet, ingestion of frequent meals, and additional carbohydrate before and during exercise appear to reduce the number of attacks. Patients need to be instructed about the risks of prolonged exercise and skipped meals.

Secondary Systemic Carnitine Deficiency This is occasionally the result of severe dietary deprivation or impaired hepatic and renal function. Such instances have been observed in patients with alcoholic-nutritional diseases and kwashiorkor, in premature infants receiving parenteral nutrition, in patients with chronic renal failure undergoing dialysis, and rarely as a complication of valproate therapy. However, most cases of systemic carnitine deficiency are due to defects of β -oxidation, described below.

Other Rare Lipid Myopathies

Defects of β -Oxidation Rarely do these defects affect muscle alone or predominantly. Practically always, other features of disordered fatty acid metabolism—liver disease, hypoketotic hypoglycemia, Reye-like syndrome, SIDS, and so on—are present in some combination. All of the β -oxidative defects are characterized by dicarboxylic aciduria. The abnormal organic acids in each case are determined by analysis of blood and urine; identification of the specific enzyme deficiency requires tissue analysis (liver and muscle homogenates, cultured fibroblasts). At the time of this writing, no less than eight specific defects of β -oxidation affecting muscle have been described; they are tabulated below.

Carnitine Acylcarnitine Translocase Deficiency This condition causes muscular weakness, cardiomyopathy, hypoketotic hypoglycemia, and hyperammonemia, which develop in early infancy, with death in the first month of life.

Long-Chain Acyl-CoA Dehydrogenase Deficiency (LCAD) The presentation is in infancy, with recurrent episodes of fasting hypoglycemic coma, muscle weakness, and myoglobinuria, and sometimes sudden death. Survivors may develop a progressive myopathy. Administration of carnitine improves the cardiac disorder and prevents metabolic attacks.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency (MCAD) This is a cause of SIDS and a Reye-like syndrome. About half of survivors develop a lipid-storage myopathy in childhood or adult life. The abnormal gene has been mapped to chromosome 1p31. Oral L-carnitine may be of therapeutic value.

Short-Chain Acyl-CoA Dehydrogenase Deficiency (SCAD) This myopathy in a limb-girdle distribution may appear initially in older children and adults, or it may follow episodic metabolic disorders in infancy.

Long-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency (HAD) This is a disease of infancy marked by episodes of Reye-like syndrome, hypoketotic hypoglycemia, lipid storage myopathy, cardiomyopathy, and sometimes sudden death.

Short-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency (SCHAD) This presents as an episodic disorder such as the one described earlier (HAD), but its onset occurs in adolescence. Recurrent attacks may be associated with myoglobinuria.

Multiple Acyl-CoA Dehydrogenase Deficiency (MADD); Glutaric Aciduria Type II (GA II) Some cases are caused by a deficiency of electron transfer flavoprotein (ETF) and others by a deficiency of electron transfer flavoprotein-coenzyme Q oxidoreductase (ETF-QO). In the severest form of MADD, infants are born prematurely and many die within the first week of life; added to the common metabolic abnormalities are multiple congenital defects and a characteristic “sweaty feet” odor. In less severe cases, the congenital anomalies are absent. In the least severe form, the onset may be in late infancy (with episodic metabolic disturbances) or in childhood or adult life (with a lipid storage myopathy and a deficiency of serum and muscle carnitine). The prenatal diagnosis of GA II is suggested by the finding of large amounts of glutaric acid in the amniotic fluid. In the milder forms of the disease, oral riboflavin (100 to 300 mg/day) may be helpful.

Muscle Coenzyme Q10 Deficiency This condition presents as a slowly progressive lipid storage myopathy from early childhood. The basic defect is in coenzyme Q10 in the respiratory chain of muscle mitochondria. The administration of coenzyme 10 has improved the myopathy.

Multisystem Triglyceride Storage Disease (Chanarin Disease)

This abnormality of lipid metabolism is distinct from the β -oxidation defects. A progressive myopathy is combined with ichthyosis and neurologic manifestations, such as developmental delay, ataxia, neurosensory hearing loss, and microcephaly. The lipid material is stored in muscle as triglyceride droplets that are nonlysosomal and non-membrane-bound.

MITOCHONDRIAL MYOPATHIES

The genetic aspects of mitochondrial diseases and the diverse and overlapping clinical syndromes that constitute this category—including the myopathic ones—are discussed in Chap. 37. The histologic change termed *ragged red fibers* reflect the mitochondrial changes of this class of diseases and is common to many of them, even without manifest symptoms of muscle disease.

THE ENDOCRINE MYOPATHIES

Thyroid Myopathies

Several myopathic diseases are related to alterations in thyroid function: (1) chronic thyrotoxic myopathy, (2) exophthalmic ophthalmoplegia (infiltrative ophthalmopathy), (3) myasthenia gravis associated with thyrotoxicosis; (4) periodic paralysis associated with thyrotoxicosis, and (5) muscle hypertrophy and slow muscle contraction and relaxation associated with myxedema and cretinism. Although they are not common, we have encountered several examples of these diseases in a single year in our general hospitals.

Chronic Thyrotoxic Myopathy This disorder, first noted by Graves and Basedow in the early nineteenth century, is characterized by progressive weakness and wasting of the skeletal musculature, occurring in conjunction with overt or covert (“masked”) hyperthyroidism. The thyroid disease is usually chronic and the goiter is of the nodular rather than the diffuse type. Exophthalmos and other classic signs of hyperthyroidism are often present but need not be. This complication of hyperthyroidism is most frequent in middle age, and men are more susceptible than women. Some degree of myopathy has been found in more than 50 percent of thyrotoxic patients. The onset is insidious and the weakness progresses over weeks and months. The muscular disorder is most often mild to moderate in degree, but it may be so severe as to suggest progressive spinal muscular atrophy (motor system disease). Muscles of the pelvic girdle and thighs are weakened more than others (Basedow paraparesis), though all are affected to some extent, even the bulbar muscles and rarely the ocular ones. However, the shoulder and hand muscles show the most conspicuous atrophy (not an obligatory feature). Tremor and twitching during contraction may occur, but we have not seen fasciculations. The tendon reflexes are of average briskness, possibly more lively than normal. Both the contraction and relaxation phases of the tendon reflexes are shortened, but usually this cannot be detected by the clinician. Serum concentrations of muscle enzymes are not increased and may be reduced. Usually the EMG is normal, without fibrillation potentials, though occasionally the action potentials are abnormally brief or polyphasic. Biopsies of muscle, except for slight atrophy of both type 1 and 2 fibers and an occasional degenerating fiber, have been normal. Administration of neostigmine has no effect. Muscle power and bulk are gradually restored when thyroid activity is reduced to normal levels.

Exophthalmic Ophthalmoplegia (Graves Ophthalmopathy)

(See also page 235) These terms refer to the co-occurrence of weakness of the ocular muscles and exophthalmos in patients with Graves disease (pupillary and ciliary muscles are always spared). The exophthalmos varies in degree, sometimes being absent at an early stage of the disease, and is not in itself responsible for the muscle weakness. Often there is orbital pain. Both the exophthalmos and the weakness of the extraocular muscles may precede the signs of hyperthyroidism, associated with the other classic features of hyperthyroidism (tachycardia, weight loss, tremor), or may follow effective treatment of the disorder. The eye signs become apparent over days or weeks. The extraocular muscle palsies or exophthalmos may occasionally be unilateral, especially at the onset of the illness. Any of the external eye muscles may be affected, usually one more than others, accounting for strabismus and diplopia; the inferior and medial recti are the most frequently affected, but upward movements are usually limited as well. The typical but not invariable sign of lid retraction imparts a staring appearance. Subtle exophthalmos can be appreciated by standing above and behind the seated patient and observing the relative positions of the lids and the eyelashes. Conjunctival edema and vascular engorgement over the insertions of the medial and lateral rectus muscles can be appreciated by inspecting the globe in its extreme lateral positions. In advanced cases, the enlarged muscle insertions themselves can be detected by inspection and palpation. These swollen muscles are visible on orbital ultrasound, computed tomography, and magnetic resonance imaging.

Examination of the eye muscles in biopsy and autopsy material has shown prominent fibroblasts, many degenerated fibers, and infiltrations of lymphocytes, mononuclear leukocytes, and lipocytes; hence the term *infiltrative ophthalmopathy*. These histopathologic findings are suggestive of an autoimmune disease—a hypothesis supported by the finding of serum antibodies that react with extracts of eye muscles (Kodama et al). Possibly the antibodies target glycosaminoglycans of the orbital fibroblasts. β -adrenergic sensitivity of muscle fibers caused by excessive thyroid hormone has also been postulated. Other factors may be involved, such as the small size of oculomotor motor units, the absence of dystrophin, and the rich mitochondrial content. The condition often runs a self-limited course, as does the exophthalmos, and therapy is difficult to evaluate. Certainly the maintenance of a euthyroid state is desirable (Dresner and Kennerdell).

Treatment If the exophthalmos is slight, topical applications of adrenergic blocking agents (guanethidine eye drops, 5%) and ophthalmic ointment to prevent corneal drying are adequate. Severe exophthalmos, marked by periorbital and conjunctival edema, and the extraocular muscle weakness may be partially controlled by high doses of corticosteroids (about 80 mg/day prednisone). Because of the hazards of protracted corticosteroid therapy, this approach should be reserved for patients who would otherwise require surgical intervention to decompress the contents of the orbit. In a number of such cases it has been possible for the patient treated with corticosteroids to weather the crisis and avoid the damaging effects of extreme exophthalmos and risks of surgery. Exophthalmos of a degree that threatens to injure the cornea or cause blindness requires tarsorrhaphy or decompression by removal of the roof of the orbit.

Thyrotoxic Periodic Paralysis This disorder closely resembles familial hypokalemic periodic paralysis (pages 1270 and 1272) and consists of attacks of mild to severe weakness of the muscles of

the trunk and limbs; usually the cranial muscles are spared. The weakness develops over a period of a few minutes or hours and lasts for part of a day or longer. In some series of patients with periodic paralysis, as many as half have had hyperthyroidism and most of them have been Asian males. Unlike the typical hypokalemic form, thyrotoxic periodic paralysis is not a familial disorder, and its onset is usually in early adult life. Nevertheless, in most of the thyrotoxic cases, the serum potassium levels have been low during the attacks of weakness, and the administration of 100 to 200 mg of potassium chloride has terminated the episodes. Propranolol in doses of 160 mg daily in divided doses is also helpful in preventing the episodes. Effective treatment of the hyperthyroidism abolishes the periodic attacks of weakness in more than 90 percent of cases. Other aspects of periodic paralysis are discussed in Chap. 54.

Myasthenia Gravis with Hyperthyroidism Myasthenia is discussed fully in Chap. 53. Here only a few remarks are made on its special relationship to thyrotoxicosis. Myasthenia gravis, in its typical autoimmune, anticholinesterase-responsive form, may accompany hyperthyroidism or, rarely, hypothyroidism, which are also considered to be autoimmune diseases. Approximately 5 percent of patients with myasthenia have hyperthyroidism, and the frequency of myasthenia gravis in patients with hyperthyroidism is 20 to 30 times that in the general population. Either condition may appear first, or they may coincide. The weakness and atrophy of chronic thyrotoxic myopathy may be added to that of the myasthenia without appearing to affect the requirement for or response to neostigmine. By contrast, hypothyroidism, even of mild degree, seems to aggravate myasthenia gravis, greatly increasing the need for pyridostigmine and at times inducing a myasthenic crisis. Also, in the latter case, thyroxine is beneficial and, with respect to myasthenia, restores the patient to the status that existed before the onset of thyroid insufficiency. The myasthenia should probably be regarded as an autoimmune disease independent of the thyroid disease, and each must be treated separately.

Hypothyroid Myopathy Abnormalities of skeletal muscle—consisting of diffuse myalgia and increased volume, stiffness, and slowness of contraction and relaxation—are common manifestations of hypothyroidism, whether in the form of myxedema or cretinism. These changes probably account for the relatively large tongue and dysarthria that one observes in myxedema. Weakness, however, is not a prominent feature. The presence of action myospasm and myokymia (both of which are rare) and of percussion myoedema and slowness of both the contraction and relaxation phases of tendon reflexes assists the examiner in making a bedside diagnosis. Cretinism in association with these muscle abnormalities is known as the *Kocher-Debré-Semelaigne syndrome*, and myxedema in childhood or adult life with muscle hypertrophy is known as the *Hoffmann syndrome*; the latter simulates hypertrophy muscularis vera and myotonia congenita. In neither cretinism nor myxedema, however, is there evidence of true myotonia, either by clinical test or by EMG, although muscle action potentials are myopathic and often show bizarre high-frequency discharges. Serum transaminase values are normal, but CK levels are usually elevated, often markedly so. Serum globulin may also be increased. Muscle biopsies have disclosed only the presence of large fibers or an increase in the proportion of small fibers (either type 1 or 2) and slight distention of the sarcoplasmic reticulum and subsarcolemmal glycogen (probably all due to disuse atrophy).

The administration of thyroxine corrects the muscle disturbance.

Pathogenesis of the Thyroid Myopathies How thyroid hormone affects the muscle fiber is still a matter of conjecture. Clinical data indicate that thyroxine influences the contractile process in some manner but does not interfere with the transmission of impulses in the peripheral nerve across the myoneural junction or along the sarcolemma. In hyperthyroidism this functional disorder enhances the speed of the contractile process and reduces its duration, the net effect being fatigability, weakness, and loss of endurance of muscle action. In hypothyroidism, muscle contraction is slowed, as is relaxation, and its duration is prolonged.

The speed of the contractile process is related to the quantity of myosin adenosinetriphosphatase (ATPase), which is increased in hyperthyroid muscle and decreased in hypothyroid muscle. The speed of relaxation depends on the rate of release and reaccumulation of calcium in the endoplasmic reticulum. This is slowed in hypothyroidism and increased in hyperthyroidism (Ianuzzo et al). The myopathic effects of hypothyroidism need to be distinguished from those of a neuropathy, which may rarely complicate hypothyroidism (page 1151).

Corticosteroid Myopathies

The widespread use of adrenal corticosteroids has created a class of muscle diseases similar to the one that occurs in the Cushing syndrome (Müller and Kugelberg). A deficiency of corticosteroids, as occurs in Addison disease, also causes generalized weakness, but without an identifiable muscle disease.

Corticosteroid and Cushing Disease Myopathy The prolonged use of corticosteroids causes the proximal limb and girdle musculature to become weak, to the point where the patient may have difficulty in elevating the arms and arising from a sitting, squatting, or kneeling position; walking, particularly up stairs, may also be hampered. Some individuals seem to be more susceptible than others. The problem often arises of distinguishing an iatrogenic steroid-induced myopathy from the weakness produced by a primary neuromuscular disease that is being treated with these medications. The EMG is either normal or mildly myopathic, with small and abundant action potentials but no fibrillations. Biopsies disclose only a slight variation in fiber size, with atrophic fibers, mainly of type 2b, but little or no fiber necrosis and no inflammatory cells. Electron microscopically, there are aggregates of mitochondria, accumulations of glycogen and lipid, and slight myofibrillar loss (disuse atrophy). The serum CK and aldolase are usually normal. These changes are the same as those that characterize Cushing disease and may suggest that diagnosis (page 488).

There is only a poor correlation between the total dose of corticosteroid and the severity of muscle weakness. Nevertheless, in patients who develop this type of myopathy, the corticosteroid dosage has usually been high and sustained over a period of months or years. All corticosteroids may produce the disorder, although fluorinated ones are said to be more culpable than others. Discontinuation or reduction of corticosteroid administration leads to gradual improvement and recovery; alternate day regimens may also be helpful.

The mechanism by which corticosteroids cause muscle weakness is not known. In corticosteroid-treated animals, there is a mea-

surable decrease in the uptake of amino acids and protein synthesis by muscle cells.

Acute Steroid Myopathy (Critical Illness Myopathy; Acute Quadriplegic Myopathy) In addition to the well-known proximal myopathy induced by the long-term use of steroids, an acute and severe myopathy has been recognized in critically ill patients. It was described initially in patients with severe asthma who were exposed to high doses of steroids. Subsequently this acute myopathy has been recognized with numerous critical systemic diseases and organ failures, again, in the context of treatment with high doses of corticosteroids and, in a few cases, with sepsis and shock alone. The use of neuromuscular blocking agents appears to play an important complementary role in the genesis of the myopathy, being a factor in over 80 percent of reported cases, but it is uncertain whether these agents alone can produce a similar process (see reviews by Gorson and Ropper, Lacomis et al, and Barohn et al).

Patients who acquire this problem have generally been exposed to high doses of corticosteroids, sometimes for only brief periods. Exceptional instances have been reported in which the myopathy was induced by doses as low as 60 mg prednisone administered for 5 days, but we have not encountered such a case. The degree and type of simultaneous exposure to neuromuscular blocking agents has varied, but the doses have generally been quite high, falling in the range of a total dose of 500 to 4000 mg of pancuronium or its equivalent over several days.

The severe muscle weakness usually becomes evident when the systemic illness subsides, as attempts are made to wean the patient from the ventilator. The tendon reflexes are normal or diminished and there may be confounding features of a polyneuropathy, which is also known to be induced by critical illness and sepsis (page 1128). Most of our patients with acute myopathy have recovered over a period of many weeks after the corticosteroid agent has been withdrawn, but a few have remained weak for as long as a year.

Serum CK is elevated, at least early in the process. The EMG discloses the characteristic features of a myopathy; often there are fibrillations as well, theorized to be due to separation of the motor end-plate region from intact segments of muscle fibers. Polyneuropathy and residual effects of neuromuscular blockade can be excluded by appropriate electrophysiologic studies. Muscle biopsy shows varying degrees of necrosis and vacuolation affecting mainly type 2 fibers. The most characteristic feature is a striking loss of thick (myosin) filaments. Severe degrees of muscle necrosis have been accompanied by massively elevated CK levels and by myoglobinuria and renal failure.

Several experimental observations may explain the apparent additive effect on muscle of corticosteroids and neuromuscular blocking agents. Animals exposed to high doses of steroids soon after muscle denervation display a selective loss of myosin, the characteristic finding of acute steroid myopathy. This depletion of myosin is reversed by reinnervation but not by withdrawal of the corticosteroids. Furthermore, denervation of muscle has been found to induce an increase in glucocorticoid receptors on the surface of the muscle. Dubois and Almon have postulated that exposure to neuromuscular blocking agents creates a functional denervation, rendering the muscle fiber vulnerable to the damaging effects of steroids. It is curious that this myopathy has not been seen after high-dose corticosteroid administration for neurologic diseases such as multiple sclerosis, but the observation of Panegyres and colleagues of a patient with myasthenia who developed a severe,

myosin-depleted myopathy following high doses of methylprednisolone supports such a dual action of denervation (at the post-synaptic membrane) and glucocorticoids.

Adrenocortical Insufficiency

Generalized weakness and fatigability are characteristic of adrenocortical insufficiency, whether *primary* in type, i.e., due to *Addison disease* (infectious, neoplastic, or autoimmune destruction of the adrenal glands or adrenal hemorrhage), or secondary to a pituitary deficiency of adrenocorticotrophic hormone (ACTH). The weakness and fatigability, however, are related to mostly water and electrolyte disturbances and hypotension, not to a primary disorder of muscle. Biopsy has not disclosed any abnormalities of muscle, and postmortem examination of the muscle in one case showed no changes. Likewise, the EMG is normal, and the tendon reflexes are retained. Addisonian weakness responds (as does hyperkalemic paralysis) to glucocorticoid and mineralocorticoid replacement.

Primary Aldosteronism Production of an excess of aldosterone by adrenal adenomas has been the subject of many articles, one of the earliest and most notable being that of Conn. Muscular weakness has been observed in three-quarters of the reported cases, and in nearly half of them there was either hypokalemic periodic paralysis or tetany. Chronic potassium deficiency may express itself either by periodic weakness or by a chronic myopathic weakness. An associated severe alkalosis causes the tetany. As in the weakness of Addison disease, there is no structural disorder of muscle except perhaps for vacuolation, which is the result of severe hypokalemia.

Diseases of Parathyroid Glands and Vitamin D Deficiency

A small proportion of patients with *parathyroid adenomas* complain of weakness and fatigability. Vicale described the first example of this disorder and remarked on the muscular atrophy and weakness and the pain on passive or active movement. The tendon reflexes were retained. A few scattered muscle fibers had undergone degeneration. Claims for a denervative process are disputed. We have not been impressed with either a myopathy or neuropathy in this disease.

In *hypoparathyroidism*, muscle cramping is prominent but there are no other neuromuscular manifestations. In both hypoparathyroidism and pseudohypoparathyroidism—the latter with characteristic skeletal abnormalities and, in some instances, mental slowness—the most important muscle abnormality is *tetany*. This is due to low ionized serum calcium, which depolarizes axons more than muscle fibers (see pages 1096 and 1276).

Osteomalacia, due to vitamin D deficiency and disorders of renal tubular absorption, often includes muscle weakness and pain as common complaints, similar to those in patients with primary hyperparathyroidism and uremia (see Layzer for further comment).

More striking than any of the foregoing disturbances, in our view, has been a chronic proximal myopathy in conjunction with hypophosphatemia associated with solitary bone cysts. In two of our patients, removal of the cyst restored serum phosphorus levels and cured the generalized muscle weakness. Also known is an uncommon syndrome of severe hypophosphatemia and generalized bone pain in association with usually benign mesenchymal tumors

of soft tissue and bone (*oncogenic hypophosphatemia*). These tumors express a type of fibroblast growth factor that induces renal wasting of phosphorous. Hypophosphatemic myopathic weakness has been noted in our critical care unit, often precipitated by hyperalimentation solutions; the onset of weakness can be so abrupt as to simulate the Guillain-Barré syndrome. The oral administration of phosphates to raise the serum phosphorus cures the nonneoplastic cases. Some cases are accompanied by pain and stiffness. Presumably the phosphorus depletion in these disorders limits the phosphorylation reactions and the synthesis of ATP in muscle.

Diseases of the Pituitary Gland

Proximal muscle weakness and atrophy have been recorded as late developments in many *acromegalic* patients. Formerly thought to be due to neuropathy, these symptoms in acromegaly have been convincingly shown by Mastaglia and colleagues to be the result of a chronic polymyopathy. The serum CK is slightly elevated in some cases, and myopathic potentials are observed in the EMG. Biopsy specimens have shown atrophy and reduced numbers of type 2 fibers but necrosis of only a few fibers. Treatment of the pituitary adenoma and correction of the hormonal changes restores strength. A mild peripheral neuropathy of sensorimotor type has also been reported in a few patients with acromegaly but is less frequent than carpal tunnel syndrome in this disease.

MYOPATHIES DUE TO DRUGS AND TOXINS

A vast number of drugs and other chemical agents have been identified as myotoxic. Curry and colleagues, in 1989, found reports (in the English literature alone) of about 100 drugs that had caused rhabdomyolysis and myoglobinuria, mostly in an idiosyncratic manner. The list continues to grow, and additional myotoxic agents can be expected to appear as new drugs are introduced. It is not practical to describe all the myotoxins individually; they are, therefore, broadly categorized and their main features listed in Table 51-2.

Toxic agents produce myopathic changes in several ways. They may act directly on muscle cells, either diffusely or locally, as occurs with intramuscular injections, or the muscle damage can be due to diverse secondary factors—electrolyte disturbances (hypokalemia), renal failure, excessive energy requirements of muscle (as occur with drug-induced seizures and malignant hyperthermia), or inadequate delivery of oxygen and nutrients (drug-induced coma with compressive-ischemic injury of muscle). The most important category is that of direct toxic effect on the muscle membrane on the internal apparatus of the cell.

Several clinical features mark a myopathy as toxic in nature: lack of pre-existing muscular symptoms; predictable delay in onset of symptoms after exposure to a putative toxin; lack of any other cause for the myopathy; and often complete or partial resolution of symptoms after withdrawal of the toxic agent. Pathologically, this group of disorders is characterized by nonspecific myopathic changes, which in most severe degrees take the form of myonecrosis (rhabdomyolysis) and myoglobinuria. This necrotizing muscle syndrome is the most frequent and serious myotoxic syndrome and is discussed later, along with its more important causes.

Necrotizing Polymyopathy (Rhabdomyolysis) with Myoglobinuria In any disease that results in rapid destruction of striated

muscle fibers (rhabdomyolysis), myoglobin and other muscle proteins may enter the bloodstream and appear in the urine. The latter is “cola”-colored (burgundy red or brown), much like the urine in hemoglobinuria. In hemoglobinuria, however, the serum is initially pink, because hemoglobin (but not myoglobin) is bound to haptoglobin, and this complex is not excreted in the urine as readily as myoglobin; also, the hemoglobin molecule is three times as large as the myoglobin molecule. (The hemoglobin-haptoglobin complex is removed from the blood plasma over a period of hours and haptoglobin may be depleted, so that hemoglobinuria is present without grossly evident hemoglobinemia.) Differentiation of the two pigments in urine is difficult; both are guaiac-positive and may be detected by a “dipstick,” a test that can be used to advantage at the bedside in appropriate circumstances. Only small differences are seen on spectroscopic examination. The most sensitive means of detecting myoglobin is by radioimmunoassay. It should be mentioned that porphyrins are another cause of discoloration of the urine. The clinical picture in porphyria is one of a polyneuropathy and not a myopathy.

Many of the causes of myonecrosis and myoglobinuria have already been mentioned above and in previous chapters. Myoglobinuria may be detected in cases of acute inflammatory myopathy, in several types of glycogenosis (see Table 51-1), in carnitine palmitoyltransferase deficiency, and as a result of poisoning or therapeutic use of a vast array of drugs (including the combination of steroids and pancuronium, discussed earlier), toxins, and venoms (see Table 51-2). Myoglobinuria is an important feature of many other medical conditions: crush injury; extensive infarction of muscle; excessive use or repeated injury of muscles as occurs in status epilepticus, generalized tetanus, malignant neuroleptic syndrome, agitated delirium, prolonged marching, conga drumming, or simply excessive exercise—although the latter always suggests an underlying metabolic disease of muscle; electrical and lightning injuries; etc. Two noteworthy conditions that are characterized by myonecrosis and myoglobinuria are acute alcoholic intoxication and malignant hyperthermia. The former is described further on and the latter in Chap. 54, with the membrane channel disorders.

Regardless of the cause of the rhabdomyolysis, the affected muscles become painful and tender within a few hours. Power of contraction is diminished. Sometimes the skin and subcutaneous tissues overlying the affected muscles (nearly always of the limbs and sometimes of the trunk) are swollen and congested. There may be a low-grade fever and leukocytosis. If myoglobinuria is mild, recovery occurs within a few days and there is only a residual albuminuria. When myoglobinuria is severe, renal damage may ensue and lead to anuric renal failure requiring dialysis. The mechanism of the renal damage is not entirely clear; probably it is not simply a mechanical obstruction of tubules by precipitated myoglobin (although this does occur). It is more likely to result from massive rhabdomyolysis and, correspondingly, there is a very high CK level in the serum.

Treatment Alkalization of the urine by ingestion or infusion of sodium bicarbonate is said to protect the kidneys by preventing myoglobin casts, but in severe cases it is of doubtful value, and the sodium may actually be harmful if anuria has already developed. Diuresis induced by mannitol or by loop diuretics such as furosemide and by the administration of intravenous fluids also reduces the chances of anuric renal failure if given in time. Therapy is much the same as for the anuria that follows shock (see *Harrison's Principles of Internal Medicine*).

Statin-Induced Myopathy With the widespread use of these lipid-lowering medications, myotoxicity has become a well-described but probably overrated problem. Symptoms range in severity from mild muscular aches with slightly elevated CK concentrations in the serum to a rare but potentially fatal rhabdomyolic syndrome. The first generation of these drugs were fungal metabolites (lovastatin, paravastatin, simvastatin) and were infrequently implicated in muscle damage, but the new synthetic ones (atorvastatin, fluvastatin, cerivastatin) are more frequently toxic, especially when given with gemfibrozil. (The last of these has reportedly led to over 50 deaths from myoglobinuric renal failure and has been removed from the market.) Few cases are this dramatic. This subject has been reviewed by Thompson.

The mechanism of muscle damage is not well understood but it is likely that inherent enzymatic defects are present in a proportion of the severe cases (see the brief review by Farmer). In addition, the chronic use of statin drugs reduces levels of both ubiquinone and small guanosine triphosphate (GTP)-binding proteins, also plausible factors in statin-induced muscle toxicity. As mentioned, the combination of one of these medications with gemfibrozil is particularly likely to result in muscle damage. Drugs in the statin class with higher lipid solubility appear to have a greater potential for toxicity as a result of their increased muscle penetration.

A clinical problem arises when the CK level is elevated but the patient taking one of these medications has no muscular symptoms. It has been our general practice to continue the medication if the elevation of CK is in the low range and does not rise over time and if the medication is considered necessary. If alternative and safe means of lowering the lipid level are available, then they should be tried in lieu of a statin but each patient's circumstances differ. In a small series, Phillips and colleagues have called attention to a similarly vexing and not uncommon problem: myopathic symptoms such as muscle stiffness, tenderness, and weakness with normal CK concentrations. A trial of discontinuing the medication may be appropriate. Finally, we have encountered a number of patients whose CK levels have remained high for months or longer after the medications have been stopped. In a few of these patients, most otherwise asymptomatic, CK levels have remained high over years but we have had no way to ensure that the test was not abnormal before taking the statin. Noted on page 1134 is a polyneuropathy in which statin drugs have been tentatively implicated.

Colchicine Myoneuropathy This condition is included here as much for its clinical interest as for its curious histopathologic features. The drug, used widely in the treatment of gout, often gives rise to a mild subacute proximal muscular weakness, but has also produced an acute necrotizing myopathy. Most instances of the latter have occurred in patients with a degree of renal failure, which allows accumulation of the drug (even though the drug is metabolized predominantly by the liver). In a few instances it has affected the cranial musculature and the diaphragm. Many cases also show clinical or electrophysiologic evidence of a polyneuropathy as pointed out by Kuncl and colleagues, leading to the term *colchicine myoneuropathy*. The reflexes are diminished and there is mild distal sensory loss. Rare cases of colchicine-induced hypokalemic periodic paralysis and also of myotonia have been reported.

The serum CK concentration may be elevated or normal. The muscle biopsy shows elements of both myopathic and neuropathic disease, with the special feature in muscle of rimmed vacuoles on

Table 51-2
Features of toxin-induced myopathies

MYOPATHIC SYNDROME	AGENT	CLINICAL FEATURES	PATHOLOGY	LABORATORY FINDINGS ^a
Necrotizing myopathy (rhabdomyolysis)	1. Statin drugs 2. Alcohol abuse 3. Clofibrate, gemfibrozil 4. Amphetamine derivatives 5. Hypervitaminosis E 6. Organophosphates 7. Snake venoms 8. High-dose corticosteroids in critical illness 9. Mushroom poisoning (<i>Amanita phalloides</i>) 10. Cocaine	Acute/subacute painful proximal myopathy; tendon reflexes usually preserved 5. Painless 7. Severe, acute intoxication 8. Neuromuscular blockers implicated 9. Loss of myosin Severe proximal and distal weakness ventilated patients on pancuronium) 2. Chronic 1. Diuretics 2. Laxatives 3. Licorice, carbenoxolone 4. Amphotericin B, toluene 5. Alcohol abuse	Necrosis, regeneration 5. Paracrystalline inclusion bodies 1. Necrosis of mainly type 2 fibers; loss of myosin; vacuolar changes 2. Type 2 fiber atrophy Necrosis, regeneration, vacuolization Proximal muscle pain and weakness, sensorimotor neuropathy, cardiomopathy	CK ↑↑, myoglobinuria +/− Blood lymphocytosis CK ↑↑, myoglobinuria +/−, hypokalemia CK ↑ Focal mitochondrial loss, vacuoles Vacuolar myopathy (rimmed vacuoles)
Hypokalemic myopathy	1. Chloroquine (>500 mg), hydroxychloroquine, quinacrine, plasmocid 2. Aminodarone 3. Perhexiline	Myalgia, proximal weakness, cardiomopathy	CK ↑	CK ↑
Impaired protein synthesis	Ipecac syrup, emetine	Proximal weakness, peripheral neuropathy; CK may be normal	CK ↑	CK ↑
Antimicrotubular myopathy	1. Colchicine 2. Vinristine			

Inflammatory myopathy	1. D-penicillamine 2. Procainamide 3. Cimetidine? Ciguatera toxin? 1. Toxic oil syndrome	Proximal muscle pain, weakness, skin changes possible	Inflammation, necrosis, regeneration
Fasciitis, perimyositis, microangiopathy	Myalgia, skin changes, peripheral neuropathy, other systems also affected	Vasculitis, connective tissue infiltration	Eosinophilia
Mitochondrial myopathy	2. Eosinophilia-myalgia syndrome 1. Zidovudine 2. Germanium 1. Cyclosporine 1. Labetalol 3. Anthracycline antibiotics 4. Rifampin, amiodarone	Proximal myalgia and weakness	Ragged red fibers, necrosis, regeneration
Various	1. Acute: IM injection of various drugs—e.g., cephalothin, lidocaine, diazepam 2. Chronic: Repeated IM injections—e.g., pethidine, pentazocine, intravenous drug abuse, antibiotics (in children)	3. Humans: only cardiomyopathy Local pain, swelling, sometimes abscess formation Induration and contracture of injected muscles	CK ↑ Focal necrosis Normal

^a CK (serum creatinine kinase): ↑ (mild), ↑↑ (moderate), ↑↑↑ (marked) elevations; myoglobinuria: +/− (may be present).

the Gomori trichome stain; the latter are more central in the muscle fibers than those seen with inclusion body myopathy.

The mechanism of the myopathy is not fully understood but is probably attributable to the drug's interference with tubulin, a protein required for the polymerization of microtubules in muscle and nerve. Weakness resolves in a matter of days or weeks when the drug is discontinued but the neuropathic features may remain.

Alcoholic Toxic Myopathy Several forms of muscle weakness have been ascribed to alcoholism. In one type, a painless and predominantly proximal weakness develops over a period of several days or weeks in the course of a prolonged drinking bout and is associated with severe degrees of *hypokalemia* (serum levels <2 meq/L). The urinary excretion of potassium is not significantly increased; depletion is probably the result of vomiting and diarrhea, which usually precede the onset of muscular weakness. In addition, serum levels of liver and muscle enzymes are markedly elevated. Biopsies from severely weakened muscles show single-fiber necrosis and vacuolation. Treatment consists of the administration of potassium chloride intravenously (about 120 meq daily for several days), after which oral administration suffices. Strength returns gradually in 7 to 14 days, and enzyme levels return to normal concomitantly.

A more dramatic myopathic syndrome, occurring acutely at the height of a prolonged drinking bout, and appropriately termed *acute alcoholic myopathy*, is manifest by severe pain, tenderness, and edema of the muscles of the limbs and trunk, accompanied in severe cases by renal damage (see Hed et al). Hypokalemia is not implicated. The muscle affection is generalized in some patients and remarkably focal in others. A swollen, painful, tender limb or part of a limb may give the appearance of a deep venous thrombosis or lymphatic obstruction. Myonecrosis is reflected by high serum levels of CK and aldolase and the appearance of myoglobin in the urine, leading in the most severe cases to fatal myoglobinuric renal failure. Indeed, in a general hospital alcoholism is one of the most common causes of rhabdomyolysis and myoglobinuria rivaled only

by status epilepticus and trauma. Some patients recover within a few weeks, but others require several months, and relapse during another drinking spree occurs frequently. Restoration of motor power is attendant upon muscle regeneration but may be complicated by polyneuropathy and other syndromes of neuromuscular disability associated with alcoholism. Haller and Drachman have produced rhabdomyolysis (with elevated CK and myoglobinuria) in rats by subjecting the animals to a brief fast following a 2- to 4-week exposure to alcohol, suggesting that a similar mechanism may be operative in alcoholic individuals.

Perkoff and his associates described what is presumably a third form of acute muscular disorder in alcoholics, characterized by severe muscular cramps and diffuse weakness, occurring in the course of a sustained drinking bout. They noted a number of biochemical abnormalities in these patients as well as in asymptomatic alcoholics who had been drinking heavily for a sustained period before admission to the hospital—elevated serum levels of CK, myoglobinuria, and a diminished rise in blood lactic acid in response to ischemic exercise, as occurs in McArdle disease. In distinction to the latter, however, myophosphorylase levels were not consistently reduced in the alcoholic patients.

From time to time one observes in alcoholics the subacute or chronic evolution of painless weakness and atrophy of the proximal muscles of the limbs, especially of the legs, with only minimal signs of neuropathy in the distal segments of the legs and feet. Cases such as these have been referred to as *chronic alcoholic myopathy*, implying a direct toxic effect of alcohol on muscle, but the data are insufficient to warrant such an assumption. Some of these cases have shown necrosis of individual muscle fibers and other signs of polymyositis; most cases seen by the authors have proved to be neuropathic in nature. This has been the experience of others as well (Faris and Reyes; Rossouw et al). Treatment follows along the lines indicated for nutritional-alcoholic neuropathy (page 990), and complete recovery can be expected if the patient abstains from alcohol and maintains adequate nutrition.

CHAPTER 52

THE CONGENITAL NEUROMUSCULAR DISORDERS

Included under this title are two sizable groups of muscle diseases—one is an assemblage of old congenital deformities that involve muscle, and the other is a unique class of hereditary diseases called congenital myopathies. Insofar as all of the disorders comprising these categories develop in utero, i.e., are congenital, it may be helpful by way of introduction to summarize briefly the main facts about the natural development and aging of muscle. Such diseases are of particular importance in pediatric neurology, for most of them attract notice at an early age.

The Development and Aging of Muscle

The commonly accepted view of the embryogenesis of muscle is that muscle fibers form by fusion of myoblasts soon after the latter differentiate from somatic mesodermal cells. Muscle connective tissue derives from the somatopleural mesoderm. The myoblasts, which are postmitotic, are spindle-shaped mononuclear cells that fuse to form muscle fibers. After fusion, a series of cellular events including the sequential activation of myogenic transcription factors leads to myofibril formation. The newly formed fibers are thin, centrally nucleated tubes (appropriately called *myotubes*) in which myofilaments begin to be produced from polyribosomes. As myofilaments become organized into myofibrils, the nuclei of the muscle fiber are displaced peripherally to a subsarcolemmal position. Once the nuclei assume a peripheral position, the myofiber is formed. The detailed mechanisms whereby myoblasts seek one another, the manner in which each of a series of fused nuclei contribute to the myotube, the formation of actin and myosin fibrils, Z-discs, and the differentiation of a small residue of satellite cells on the surface of the fibers are reviewed by Rubenstein and Kelly.

The mechanisms that determine the number and arrangement of fibers in each muscle are not as well understood. Presumably the myoblasts themselves possess the genetic information that controls the program of development, but within any given species there are wide familial and individual variations, which account for obvious differences in the size of muscles and their power of contraction.

The number of fibers assigned to each muscle is probably attained by birth, and growth of muscle thereafter depends mainly on the enlargement of fibers. Although the nervous system and musculature develop independently, muscle fibers continue to grow after birth only when they are active and under the influence of nerve. Measurements of muscle fiber diameters from birth to old age show the growth curve ascending rapidly in the early postnatal years and less rapidly in adolescence, reaching a peak during the third decade. After puberty, growth of muscle is less in females than in males, and such differences are greater in the arm, shoulder, and pelvic muscles than in those of the leg; growth in ocular muscles is about equal in the two sexes. At all ages, disuse of muscle decreases fiber size by as much as 30 percent (at the expense of myofibrils), and overuse increases the size by about the same amount (work hypertrophy). Normally, type 1 (oxidative enzyme-rich) fibers are slightly smaller than type 2 (phosphorylative en-

zyme-rich) fibers; the numerical proportions of the two fiber types vary in different muscles in accordance with their natural functions.

During late adult life, the number of muscle fibers diminishes and variation in fiber size increases. The variations are of two types: *group atrophy*, in which clusters of 20 to 30 fibers are all reduced in diameter to about the same extent, and *random single-fiber atrophy*. Also, there is enlargement of other fibers. The exercising of young animal muscle causes a hypertrophy of high-oxidative type 1 fibers and an increase in the proportion of low-oxidative type 2 fibers; aging muscle lacks this capacity—exercise produces only an increase in the proportion of type 2 fibers (Silbermann et al.). No such data are available in humans, but clinical observation suggests that with aging, the capacity of muscle to respond to intense, sustained exercise is diminished. Also, muscle cells, like other cells of postmitotic type, are subject to aging changes (lipofuscin accumulation, autophagic vacuolization, enzyme loss) and to death. Group atrophy, present to a slight degree in 90 percent of gastercnemii in individuals more than 60 years of age, represents denervation effect from an aging-related loss of lumbar motor neurons and peripheral nerve fibers. Further comments regarding muscle and aging can be found in Chap. 29.

Denervation from spinal motor neuron or nerve disease at every age has roughly the same effect—namely, atrophy of muscle fibers (first in random distribution, then in groups) and later, degeneration. Muscle necrosis at all ages excites a regenerative response from sarcolemmal and satellite cells in any intact parts of the fibers. Presumably, if this occurs repeatedly, the regenerative potential wanes, with ultimate death of the fiber—leading to permanent depopulation of fibers with the expected muscle weakness.

CONGENITAL DEFORMITIES INVOLVING MUSCLE

Congenital Fibrous Contractures of Muscle and Joint Deformities

Arthrogryposis (Arthrogryposis Multiplex Congenita) (Table 52-1) *Multiple congenital contractures, multiple congenital articular rigidities, and amyoplasia congenita* are some of the names that have been applied to congenital deformity and rigidity of many joints. This disorder, now generally referred to as *arthrogryposis*

Table 52-1
The main causes of arthrogryposis

- Werdnig-Hoffmann motor neuron disease
- Myotonic dystrophy
- Congenital myasthenia gravis (see Chap. 53)
- Congenital polymyopathy
- Neonatal neuropathy
- Prader-Willi syndrome
- Amyoplasia (focal arthrogryposis)

(literally, curved joints), has been estimated to occur once in 3000 births. The deformities result from a lack of movement during fetal development and can therefore be produced by any disorder that immobilizes the developing embryo—whether it be a lack of anterior horn cells, peripheral nerves, the motor end plate (as in an infant born to a myasthenic mother), or muscle as discussed in Chap. 48. Often there are associated developmental defects of the nervous system and somatic structures—low-set ears, wide and flat nose, micrognathia, and high-arched palate; less often, there is a short neck, congenital heart disease, hypoplasia of the lungs, and cryptorchidism.

Of the many conditions that underlie arthrogryposis, *developmental abnormalities of the anterior horn cells* (mainly Werdnig-Hoffmann disease, as discussed in Chap. 39) are by far the most common. A failure in development of anterior horn cells results in an uneven smallness and paresis of limb muscles. The unopposed contraction of relatively normally innervated muscles sets the fixed deformities. In a less common group of myopathic causes of arthrogryposis, the nervous system is usually intact and the disease is that of a polymyopathy or congenital muscular dystrophy. It is of interest that in the myopathic variety, the limbs are fixed in a position of flexion at the hips and knees and adduction of the legs, in contrast to the variable postures of the myelopathic (anterior horn cell) form. Also, the latter is more frequently conjoined with multiple anomalies than is the myopathic type. In addition to these two well-recognized types, occasional cases of arthrogryposis are attributable to a neonatal neuropathy, neonatal myasthenia gravis, and the Prader-Willi syndrome (causing intrauterine hypotonia) as noted in Table 52-1.

An infant with arthrogryposis should be evaluated with an electromyogram (EMG) that is interpreted by an experienced electromyographer, and by a biopsy of muscle for the detection of group atrophy and of the congenital polymyopathies described further on in this chapter. Both of these tests are quite difficult to interpret in the premature and term infant with an incompletely formed nervous system. In many circumstances, it is valuable to delay them until several weeks of postterm development. Sometimes the electrophysiologic and biopsy tests may have to be repeated after several weeks or more to give a definitive diagnosis. If the initial evaluations are unrevealing, an imaging study of the brain to detect cerebral malformations and high-resolution banding of chromosome structure (for Prader-Willi syndrome) may prove useful additional tests.

Congenital Focal Fibrous Contractures This term refers to a fixation of limb posture due to a developmental lack or destruction of muscles, with shortening and fibrosis of supporting tissue and ligaments. A surprising number of deformities in infants and children are traceable to this type of defect. The most common are congenital clubfoot (talipes), congenital torticollis, congenital elevation of the scapula (Sprengel deformity), and congenital dislocation of the hips. In all these conditions the postural distortion is produced and maintained either by a weakened, fibrotic muscle or by a normal one that is contracted and shortened because of the absence of a countervailing antagonist. Trauma to a muscle during intrauterine life or at birth may lead to fibrosis and to fibrous contracture in some cases.

Congenital Clubfoot Here the deformity may be one of plantar flexion of the foot and ankle (talipes equinus), inversion (talipes varus or clubfoot), eversion (talipes valgus or splayfoot), or dorsiflexion of foot and ankle (talipes calcaneus). About 75 percent of

all cases are of the equinovarus clubfoot variety (i.e., the foot turns downward and inward). Usually both feet are affected. Multiple incidence in one family may occur. Several explanations of cause and pathogenesis have been offered: fetal malposition, an embryonic abnormality of tarsal and metatarsal bones, a primary defect in nerves or anterior horn cells of the spinal cord, or a congenital dystrophy of muscle. No one theory explains all cases and available pathologic data exclude a single cause and pathogenesis. In some instances clubfoot is the only recognizable congenital abnormality, but more often it occurs as a manifestation of generalized arthrogryposis (see later) and is an indicator of a more widespread involvement of the central nervous system. (See Kakulas and Adams and also Banker for pertinent literature on the subject.)

Congenital Torticollis (Wryneck) This disorder begins during the first months of life and, unlike the torticollis of adults discussed in Chap. 6, it is not the result of a dystonia but instead is due to congenital shortening of the sternocleidomastoid muscle, which is firm and taut. The head is inclined to one side and the occiput slightly rotated to the side of the affected muscle. This disorder is nonfamilial and is usually ascribed to injury of the sternocleidomastoid at birth. Whether the injury is a purely mechanical one to the muscle itself or is due to ischemia stemming from arterial or venous occlusion (or an entirely different cause) is not totally clear. It often gives rise to a sternocleidomastoid tumor (actually a pseudotumor) that appears, on exploration, as a pale, spindle-shaped swelling of the muscle belly. The histologic findings are similar to those of Volkmann contracture, i.e., replacement of the muscle fibers by relatively acellular connective tissue, suggesting that an ischemic mechanism underlies the defect in some cases.

Congenital Absence of Muscles (Amyoplasia)

It is well known that some individuals are born without certain muscles. This pertains not only to certain inconstant and functionally unimportant muscles, such as the palmaris longus, but also to more constant and substantial ones as well. The muscles found to be absent most frequently are the pectoralis, trapezius, serratus anterior, and quadriceps femoris, but many others are missing in isolated cases.

Congenital absence of muscle is usually associated with congenital anomalies of neighboring nonmuscular tissues. For example, congenital absence of the pectoral muscle is often accompanied by aplasia or hypoplasia of the mammary or of syndactyly and microdactyly. Agenesis of the pectoral muscle may also be associated with scoliosis, webbed fingers, and underdevelopment of the ipsilateral arm and hand (Poland syndrome). Another unusual syndrome consists of congenital absence of portions of the abdominal muscles ("prune belly"), often in association with arthrogryposis and a defect of ureters, bladder, and genital organs. There is also an association in a few cases between a congenital amyoplasia and facioscapulohumeral muscular dystrophy.

Restricted Nuclear Amyotrophies

In another group of restricted palsies, the essential abnormality appears to lie in the central nervous system (nuclear amyotrophies). One of the most frequent is congenital ptosis due to an inborn defect of the innervation of the levator palpebrae muscles. Complete paralysis of all muscles supplied by the oculomotor nerve, due apparently to hypoplasia of the third nerve nuclei, may be

observed in several members of a family and occasionally in only one member. As discussed in Chap. 14, congenital Horner syndrome may be familial; it is associated with depigmentation of the iris (heterochromia iridis). Bilateral abducens palsy is often associated with bifacial palsy in the newborn and is known as the *Möbius syndrome*; this usually nonfamilial anomaly, the cause of which is thought to be a nuclear hypoplasia or aplasia, is discussed with the developmental disorders (page 873). In these familial nuclear amyotrophies the muscles develop independently of the nervous system but have no prospect of attaining their natural growth and function—and indeed of surviving—because of failure of innervation. It is a kind of congenital denervation hypotrophy. Of course, a primary muscle defect may also give rise to bifacial weakness, as in facioscapulohumeral muscular dystrophy.

RELATIVELY NONPROGRESSIVE AND SLOWLY PROGRESSIVE CONGENITAL POLYMYOPATHIES

(See Table 52-2)

Beginning in 1956, with the account by Shy and Magee of a patient whose muscle fibers showed a peculiar central densification of sarcoplasm ("cores"), a new class of hereditary diseases of muscle was delineated. The more common and better-defined members of this group are the *central core*, *nemaline* (rod-body), *centronuclear myopathies* and *myofibrillar degeneration*, and *myopathy with tubular aggregates*. As the names imply, in each of these diseases there is no loss of muscle fibers but within each fiber there is a distinctive morphologic abnormality. These illnesses may express themselves early in life by a lack of muscle bulk, hypotonia, weakness of the limbs, and often with additional mild dysmorphic features of other parts of the body. A variety of other morphologic types of congenital myopathy have been described, but they are relatively uncommon and some are of dubious specificity; they are mentioned only briefly.

Further study has revealed that the diseases of this group are not confined to infancy and early childhood and some of them, especially those present at birth, are not as benign as their early descriptions implied. Each of the entities mentioned above has been observed at a later age, even in middle adult life. Indeed, if the disease is mild, there is often no way of deciding whether it had been present since birth.

The characteristic feature of most of these myopathies is *lack of progression or extremely slow progression*, in contrast to the more rapid pace of many muscular dystrophies, of Werdnig-Hoffmann disease, and of other forms of hereditary motor system disease of childhood and adolescence. Exceptionally, an example of more rapid progression of a congenital myopathy has been reported, and prior to the use of histochemical and electron microscopic techniques, such patients were usually considered to have a "benign muscular dystrophy." Familial occurrence has also been established in some types, so the clinical line of separation between this group of diseases and some of the more slowly progressive muscular dystrophies may in certain cases remain ambiguous. There is no specific treatment for any of the congenital myopathies.

As mentioned earlier, the characteristic lesions in the congenital myopathies are revealed most clearly by the systematic application of histochemical stains to frozen sections and by phase and electron microscopy. Some of the abnormalities are also disclosed by the conventional stains used in light microscopy, but as a group their identification has been the product of newer histologic techniques.

A word of caution is in order about the specificity of some of the morphologic changes and the classifications of the congenital myopathies based upon these changes. It is inadvisable to assume that a change in a single organelle or a subtle change in the sarcoplasm of a muscle fiber can be relied upon to characterize a pathologic process. Indeed, as more careful studies were made of this class of disease, the specificity of the lesions came to be questioned. For example, central cores are sometimes found in the same

Table 52-2
The congenital polymeopathies

TYPE	GENETICS	GENE OR CHROMOSOME	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
Central core disease	AD, AR	Ryanodine receptor	1st–2nd	1–10 x	Diffuse myopathy presenting in infancy Proximal myopathy beginning in adolescence Risk of malignant hyperthermia May include mental retardation
Nemaline rod myopathy	AD, AR	α -Tropomyosin Nebulin β -Tropomyosin Ryanodine receptor Troponin T1 α -Actin	1st–2nd	1–2 x	Diverse phenotypes May present as severe congenital myopathy or as childhood-onset myopathy May include facial weakness, high arched palate, and high pedal arches
Myotubular myopathy	AD, AR, X-linked	Myotubularin MYF6	1st	1–4 x	Proximal and distal weakness May include facial weakness, ophthalmoparesis, ptosis
Myofibrillar myopathy		Desmin α B-crystallin Myotilin	2nd–4th	1–5 x	Begins distally; progresses to diffuse weakness Cytoplasmic protein aggregates in muscle associated with amyloid proteins Often prominent cardiac involvement

AD, autosomal dominant; AR, autosomal recessive; X-linked, X-linked recessive; CK, creatine kinase.

muscle as nemaline bodies, and so on, and each of the denotative lesions has been reported in association with other conditions. Nevertheless, the prominence of the morphologic change in any individual case, along with certain characteristic clinical features, permits an accurate diagnosis to be made.

The main examples of this category are summarized in Table 52-2.

Central Core Myopathy In the original family described by Shy and Magee, five members (four males) in three successive generations were affected, suggesting an autosomal dominant pattern of inheritance. The youngest was 2 years old; the oldest, 65 years. In each, there was weakness and hypotonia soon after birth ("floppy infant") and a general delay in motor development, particularly in walking, which was not achieved until the age of 4 to 5 years; always the patient had had difficulty in arising from a chair, climbing stairs, and running. The weakness was greater in proximal than in distal muscles, though the latter did not escape, and shoulder-girdle muscles were affected less than those of the pelvic girdle. Facial, bulbar, and ocular muscles were spared. The tendon reflexes were hypoactive and symmetrical. Muscle atrophy was not a prominent feature, though poor muscular development was present in one patient and has since been reported in others. There were no fasciculations, cramps, or myotonia, but cramps following exercise have been described in other families. The electrocardiograms were normal.

The disease is rare, but as additional cases were discovered, milder forms came to be recognized, and in some of them, the symptoms first appeared in adult life. Originally some of these patients were thought to have limb-girdle dystrophy because of the disproportionate involvement of proximal muscles. In other families, such as the one reported by Patterson and colleagues, the disease was first recognized in middle adult life with the rapid evolution of a proximal myopathy. Dislocation of the hips, pes cavus or pes planus, and kyphoscoliosis have been found in a few children. Arthrogryposis is rare. In the majority of cases the progress of the disease is extremely slow, with slight worsening over many years. These represent the two extremes of the process.

The EMG reveals only brief, small-amplitude motor unit potentials with a normal interference pattern. Serum concentration of CK is normal or only slightly elevated, as it is in all the congenital myopathies.

The disease has another remarkable attribute in that every patient is a potential candidate for the development of *malignant hyperthermia* and should wear a bracelet or be otherwise identified to indicate vulnerability to this anesthetic-induced complication. The gene for central core disease has been mapped to chromosome 19q13.1, where it is linked to the ryanodine receptor gene—a mutation of which is also implicated in the causation of a small number of cases of malignant hyperthermia (see Chap. 54, page 1272).

Pathologically, the majority of the muscle fibers appear normal in size or enlarged, and no focal destruction or loss of fibers can be found. The unique feature of the disease is the presence in the central portion of each muscle fiber of a dense, amorphous condensation of myofibrils or myofibrillar material. This altered zone characteristically lacks mitochondria and other organelles and gives a positive periodic acid-Schiff (PAS) reaction and a dark blue coloration with the Gomori trichrome stain, contrasting with the normal blue-green color of the peripheral myofibrils. Within the core, there is a lack of phosphorylase and oxidative enzymes. Most of the cores are in type 1 fibers, which predominate. These

cores run the length of the muscle fiber, thus differing from the multiple cores or minicores that are seen in oculopharyngeal and other forms of muscular dystrophy.

Nemaline (Rod-Body) Myopathy This disorder also expresses itself by hypotonia and impaired motility in infancy and early childhood, but—unlike the case in central core disease—the muscles of the trunk and limbs (proximal greater than distal), as well as the facial, lingual, and pharyngeal muscles, are strikingly thin and hypoplastic. Several forms have been observed. One is congenital, with generalized weakness in the neonatal period, making breathing and feeding difficult. The limbs are flaccid and areflexic ("floppy"). Pneumonia and death occur within weeks to months. In forms that permit longer survival, the weakness is less severe, involving mainly the proximal muscles. Tendon reflexes are diminished or absent. The young child with this disease usually suffers from inanition and frequent respiratory infections, which may shorten life. Strength slowly improves with growth, the latter process evidently counteracting the advance of the disease.

A slender appearance, narrow face, open mouth, narrow, arched palate, and kyphoscoliosis are regular but not invariable accompaniments of nemaline myopathy. These dysmorphic features are not typical of the other congenital polymyopathies. Pes cavus or clubfoot may be added. Some of the milder cases reach adulthood, at which time a cardiomyopathy may threaten life. A. G. Engel as well as W. K. Engel and Reznick have observed individuals who first showed signs of the disease in middle age; the weakness was mainly in proximal muscles and the dysmorphic and skeletal abnormalities of the childhood form were lacking. The EMG is "myopathic," and serum enzymes are normal or only slightly elevated.

Cases of nemaline myopathy have come to attention during adulthood in which there is disproportionate involvement of the respiratory muscles (a feature shared with the adult appearance of acid maltase deficiency). Usually, there had been a history of poor physical performance through earlier life.

Nemaline myopathy appears to be genetically heterogeneous. The pattern of inheritance is most often autosomal dominant, with variable penetrance. In some families there has been an autosomal recessive or an X-linked pattern of inheritance. Studies of the various gene defects have begun to clarify the uncertainties about inheritance and explain the relationships between the different forms of the disease. The genes implicated in nemaline myopathy include alpha-tropomyosin, beta-tropomyosin, alpha-actin, nebulin, tropinin, and the ryanodine receptor (the last of these is more commonly implicated in central core disease, as mentioned earlier; see Table 52-1).

The disease is so named for the rods or coils of thread-like structures in pathology material. Frozen muscle tissue stained with Gomori trichrome discloses the characteristic lesion, which can be seen under the light microscope. Myriads of bacillus-like rods, singly and in small packets, are seen beneath the plasma membrane of the muscle fiber. They are composed of material that resembles that of Z bands under the electron microscope, and often actin filaments are attached, just as they are to Z bands. The type 1 fibers, which usually predominate, are smaller than normal, as in central core disease. The size of the motor neurons has been reported to be reduced. The weakness is probably related to a smallness and reduction in the number of muscle fibers and possibly to focal interruption of their cross-striations, particularly the Z bands.

Centronuclear or Myotubular Myopathy In this familial disease, hypotonia and weakness become manifest soon after birth or in infancy or early childhood. Rarely, in the mildest form, the diagnosis does not become evident until adult years. All the striated skeletal muscles are involved to some degree, but distinctive features are ptosis and ocular palsies combined with weakness of facial, masticatory, lingual, pharyngeal, laryngeal, and cervical muscles in most of the infants with this disease, but not in adults. In the limbs, distal weakness keeps pace with proximal weakness. The limbs remain thin and areflexic throughout life. Motor development is necessarily retarded, though some improvement with maturation can occur; later, however, motor functions that had been acquired may be lost as the disease slowly advances. Several patients have shown signs of cerebral abnormality, with seizures and an abnormal electroencephalogram (EEG), but this may not be part of the disease. Needle EMG examination shows the usual myopathic pattern, as well as positive sharp waves and fibrillation potentials in some cases. Abundant spontaneous activity should suggest the diagnosis of centronuclear myopathy (Griggs et al).

Heckmatt and colleagues have classified this disorder into three types, based on severity, mode of presentation, and genetic pattern: (1) a severe neonatal X-linked recessive type; (2) a less severe early-infantile, late-infantile, or childhood autosomal recessive type; and (3) a still milder late childhood–adult autosomal dominant type. The primary defect in the X-linked form is a mutation in the gene that encodes a protein designated myotubularin; presumably this plays a role in myotube maturation. At least one autosomal dominant form has been ascribed to mutations in the protein MYF6, a helix-loop-helix protein that appears to function as a myogenic transcription factor.

The outstanding pathologic features of the disease are the smallness of muscles and their constituent fibers and central nucleation. In one group of centronuclear myopathies, there is hypertrophy of type 1 fibers (Bethlem et al, Karpati et al). Surrounding most of the centrally placed nuclei is a clear zone, in which there is a lack of organization of contractile elements. Because of central nucleation, the disease has incorrectly been referred to as *myotubular myopathy*, implying an arrest in development of muscle at the myotubular stage. Actually, the nature of the pathologic process is obscure. The small, centrally nucleated fibers do not really resemble typical myotubes. Also, there is evidence from electron microscopic studies of changes in the central parts of the fibers (lack of enzymatic activity in the clear zones surrounding the nuclei), leading in all probability to fiber loss. Such changes argue against a purely developmental abnormality.

Myopathy with Tubular Aggregates The accumulation of tubular aggregates in the subsarcolemmal or more interior regions of muscle fibers was first observed in patients with hypokalemic periodic paralysis and myotonia congenita and later with a number of diverse conditions, such as chronic drug intoxication, hypoxia, and congenital myasthenic syndromes. However, tubular aggregates are also the defining feature of several purely myopathic syndromes: (1) A slowly progressive muscular weakness, in a limb-girdle distribution, with onset in childhood or early adult life; inheritance is either autosomal dominant or recessive in type. (2) A childhood onset of proximal weakness, easy fatigability, and myasthenic features; heredity is autosomal recessive. This syndrome may respond to pyridostigmine. (3) Muscle pain, cramps, and stiffness induced by exercise; the cases to date have been sporadic.

The histologic changes are readily overlooked in paraffin sections. Cryostat sections show masses of material that is basophilic with hematoxylin and eosin and bright red with Gomori trichrome and shows an intense reaction with NADH dehydrogenase. By electron microscopy, the bundles of tubular aggregates are sharply demarcated from myofibrils.

Other Congenital Myopathies The foregoing congenital myopathies—central core, nemaline, centronuclear, and tubular aggregate types—are well-defined clinicopathologic entities. In addition, other far less common types have been described, each named according to a distinctive dysmorphic alteration of organelles in muscle fibers in histochemical and electron microscopic preparations. In none of these additional types has the pattern of inheritance or the gene locus been identified. Some of these myopathies—*multicore (minicore)*, *fingerprint body*, *sarcotubular*—have been reported in only a few cases, quite insufficient to allow their categorization as disease entities. Two other types—*congenital fiber type disproportion* and *congenital fiber type predominance*—originally designated as congenital myopathies, have proved to be nonspecific histochemical alterations observed in many infants and children with congenital developmental abnormalities, delays in motor development, and other conditions. Other putative congenital myopathies include so-called *reducing body*, *trilaminar*, and *cap disease*; *zebra body*; and *familial myopathy with lysis in type I fibers*, among others. They most likely represent nonspecific reactions in muscle or fixation artifacts; as yet there is no evidence that any one of them represents a clinicopathologic entity.

Myofibrillar Myopathy Beyond the uncertain entities noted earlier, the field of chronic myopathies has been muddled by a plethora of reports describing a variety of curious inclusions in muscle fibers, under a bewildering array of terms: *myopathy with inclusion bodies*, *atypical myopathy with myofibrillar aggregates*; *autosomal dominant myopathy with myofibrillar inclusions*; *cardioskeletal myopathy with intrasarcoplasmic dense granulofilamentous material*; *cytoplasmic body myopathy*; *spheroid body myopathy*; *myopathy with characteristic sarcoplasmic bodies and skeleton (desmin) filaments*; *myopathy with Mallory-body-like inclusions*; and *familial cardiomyopathy with subsarcolemmal vermiciform deposits*. Implied by these reports was the notion that each of these structural abnormalities represented a new and distinctive myopathy.

More recently, in a careful light microscopic evaluation of both published reports and their own cases, Nakano and Engel and their colleagues have convincingly demonstrated that the many reported structural changes were the consequence of a single pathologic process—a focal dissolution of myofibrils, followed by an accumulation of the products of the degradative process. These authors proposed the term *myofibrillar myopathy* to encompass the entire spectrum of these pathologic changes. Mutations of one of the various proteins that relate to the Z-disc (the connection between adjacent sarcomeres, which are the structural units of the myofibril) of muscle seem to be the unifying feature. Many of these abnormalities can be traced to a dominant mutation in the genes coding for the filament proteins myotilin and desmin and in the chaperone protein $\alpha\beta$ -crystallin, as described in the review by Selcen and colleagues cited later. Presumably, mutations in either gene predispose to protein aggregation, the former by destabilizing desmin and the latter by altering the capacity of the $\alpha\beta$ -crystallin to facilitate normal desmin folding.

The diagnosis of myofibrillar myopathy (by biopsy) is usually made in adult life. Men and women are equally affected. Slowly progressive weakness of the muscles of limbs and trunk is the main clinical feature. Both proximal and distal muscles are affected, more in the legs than in the arms. Hyporeflexia is usual. Cardiac involvement, usually abnormalities of conduction, is present in about one quarter of the patients. The pattern of inheritance is most often autosomal dominant, but autosomal recessive and X-linked patterns also have been described. An astonishing 63 patients have been studied by Selcen and associates; their article can be consulted for further details.

Genetically there is considerable heterogeneity. At the time of writing, no fewer than five chromosomal loci for myofibrillar myopathy have been documented, and more are likely to exist (Engel). Predictably, therefore, a more sharply defined disease or diseases will emerge with further study of the category of myofibrillar myopathy.

As stated in the introductory section, there is currently no treatment for any of the congenital polymyopathies.

THE SPINAL MUSCULAR ATROPHIES OF INFANCY AND CHILDHOOD

Obviously this important group of diseases, appearing as they do in the same periods of life as the congenital polymyopathies and of certain of the congenital muscular dystrophies, must figure in the differential diagnosis of early-onset muscle weakness, hypotonia, and of arthrogryposis. Indeed, they represent the main problems faced by the clinical myologist studying diseases of the infant and child. Their hereditary nature, their progression to fatal outcome or delayed motor attainments, and their tendency in certain instances to produce disabling contractures are shared with the primary muscle diseases. Fortunately the proper application of current laboratory techniques sets them apart in most instances. In deference to their neuronal origin, the authors have decided to place them with the other degenerative diseases (see pages 945 to 947).

CHAPTER 53

MYASTHENIA GRAVIS AND RELATED DISORDERS OF THE NEUROMUSCULAR JUNCTION

Included under this title is a group of diseases affecting the neuromuscular junction, the most important of which is myasthenia gravis. As a group, these disorders exhibit several characteristic and striking features, the essential one being a fluctuating weakness and fatigability of muscle. Some degree of weakness is usually present at all times, but it is made worse by activity. The weakness and fatigability reflect physiologic abnormalities of the neuromuscular junction that are demonstrated by clinical signs and by special electrophysiologic testing. As an aid to understanding the diseases discussed in this chapter, the reader should consult the discussion of the structure and function of the neuromuscular synapse given in Chap. 48.

MYASTHENIA GRAVIS

The main feature of myasthenia gravis, referred to simply as myasthenia, is a fluctuating weakness of certain voluntary muscles, particularly those innervated by motor nuclei of the brainstem, i.e., ocular, masticatory, facial, deglutitional, and lingual. Manifest weakening during continued activity, quick restoration of power with rest, and dramatic improvement in strength following the administration of anticholinesterase drugs such as neostigmine are the other notable characteristics of the weakness.

Historical Note Several students of medical history affirm that Willis, in 1672, gave an account of a disease that could be none other than myasthenia gravis. Others give credit to Wilks (1877) for the first description and for having noted that the medulla was free of disease, in distinction to other types of bulbar paralysis. The first reasonably complete accounts were those of Erb (1878), who characterized the disease as a bulbar palsy without an anatomic lesion, and of Goldflam (1893); for many years thereafter, the disorder was referred to as the *Erb-Goldflam syndrome*. Jolly (1895) was the first to use the name *myasthenia gravis*, to which he added the term *pseudoparalytica* to indicate the lack of structural changes at autopsy. Also it was Jolly who demonstrated that myasthenic weakness could be reproduced in affected patients by repeated faradic stimulation of the relevant motor nerve and that the “fatigued” muscle would still respond to direct galvanic stimulation of its membrane. Interestingly, he suggested the use of physostigmine as a form of treatment, but there the matter rested until Reman, in 1932, and Walker, in 1934, demonstrated the therapeutic value of the drug. Campbell and Bramwell (1900) and Oppenheim (1901) each analyzed over 60 cases and crystallized the clinical concept of the disease. The relationship between myasthenia gravis and tumors of the thymus gland was first noted by Laquer and Weigert in 1901, and in 1949 Castleman and Norris gave the first detailed account of the pathologic changes in the gland.

In 1905 Buzzard published a careful clinicopathologic analysis of the disease, commenting on both the thymic abnormalities and the infiltrations of lymphocytes (called *lymphorrhages*) in muscle. He postulated that an “autotoxic agent” caused the muscle

weakness, the lymphorrhages, and the thymic lesions. He also commented on the close relation of myasthenia gravis to Graves disease and Addison disease, which are all now considered to have an autoimmune basis. In 1960, Simpson and, independently, Nastuk and coworkers theorized that an autoimmune mechanism must be operative in myasthenia gravis. Finally, in 1973 and subsequently, the autoimmune nature of myasthenia gravis was established through a series of investigations by Patrick and Lindstrom, Fambrough, Lennon, and A. G. Engel and their colleagues (see further on, under “Etiology and Pathogenesis”).

These and other references to the early historical features of the disease are to be found in the reviews by Viets and by Kakulas and Adams; A. G. Engel’s monograph (1999) is an excellent modern reference.

Clinical Manifestations

Myasthenia gravis, as the name implies, is a muscular weakness formerly with a grave prognosis. Repeated or persistent activity of a muscle group exhausts its contractile power, leading to a progressive paresis, and rest restores strength, at least partially. These are the identifying attributes of the disease; their demonstration, assuming that the patient cooperates fully, is sometimes enough to establish the diagnosis.

The special vulnerability of certain muscles gives myasthenia a characteristic stamp. Usually the eyelids and the muscles of the eyes—and somewhat less often of the face, jaws, throat, and neck—are the first to be affected. Infrequently the initial complaint is referable to the limbs. More specifically, the weakness of the levator palpebrae or extraocular muscles is the initial manifestation of the disease in about half the cases, and these muscles are involved eventually in more than 90 percent. Ocular palsies and ptosis (weakness of eyelid opening) are usually accompanied by weakness of eye closure, a combination that is virtually always myopathic and not neuropathic in origin, e.g., observed in myasthenia and muscular dystrophy. Diplopia in myasthenia does not correspond to the innervatory pattern of a nerve but is the result instead of asymmetric weakness of several muscles in both eyes. As the disease advances, it often spreads from the cranial to the limb and axial muscles. The onset of weakness is usually insidious, but there are instances of fairly rapid development, sometimes apparently initiated by an emotional upset or infection (usually respiratory). In most patients, however, a precipitating event cannot be identified. Symptoms may first appear during pregnancy or, more commonly, in the puerperium or in response to drugs used during anesthesia. *Thymic abnormalities* of several types are closely connected with the disease, as elaborated further on, and weakness may begin months or years after removal of a thymoma.

Certain ocular signs are highly characteristic of myasthenia. Sustained upgaze for 30 or more seconds will usually induce or exaggerate ptosis and may uncover a myasthenic ocular motor

weakness. Cogan described a twitching of the upper eyelid that appears a moment after the patient moves the eyes from a downward to the primary position ("lid-twitch" sign). Or, after sustained upward gaze, one or more twitches may be observed with closure of the eyelids or during horizontal movements of the eyes. Repeated ocular versions induced by tracking a target or by an optokinetic stimulus may disclose progressive paresis of the muscles that carry out these movements. Unilateral painless ptosis without ophthalmoplegia or pupillary abnormality in an adult will most often prove to be due to myasthenia. Usually there is subtle ptosis of the other eye that can be revealed by manually elevating the more affected eyelid. Attempts by the patient to overcome the ptosis may impart a staring expression of the opposite eye. Bright sunlight is said to aggravate the ocular signs and cold, to improve them. The application of an ice pack over the eye often relieves the ptosis for a brief period.

Muscles of facial expression, mastication, swallowing, and speech are affected in 80 percent of patients at some time in the illness, and in 5 to 10 percent these are the first or only muscles to be involved. Less frequent is an initial or early involvement of the flexors and extensors of the neck, muscles of the shoulder girdle, and flexors of the hips. (This pattern may be associated with a special autoantibody as discussed later.) Of the trunk muscles, the erector spinae are the most frequently affected. In the most advanced cases, all muscles are weakened, including the diaphragmatic, abdominal, and intercostal muscles and even the external sphincters of the bladder and bowel. The involvement of any group of muscles closely parallels their degree of weakness early in the disease. The clinical rule holds that the proximal muscles are far more vulnerable than distal ones, as they are in almost all other forms of myopathy.

The other characteristic feature of myasthenic weakness is its tendency to increase as the day wears on or with repeated use of an affected muscle group, but patients seldom volunteer this information. A few patients report being paradoxically worse on awakening, especially if they have not received medication during the night. In broad terms, therefore, myasthenia gravis may be conceived as a fluctuating and fatigable oculofaciobulbar palsy.

To reiterate the topographic attributes of the illness, *combined weakness of the extraocular muscles, levators, and orbicularis oculi combined with normal pupillary responses to light and accommodation is virtually diagnostic of myasthenia*, especially if the function of these muscles is restored after a period of rest. Facial mobility and expression are altered: the natural smile becomes transformed into a snarl; the jaw may sag, so that it must be propped up by the patient's hand; chewing tough food may be difficult, and the patient may have to terminate a meal because of inability to masticate and swallow. It may be more difficult to eat after talking, and the voice fades and becomes nasal after sustained conversation. Women may complain of inability to fix their hair or makeup because of fatigue of the shoulders, or of difficulty in applying lipstick because they are unable to purse and roll their lips. Weakness of the neck muscles causes fatigue in holding up the head. In cases with generalized weakness, there may be difficulty in retaining flatus because of weakness of the external sphincter.

A temporary increase in weakness may follow vaccination, menstruation, and exposure to extremes of temperature. A peculiarity of myasthenic muscle contraction that may be observed occasionally is a sudden lapse of sustained posture or interruption of movement resulting in a kind of irregular tremor, similar to that of normal muscle nearing the point of exhaustion. A dynamometer

demonstrates the rapidly waning power of contraction of a series of hand grips, and repetitive stimulation of a motor nerve at slow rates while recording muscle action potentials the same decremental strength in a more quantitative fashion (see Fig. 45-5A and further on).

Weakened muscles in myasthenia gravis undergo atrophy to only a minimal degree or not at all. Tendon reflexes are seldom altered. Even repeated tapping of a tendon does not usually tax muscles to the point where contraction fails. Smooth and cardiac muscles are not involved and other neural functions are preserved. The tendon reflexes are unaffected. Weakened muscles, especially those of the eyes and back of the neck, may ache, but pain is seldom an important complaint. Paresthesias of the face, hands, and thighs are reported infrequently but are not accompanied by demonstrable sensory loss. Anosmia and ageusia have been mentioned as rare findings, but they may be coincidental. The tongue may display one central and two lateral longitudinal furrows (trident tongue), as pointed out originally by Buzzard.

Certain *epidemiologic features* of the disease are of clinical interest. Its prevalence is variously estimated to be from 43 to 84 per million of the population and the annual incidence rate, approximately 1 per 300,000. The disease may begin at any age, but onset in the first decade is relatively rare (only 10 percent of cases occur under the age of 10 years). The peak age of onset is between 20 and 30 years in women and between 50 and 60 years in men. Under the age of 40, females are affected two to three times as often as males, whereas in later life, the incidence in males is higher (3:2). Of patients with thymomas, the majority are older (50 to 60 years), and males predominate.

To facilitate clinical staging of therapy and prognosis, the following classification, introduced by Osserman, remains useful (the relative incidence of each type is indicated and "drug response" refers to treatment with an anticholinesterase):

- I. Ocular myasthenia (15 to 20 percent)
- II. A. Mild generalized myasthenia with slow progression; no crises; drug-responsive (30 percent)
- B. Moderately severe generalized myasthenia; severe skeletal and bulbar involvement but no crises; drug response less than satisfactory (25 percent)
- III. Acute fulminant myasthenia; rapid progression of severe symptoms with respiratory crises and poor drug response; high incidence of thymoma; high mortality (15 percent)
- IV. Late severe myasthenia; symptoms same as III, but resulting from steady progression over 2 years from class I to class II (10 percent)

Others, for example Compston and colleagues have proposed a classification based on a constellation of the age of onset, presence or absence of thymoma, antibody level against acetylcholine receptors (AChR), and association with HLA haplotypes: (1) myasthenia gravis with thymoma—no sex or HLA association, high AChR antibody titer; (2) onset before age 40, no thymoma—female preponderance and an increased association with HLA A1, B8, and DRW3 antigens; (3) onset after age 40, no thymoma—male preponderance, increased association with HLA A3, B7, and DRW2 antigens, low AChR antibody titer. The last group includes a proportion of older men with purely ocular symptoms (Osserman type I). Classifications such as these are meant to capture certain types or contexts of myasthenia more than to convey the severity of illness.

The course of the illness is extremely variable. Rapid spread from one muscle group to another occurs in some, but in others, the disease remains unchanged for months before progressing. Remissions may take place without explanation, usually in the first years of illness, but these happen in less than half the cases and seldom last longer than a month or two. If the disease remits for a year or longer and then recurs, it then tends to be progressive. Relapse may be occasioned by the same events that preceded the onset of the illness, especially infections. In Simpson's opinion, and this coincides with our observations, the danger of death from generalized myasthenia gravis is greatest in the first year after onset of the disease. A second period of danger in progressive cases is from 4 to 7 years after onset. After this time the disease tends to stabilize and the risk of severe relapse diminishes. Fatalities relate mainly to the respiratory complications of pneumonia and aspiration. The mortality rate in the first years of illness, formerly in excess of 30 percent, is now less than 5 percent, and with appropriate therapy, most patients are able to lead productive lives. The course is altered by thymectomy (as discussed further on).

One aspect of interest is the timing and frequency of conversion from ocular and restricted oropharyngeal patterns of weakness to more widespread involvement including the diaphragm. Bever and coworkers have confirmed the general impression that an increasing duration of purely ocular myasthenia is associated with a decreasing risk of late generalization of weakness. These authors found in a retrospective study of 108 patients that only 15 percent of the observed instances of generalization occurred after 2 years of isolated ocular manifestations. A later age at onset was also associated with a higher incidence of fatal respiratory crises. In general, patients whose disease begins at a younger age run a more benign course. Grob and colleagues, who recorded the course of an astonishing 1036 patients for a mean duration of 12 years, found that the clinical manifestations remained confined to the extraocular muscles and orbicularis oculi in 16 percent. Their data further indicated that if localized ocular myasthenia had been present for only a month, there was a 60 percent likelihood that the disease would become generalized, but in those cases that remained restricted for more than a year, only 16 percent became generalized. In contrast, of 37 consecutive cases carefully studied by Weinberg and colleagues in our clinic with only ocular signs, 17 became generalized within a period of 6 years. Also informative in Grob's series was that in two-thirds of 750 patients with generalized weakness, the disease attained its maximum severity within a year of onset, and in 83 percent, within 3 years. It has been stated that the progression of symptoms is more rapid in male than in female patients.

With regard to prognosis, it is not widely recognized that isolated muscle groups may occasionally remain permanently weak even when the ocular and generalized weakness has resolved. The muscles most often affected in this way are the anterior tibialis, triceps, and portions of the face.

The long-term outlook for children with myasthenia is better than it is for adults, and their life expectancy is only slightly reduced. Rodriguez and colleagues followed a group of 149 children for an average of 17 years; 85 of them had thymectomies, one of the main treatments for myasthenia as discussed further on. Approximately 30 percent of the nonthyrectomized and 40 percent of the thyrectomized patients underwent remission and were free of symptoms, usually in the first 3 years of illness. Those children with bulbar symptoms and no ocular or generalized weakness had the most favorable outcome.

The special and relatively common problem of myasthenic crisis is discussed in a later section.

Thymic and Other Disorders Associated with Myasthenia *Thymic tumors* occur in 10 to 15 percent of patients with myasthenia gravis, and a nonneoplastic lymphofollicular hyperplasia of the thymic medulla occurs in 65 percent or more. Thymomas with malignant characteristics may spread locally in the mediastinum and to regional lymph nodes, but they rarely metastasize beyond these structures; when they do spread, the lungs and liver are usually affected. It should be emphasized that thymic tumors may be missed in plain films of the chest and should be sought by CT scanning. The significance of thymic disorders is discussed further on.

Although not directly relevant to myasthenia, it is of interest to neurologists that a number of other curious neurologic disorders occur in association with thymoma. Among our own cases over the years were two instances of a "limbic encephalitis" with memory loss and confusion that could not be differentiated from the better-described paraneoplastic variety of encephalitis (page 585), one case of midbrain encephalitis, one of Morvan's fibrillary chorea (discussed in the following chapters), and one of aplastic anemia. Such cases appear in the literature from time to time and all are thought to have a humoral immune basis.

Of biologic importance is the coexistence of myasthenia gravis and other autoimmune diseases. *Thyrototoxicosis* (5 percent of myasthenic patients—page 1236), lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, mixed connective tissue disease, anticardiolipin antibody, and (curiously) polymyositis have all been associated with myasthenia more often than can be explained by chance. A large proportion of young women with myasthenia have moderately elevated titers of antinuclear antibody without the clinical manifestations of systemic lupus.

Familial occurrence of myasthenia is known, but it is rare. Many such cases prove to have one of the rare genetically determined myasthenic syndromes and not the acquired autoimmune form of disease (see further on). More common is a family history of one of the other autoimmune diseases enumerated earlier. For example, in the series reported by Kerzin-Storror and associates, 30 percent had a maternal relative with one of these disorders of clearly established autoimmune nature, suggesting that myasthenia gravis patients inherit a susceptibility to autoimmune disease. There have also been numerous case reports of the concurrence of myasthenia and multiple sclerosis, again suggesting a common autoimmune basis, but the statistical association here is less certain.

Pathologic Features of the Thymus and of Muscle Reference has already been made to the prominent involvement of the *thymus gland* in myasthenia gravis. As mentioned, true neoplasms of the gland are found in about 10 to 15 percent of patients, but of greater import is that fully 65 percent of the remaining patients show a striking degree of hyperplasia of the medulla of the thymus characterized by lymphoid follicles with active germinal centers. Hyperplasia is even more frequent in younger patients in the third and fourth decades. The cells in the centers of the follicles are histiocytes; they are surrounded by helper T lymphocytes, B lymphocytes, and plasma cells; and immunoglobulin G (IgG) is elaborated in the germinal follicles. These resemble the cellular reaction that is observed in the thyroid of Hashimoto thyroiditis. Since the latter disease has been reproduced in animals by injecting extracts of thyroid with Freund adjuvants, it has been suggested that the so-

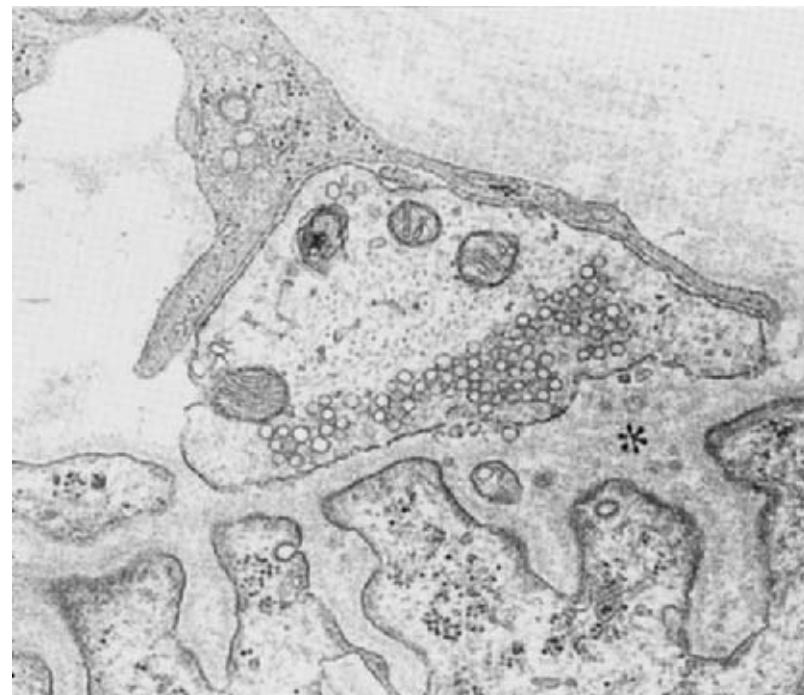

called thymitis or myasthenia gravis is the result of a similar autoimmune sensitization but the inciting events for this process are entirely unknown. Immunosuppression with steroids causes involution of the thymus.

With regard to thymic tumors, two forms have been described: one composed of histiocytic cells like the reticulum cells in the center of the follicles, and the other predominantly lymphocytic and considered to be lymphosarcomatous. Some of the tumors have a high proportion of spindle-shaped cells. Overlapping types have been common in our material. Thymic tumors may be unattended by myasthenia, though myasthenia has eventually developed in all of our cases, sometimes 15 to 20 years after the tumor was first recognized and removed surgically. According to Brill et al, the severity of myasthenic symptoms is no different in patients with thymoma than it is from that in patients without a tumor, but our impression has been that patients with tumors, particularly children, sometimes have a peculiar clinical course; we have observed with some frequency unexpected sudden remissions and severe relapses, as well as resistance to medications.

Many contemporary studies, including over 40 autopsies at our hospitals, have confirmed Erb's original contention that myasthenia gravis is a disease without a central nervous system lesion. The brain and spinal cord are normal unless damaged by hypoxia and hypotension from cardiorespiratory failure. Furthermore, the *muscle fibers* are generally intact, although in fatal cases with extensive paralysis, isolated fibers of esophageal, diaphragmatic, and eye muscles may undergo segmental necrosis with variable regeneration (Russell). Scattered aggregates of lymphocytes (lymphorrhages) are also observed, as originally noted by Buzzard, but none of these changes in muscle explain the widespread and severe weakness. The lymphorrhages, which are found more frequently in the tumor cases, are not confined to the vicinity of the motor end plates.

The main ultrastructural alterations occur in the *motor end plate*. These changes, elegantly demonstrated by A. G. Engel and associates, consist of a reduction in the area of the nerve terminal, a simplification of the postsynaptic region (sparse, shallow, abnormally wide or absent secondary synaptic clefts) and a widening of the primary synaptic cleft (Fig. 53-1). However, the number and size of the presynaptic vesicles and their quanta of ACh are within the normal range. The observation of regenerating axons near the junction, the many simplified junctions, and the absence of nerve terminals supplying some postsynaptic regions suggested to Engel and coworkers that there was an active process of degeneration and repair of the neuromuscular junction, particularly of the postsynaptic side.

Etiology and Pathogenesis The clear demonstration of an *immunologic mechanism* operative at the neuromuscular junction has been the most significant development in our understanding of myasthenia gravis. Patrick and Lindstrom discovered that repeated

A

B

Figure 53-1. A. End plate from a patient with myasthenia gravis. The terminal axon contains abundant presynaptic vesicles, but the postsynaptic folds are wide and there are few secondary folds. The loose junctional sarcoplasm is filled with microtubules and ribosomes. The synaptic cleft (asterisk) is widened. (From Santa et al by permission.) B. Normal end plate for comparison. (Courtesy of Dr. A. G. Engel.)

immunization of rabbits with AChR protein obtained from the electric eel caused a muscular weakness (contrary to what is stated in some books, their discovery was not accidental). Lennon and colleagues recognized this model as being similar to that of myasthenia gravis. Soon thereafter Fambrough and coworkers demonstrated that the basic defect in myasthenia gravis was a marked reduction in the number of AChR on the postsynaptic membrane of the neuromuscular junction. These observations were followed

by the creation of an experimental model of the disease and the demonstration that experimentally induced myasthenia had clinical, pharmacologic, and electrophysiologic properties identical with those of human myasthenia gravis—i.e., decreased miniature end-plate potentials (MEPPs), decremental response on neuromuscular stimulation at 3 Hz, and correlation of weakness with the number of labeled antibodies attached to the receptor sites (Engel et al). It was also shown that humoral antibodies directed against protein components of AChR could transfer the myasthenic weakness to normal animals and that the weakness as well as the physiologic abnormalities could be reversed by the administration of anticholinesterase drugs. Thus, the accumulated evidence satisfied the criteria for the diagnosis of an autoantibody-mediated disorder (Drachman).

The present view is that myasthenic weakness and fatigue are due to the failure of effective neuromuscular transmission on the postsynaptic side. The greatly reduced number of receptors and the competitive activity of anti-AChR antibodies (see later) produce end-plate potentials of insufficient amplitude to generate action potentials in some nerve fibers. By the cumulation of blocked transmission at many end plates, there results a reduction in the contractile power of the muscle. This deficiency is reflected first in the ocular and cranial muscles, the ones that are both the most continuously active muscles and have the fewest AChR per motor unit. Fatigue is understandable as the result of the normal decline in the amount of ACh released with each successive impulse.

Antibodies to AChR protein are present in over 85 percent of patients with generalized myasthenia and in 60 percent of those with ocular myasthenia (Newsom-Davis). Antibodies are also present in infants with neonatal myasthenia gravis and in animal species known to have a naturally occurring myasthenia. The presence of receptor antibodies has proved to be a reasonably sensitive and reliable test of the disease, as discussed later under “Measurement of Receptor Antibodies in Blood.” The manner in which antibodies that are situated in the intracellular compartment (such as MuSK discussed below) cause weakness is not known.

How the antibodies act at the receptor surface of the end plate has also been investigated, but the matter is complex. Neuromuscular transmission is probably impaired in several ways: (1) The antibodies may block the binding of ACh to the AChR. (2) Serum IgG from myasthenic patients has been shown to induce a two- to threefold increase in the degradation rate of AChR. This may be the result of the capacity of antibodies to cross-link the receptors, which are gathered into clusters in the muscle membrane and then internalized by a process of endocytosis and degraded. (3) Antibodies may cause a complement-mediated destruction of the postsynaptic folds (Engel and Arahata). The latter two mechanisms would be expected to reduce the number of AChR at the synapse.

Although the evidence that an autoimmune mechanism is responsible for the functional disorder of muscle in myasthenia gravis is incontrovertible, the source of the autoimmune response has not been established. Because most patients with myasthenia have thymic abnormalities and a salutary response to thymectomy, it is logical to implicate the lymphoid reaction in this gland in the pathogenesis of the disease. Both T and B cells from the myasthenic thymus are particularly responsive to the AChR, more so than analogous cells from peripheral blood. Moreover, the thymus contains “myoid” cells (resembling striated muscle) that bear surface AChR. However, it is not known with certainty that thymic myoid cells are the foci of immunologic stimulation in myasthenia gravis. The most obvious objection is that such cells are even more abundant

in the normal than in the myasthenic thymus (according to Schlueter et al). Another suggested pathogenesis, yet unconfirmed, is that a virus with a tropism for thymic cells might injure such cells and induce antibody formation. A viral infection might at the same time have a potential for oncogenesis, accounting for thymic tumors, but this is all speculative. Scadding and associates have suggested a somewhat different mode of thymic involvement; they have shown that thymic lymphocytes from patients with myasthenia gravis can synthesize anti-AChR antibody, both in culture and spontaneously.

Diagnosis In patients who present with a changeable diplopia and the typical myasthenic facies—unequally drooping eyelids, relatively immobile mouth turned down at the corners, a smile that looks more like a snarl, a hanging jaw supported by the hand—the diagnosis can hardly be overlooked. However, only a minority of patients present in this stage of the disease, and infrequently is there a clear recognition, even by the patient, that the muscles tire during activity and as the day progresses. Ptosis, diplopia, difficulty in speaking or swallowing, or weakness of the limbs are at first mild and inconstant and may be mistaken for a cerebrovascular disease. However, the finding that sustained activity of small cranial muscles results in weakness (e.g., increasing droop of eyelids while looking at the ceiling or diplopia when fixating in lateral or vertical gaze or reading for 2 to 3 min) and that contraction improves after a brief rest is virtually diagnostic, even in the early stages of the disease. Any other affected group of muscles may be critically tested in similar fashion. The characteristic ocular signs have already been described. For confirmation, or if the diagnosis remains in doubt, the measurement of specific antibody (anti-AChR), electromyography, and certain pharmacologic tests described below are necessary. Several special diagnostic problems are summarized further on.

Electrophysiologic Testing Characteristic of myasthenia is a rapid reduction in the amplitude of compound muscle action potentials evoked during a series of repetitive stimulations of a peripheral nerve at a rate of 3 per second (*decrementing response* as shown in Fig. 45-5A). Reversal of this response by neostigmine or edrophonium has been a reliable confirmatory finding in most cases. A decremental response to stimulation can usually be obtained from the facial, hand, or proximal limb muscles, which may or may not be clinically weak. During a progressive phase of the disease or during steroid therapy, a slight initial incrementing response may be obtained, not to be confused with the marked incrementing response after voluntary contraction that characterizes the Lambert-Eaton syndrome (see further on).

Single-fiber electromyography (EMG) represents an even more sensitive method of detecting the defect in neuromuscular transmission. This technique demonstrates an inconstancy of the normally invariant interval between the firing of fibers connected to the same motor unit (“jitter”—see page 1106) or a blocking of successive discharges from single muscle fibers belonging to the same motor unit. The test requires a great deal of cooperation from the patient; it requires that contraction of a muscle be sustained at just the right amplitude in order to isolate the firing of single muscle fibers from the same unit. With patience on the part of the electromyographer, it is also possible to detect such pairs of fibers by electrical stimulation of a nerve. Nerve conduction velocities and distal latencies are normal unless there is a coincidental polyneuropathy.

Edrophonium (Tensilon) and Neostigmine Tests Equally valuable to electrophysiologic testing are the edrophonium (Tensilon)

and neostigmine tests. These drugs are anticholinesterase inhibitors that prolong and exaggerate the effects of ACh in the synapse and thereby provide an increment in muscle power in the patient with myasthenia. The tests are performed in the following manner. After the measurement of strength in a cranial (usually the levator palpebrae or an extraocular muscle) or limb muscle (by dynamometry) or vital capacity, 1 mg (0.1 mL) of edrophonium is given intravenously; if this dose is tolerated and no definite improvement in strength occurs after 45 s, another 3 to 6 mg is injected. If there is no response after another 45 s, an additional 3 to 5 mg may be given over approximately 1 min. A total dose of 10 mg is rarely necessary. Most patients who respond do so after 3 to 5 mg have been administered. The mild muscarinic effects of edrophonium (nausea, vomiting, bowel activation, sweating, salivation) can be blocked by pretreatment with atropine 0.8 mg subcutaneously.

The clinical effect of improved ptosis, extraocular movements, oropharyngeal function, arm and shoulder abduction, or vital capacity persists for no more than 4 to 5 min. One caution: some patients deteriorate immediately but briefly after the edrophonium test as a result of an increase in pulmonary secretions. A positive test consists of visible (objective) improvement in muscle contractility, complete fusion of diplopia, or total resolution of fatigable ptosis. The report of subjective improvement alone is not dependable, and one must be distrustful of equivocal test results, which may occur with ocular palsies due to tumors, thyroid disease, Guillain-Barré syndrome (GBS), progressive supranuclear palsy, or carotid aneurysms (pseudo-ocular myasthenia). The use of the edrophonium test in the diagnosis of so-called cholinergic crisis is discussed further on.

The use of neostigmine is sometimes preferable to edrophonium because the longer duration of its effect allows more deliberate and repeated testing of muscle function. Neostigmine methysulfate is injected intramuscularly in a dose of 1.5 mg. As with the edrophonium test, atropine sulfate (0.8 mg) should be given several minutes in advance to counteract muscarinic effects. (Less preferably, neostigmine may be given intravenously in a dose of 0.5 mg, but its effect is brief.) After intramuscular injection, objective and subjective improvement occurs within 10 to 15 min, reaches its peak at 20 min, and lasts up to 1 h, allowing for careful verification of the neurologic improvement. A trial of oral prostigmine, 15 mg every 4 h during the day, is sometimes recommended in doubtful cases, but we have been misled more often than helped by it.

A negative test with an anticholinesterase does not exclude myasthenia gravis but is a strong point against the diagnosis. In a small number of patients who later prove to have myasthenia gravis, the edrophonium and neostigmine tests (and EMG and AChR antibody measurements) may be entirely normal during the first episode or even after several episodes of ocular myasthenia. Only later, for inexplicable reasons, do these tests become positive. Finally, it should be noted that the anticholinesterase-inhibiting drugs carry a rare risk of ventricular fibrillation and cardiac arrest, so that testing should be carried out preferably where emergency support is accessible.

Measurement of Receptor Antibodies in Blood As stated earlier, the detection of *anti-AChR antibodies* provides a sensitive and highly specific test for the diagnosis of myasthenia. The radioimmunoassay method of detection has been the most accurate and widely used. Serum antibody against AChR can be found in 80 to 90 percent of patients with generalized myasthenia gravis and about 60 percent of those whose symptoms are restricted to the ocular

muscles (Vincent and Newsom-Davis). For the most part, adults with myasthenia whose sera are persistently negative for AChR antibodies do not differ clinically or electromyographically from those with antibodies, with the exception noted below. Persistently negative AChR antibody tests are more frequently found in patients with ocular myasthenia than in patients with generalized weakness. Patients with a thymoma and severe generalized myasthenia are practically always seropositive. Interestingly, the antibody titers may remain elevated during clinical remissions.

Some instances of "seronegative" disease are due to antibody production against unusual epitopes that are located on or near the AChR; their detection requires a special panel of tests. Recently, the majority of such cases have been ascribed to IgG antibodies directed against a muscle-specific kinase (MuSK). This enzyme plays a role in supporting the normal structure of the postsynaptic membrane and in the arrangement of AChR, but its main function may be in developmental synaptic differentiation. Scuderi and colleagues and others have proposed that patients with MuSK antibody, mostly women, have a special clinical syndrome of prominent oculobulbar weakness, often with persistently severe disease and respiratory crises (see also Evoli et al). Others have reported the opposite, a pattern of mainly neck and proximal weakness that simulates a classical myopathy.

Also of interest, but not used in routine diagnosis, is the presence of *antibodies directed against striated muscle* in almost half of myasthenic patients and an even higher incidence (stated to be 85 percent) in patients who also have a thymoma.

Each of the commonly used diagnostic tests proves to be about equally reliable. Kelly and coworkers obtained positive results with single-muscle-fiber recording in 79 percent, with the antireceptor antibody test in 71 percent, and with the edrophonium test in 81 percent. Combined, they confirmed the diagnosis in 95 percent of clinically suspected cases. Presumably, had the anti-MuSK receptor antibody test been available, the sensitivity of serologic diagnosis would have been higher.

In keeping with the observation of some myasthenic patients that their weakness improves in the cold, a test has been devised in which an ice pack is placed over a ptotic eyelid for 2 min or to the limit of the patient's tolerance. Sethi and colleagues found that ptosis was diminished in 8 of 10 patients. We have been unsuccessful in demonstrating this effect consistently, but it may be a useful adjunctive test.

Other diagnostic tests performed routinely in essentially all patients thought to have myasthenia gravis include CT of the chest (for the detection of thymic enlargement or thymoma), tests of thyroid function for reasons discussed further on, and, in cases of uncertain diagnosis, magnetic resonance imaging of the cranium and orbits to exclude compressive and inflammatory lesions of the cranial nerves and ocular muscles.

Special Diagnostic Problems We have encountered or been distracted by the following clinical problems in myasthenia:

1. *The concurrence of myasthenia gravis and thyrotoxicosis.* As indicated on page 1236, thyrotoxicosis may produce a characteristic ocular myopathy. There is no certain evidence that thyrotoxicosis aggravates myasthenia gravis; some have even observed an inverse relationship between the severity of the two conditions. Hypothyroidism, however, does worsen myasthenia gravis. The ophthalmoplegia of thyrotoxicosis can usually be distinguished by the presence of an associated ex-

- ophthalmos (early in the disease, exophthalmos may be absent), lack of ptosis, and the lack of definitive response to neostigmine. Polymyositis and inclusion body myopathy are differentiated from myasthenia by lack of involvement of extraocular muscles, but they may affect oropharyngeal muscles as does myasthenia. Finding the signs of these diseases in combination with those of myasthenia indicates a concurrence of two independent autoimmune diseases.
2. *The neurasthenic or depressed patient who complains of weakness when actually referring to fatigability.* There is no ptosis, strabismus, or dysphagia, though a neurotic individual may complain of diplopia (usually of momentary duration when drowsy) and also of tightness in the throat (*globus hystericus*). A number of such patients claim improvement with neostigmine, but objective weakness and reversal thereof is always uncertain. Conversely, myasthenia is as often mistaken for hysteria or other emotional illness, mainly because the physician is unfamiliar with myasthenia (or with hysteria) and has been overly impressed with the precipitation of the illness by an emotional crisis. Fatigability is a feature of all of these conditions, but only in the psychiatric ones does it extend to the sphere of mental endurance. Moreover, those with myasthenia do not usually complain of fatigue, meaning of the body and mind, whereas these are frequent complaints in psychiatric conditions. A similar problem that has arisen frequently on our services pertains to judging breathlessness due to anxiety or cardiopulmonary disease in a patient with presumed myasthenia. Careful appraisal of the breathing pattern and determination of the vital capacity and more accurate spirometric measurements are helpful here.
 3. *Progressive external ophthalmoplegia and other restricted myopathies, including the congenital myasthenic states.* These may be mistaken for long-established myasthenia gravis. It should be emphasized that the extraocular muscles and levator palpebrae may be permanently damaged by myasthenia and cease to respond to neostigmine. Another possibility is that restricted ocular myasthenia may not respond to anticholinesterase drugs from the beginning and the diagnosis of myasthenia is erroneously excluded. One must then turn to other muscles for clinical and electromyographic and serologic confirmation of the diagnosis.
 4. *Myasthenia with dysarthria and dysphagia, but without ptosis or obvious strabismus.* These may be mistaken for multiple sclerosis, polymyositis, inclusion body myopathy, stroke, motor neuron disease, or some other neurologic disease. Testing with an anticholinesterase inhibitor, single-fiber recording, and measurement of antibodies usually clarifies the matter.
 5. *The initial manifestations of botulism*—blurred vision, diplopia, ptosis, strabismus, and ophthalmoparesis—may be mistaken for myasthenia gravis of acute onset. In botulism, however, the pupils are usually large and unreactive, and the eye signs are followed in rapid succession by involvement of bulbar, trunk, and limb muscles. Similarly, the *oculopharyngeal-brachial and Fisher variants of GBS* in their early stages have many of the features of myasthenia, including ptosis that may be partially responsive to anticholinesterase drugs. The loss of tendon reflexes or the development of ataxia in GBS and detailed electrophysiologic testing distinguishes the two conditions.
 6. *Intoxication with organophosphate insecticides*, because of

their capacity to induce a cholinergic crisis, may be confused with a myasthenic crisis (see further on).

Certain other small clinical points may be helpful in differentiating myasthenia from other diseases that affect the cranial musculature. Acral paresthesias and areflexia in the limbs make the diagnosis of GBS at once apparent. A hanging jaw and hanging head are indicative of myasthenia, while complete or asymmetric facial paresis is more typical of GBS. Botulism usually affects the pupillary convergence reaction, and GBS does so only when there is complete internal and external ophthalmoplegia; diphtheria affects mainly the accommodative reaction early on. From time to time, the question of midbrain stroke due to basilar artery occlusion arises in a case with total ophthalmoplegia; it should be recalled that the level of consciousness is reduced if vertical gaze and pupillary reactions are lost in cases of basilar artery occlusion; such is not the case in neuromuscular diseases. A number of rare metabolic diseases of muscle, particularly myoadenylate deficiency, can cause muscular fatigue, but they do not affect the oculopharyngeal muscles. The myasthenic syndrome of Lambert-Eaton, discussed further on, only occasionally affects the ocular muscles. Ocular paresis, as may occur in nemaline polymyopathy, oculopharyngeal dystrophy, and thyrotoxic ophthalmic disease, come on too slowly in most cases to be confused with myasthenia gravis. On occasion, the eye movements in myasthenia simulate an internuclear ophthalmoplegia or other central appearing sign, even to the extent of including nystagmus in an abducting eye.

Treatment The treatment of this disease involves the careful use of two groups of drugs—anticholinesterases and immunosuppressants—thymectomy, and, in special circumstances, plasma exchange and intravenous immune globulin.

Anticholinesterase Drugs The two drugs that have given the best results in ameliorating myasthenic weakness are neostigmine (Prostigmin) and pyridostigmine (Mestinon), the latter being preferred by most clinicians and patients. The usual dose of pyridostigmine is 30 to 90 mg given every 6 h (typically a 60-mg pill is tried first); the oral dose of neostigmine ranges from 7.5 to 45 mg given every 2 to 6 h. Delayed-action forms of both drugs are available but are given at bedtime mainly to patients who complain of weakness during the night or early morning hours. The dosage of these drugs and their frequency of administration vary considerably from patient to patient, but we agree with Drachman that the maximal useful dosage of pyridostigmine rarely exceeds 120 mg given every 3 h. The dose-equivalents of these various drugs are shown in Table 53-1.

Table 53-1
Dose-equivalents for drugs used in the treatment of myasthenia gravis

	DOSE EQUIVALENT	ONSET	TIME TO MAXIMUM RESPONSE
Pyridostigmine (Mestinon)	60 mg (oral)	40 min	1 h
Neostigmine oral (Prostigmin)	15 mg	1 h	1.5 h
Neostigmine IM	1.5 mg	30 min	1 h
Neostigmine IV	0.5 mg	Immediate	20 min

For mild cases without thymic tumor, for patients in partial remission after thymectomy, and for purely ocular myasthenia, the use of anticholinesterase drugs may be the only form of therapy necessary for some period of time (ocular myasthenia often responds well to small doses of corticosteroids as noted further on). Although these drugs seldom relieve symptoms completely (the response of ocular symptoms is typically incomplete), most such patients are able to remain functional.

If the response to anticholinesterase drugs is poor and progressively larger doses are not relieving symptoms, there is always the danger of a so-called *cholinergic crisis*. In our own experience with more than 60 patients of severe myasthenia in an intensive care unit, we have been persuaded of the occurrence of a cholinergic crisis only rarely. This consists of a relatively rapid increase in muscular weakness, usually coupled with the adverse muscarinic effects of the anticholinesterase drug (nausea, vomiting, pallor, sweating, salivation, bronchorrhea, colic, diarrhea, miosis, bradycardia). An impending cholinergic effect is betrayed by constriction of pupils. If the blood pressure falls as a result of bradycardia, 0.6 mg atropine sulfate should be given slowly by the intravenous route. Edrophonium may be used to determine whether weakness is due to an excess of anticholinesterase medications. However, this test has been misleading and undoubtedly has contributed to an overestimation of the frequency and importance of the cholinergic crisis. Infection or the natural course of the disease ("myasthenic crisis" as discussed later) has been a far more common cause of acutely worsening weakness and respiratory failure.

Corticosteroids For the patient with myasthenia with moderate to severe generalized weakness who is responding inadequately to anticholinesterase drugs, the long-term administration of corticosteroids is the most consistently effective form of treatment as described in a large series of patients by Pascuzzi et al. Small doses of corticosteroids (15 to 25 mg prednisone daily) alone or in combination with azathioprine (see later) are also often adequate to control ocular myasthenia. However, one must be prepared to contend with the side effects of long-term corticosteroid therapy, and we hesitate to undertake such a program in children or patients with severe diabetes or other diseases that are likely to be aggravated.

The usual form of corticosteroid therapy is prednisone (or corresponding doses of prednisolone), beginning with 15 to 20 mg/day and increasing the dose gradually until a satisfactory clinical response is obtained, or until a daily dose of 50 to 60 mg is reached. *With higher doses or more rapid elevations of the doses, worsening in the first week is common*, and hospitalization and careful observation for respiratory difficulty is advisable. Improvement after the initiation of corticosteroids occurs slowly over a few weeks. Once the maximal effect from prednisone has been attained, the dosage can be reduced gradually over months to the lowest point at which it is still effective. The usual practice has been to then institute an alternate-day schedule, which diminishes the side effects. Our patients have done better with a modest difference in dose from one day to the next, rather than omitting a dose entirely on alternate days. Potassium supplements and antacids should be prescribed liberally if needed, as with any chronic corticosteroid regime. At the outset of steroid therapy, anticholinesterase drugs are given simultaneously; as the patient improves, the dosage of the latter may be adjusted downward.

Azathioprine (Imuran) and Other Immunosuppressive Drugs Azathioprine is a useful adjunct to steroids and can be effective alone in patients who cannot tolerate or fail to respond to prednisone. It has been possible to manage the disease reasonably well

in a few patients with azathioprine alone. Treatment begins with 50 mg (1 tablet) twice daily for a few days; if this is tolerated, the dosage is raised to 2 to 3 mg/kg per day (150 to 250 mg daily). The number of positive responses is much the same as with prednisone. However, improvement occurs much more slowly with azathioprine, and a significant response may not be evident for many months to a year (Witte et al). Liver function tests and blood cell count should be checked regularly. The Myasthenia Gravis Clinical Study Group found that the most severe forms of the disease, particularly those resistant to prednisone or azathioprine alone, benefit from the combination of the two medications. Many neurologists, including the present authors, begin by prescribing both medications early in the illness with the plan of reducing the corticosteroid dose in the third or fourth month.

Mycophenolate (CellCept) is currently being used as an adjunct to corticosteroids and has been beneficial in several small trials. The clinical improvement suggested by these studies has generally occurred sooner than it does with azathioprine (Meriggioli and colleagues). Diarrhea was the main adverse effect. Our initial impression is that mycophenolate may be preferable to most of the adjunctive medications and, in some milder cases, may be effective alone.

Cyclophosphamide, administered in intravenous pulses, has been used by De Feo and coworkers; they were able to remove 5 of their 12 patients from steroids but the appropriate use of this potent agent is not clear and we have resorted to it infrequently. Drachman and colleagues describe a regimen of high-dose cyclophosphamide (50 mg/kg/d for 4 consecutive days) followed by granulocyte-stimulating factor to "reboot" the immune system in refractory cases. This approach has risks but may be justified if all other measures have failed in severe instances of the disease. Liver function and white blood cell count should be monitored regularly. The clinical effects of the immunosuppressive agent *cyclosporine* are much like those of azathioprine but become evident more rapidly, in a matter of a month or two (Tindall et al). It is given in two divided doses daily, to a total of about 6 mg/kg but not often used currently because of serious side effects (hypertension, nephrotoxicity) and its high cost. Because of the success of alternative regimens, we have had occasion over the years to use cyclosporine only once for myasthenia.

Plasma Exchange and Intravenous Immune Globulin For severe myasthenia that is refractory to treatment with anticholinesterase drugs and prednisone, or during an acute worsening, one must resort to other measures. Striking temporary remissions (2 to 8 weeks) may be obtained by the use of *plasma exchange*. This form of treatment may be lifesaving during a myasthenic crisis, as noted later. It is also useful before and after thymectomy and at the start of immunosuppressive drug therapy. The number and volume of exchanges required in these circumstances is somewhat arbitrary, but they tend to be less than those required for GBS; several exchanges of 2 to 3.5 L each (totaling approximately 125 mL/kg), performed over a week, usually suffice. The removed plasma is replaced with albumin and saline. It has been estimated that a 2-L exchange will remove 80 percent of circulating antibodies and that this will be reflected in reduced ACh antibody levels in 3 to 5 days. However, there is only an approximate correlation between a reduction in the titer of anti-AChR antibody and the degree of clinical improvement. In a crisis requiring plasma exchanges and mechanical ventilation, it has been our practice to discontinue or curtail the use of anticholinesterase drugs and resume them as the patient is being weaned from the ventilator. Also, it may be that sensitivity

to these drugs may be enhanced in the hours after an exchange, so that their dosages must be adjusted accordingly. Plasma exchange is also helpful in limiting the aforementioned weakness that is often induced by the institution of high-dose corticosteroids.

A small number of patients respond so well to plasma exchange and find the side effects of steroids so intolerable that they choose to be maintained with two to three exchanges every several weeks or months. Immunoadsorption, a technique similar to plasma exchange that removes antibodies and immune complexes by running blood over a tryptophan column, is less cumbersome than conventional plasma exchange and has been effective, but experience with this procedure is limited.

Intravenous immune globulin is similarly useful in the short-term control of acutely worsening myasthenia. The usual dose is 2 g/kg given in divided doses over 3 to 5 days. Several small series suggest that the effect is equivalent to a series of plasma exchanges. However, neither plasma exchange nor immune globulin has been subjected to systematic study or comparison, and it should be emphasized that while these measures are invaluable in deteriorated patients or those in crisis, they offer only short-term benefit and are not used regularly in the treatment of most patients.

Thymectomy This operation, first introduced by Blalock, is considered an appropriate procedure in practically all patients with uncomplicated myasthenia gravis between puberty and 55 years of age. The surgery is performed electively and not during an acute deterioration of myasthenia. The remission rate after thymectomy is approximately 35 percent provided that the procedure is done in the first year or two after onset of the disease, and another 50 percent will improve to some extent (Buckingham et al). The remission rate is progressively lower but not negligible if the operation is postponed beyond this time. In patients with myasthenia restricted to the ocular muscles for a year or longer, the prognosis is so good that thymectomy is unnecessary. The response to thymectomy is usually not evident for several months and is maximal by 3 years. In favorably responding cases, levels of circulating receptor antibody are reduced or disappear entirely. If possible, thymectomy should be postponed until puberty because of the importance of the gland in the development of the immune system, but juvenile myasthenia is also quite responsive. The results are not as predictable in patients who harbor a thymoma.

A suprasternal approach for removal of the gland has been developed and results in less postoperative pain and morbidity than occurs with a transsternal thoracotomy, but the transsternal operation is preferable because it assures a more complete removal of thymic tissue. Thymectomy is best performed in a hospital where there is close collaboration between the thoracic surgeon and the neurologist. If the patient is very weak preoperatively, a course of plasma exchange or immune globulin may be tried preceding the surgical procedure. Large "stress doses" of corticosteroids seem not to be necessary in most patients who have been taking these medications chronically. After operation, respiratory assistance must be available. Neostigmine, intramuscularly, may be given every 3 to 6 h postoperatively. Usually the dose requirement is about 75 percent of that taken before surgery. As improvement occurs, oral medications are resumed since remission is not anticipated for many months.

The benefit of thymectomy in children has already been described under "Clinical Manifestations." Thymectomy is also a safe and effective treatment in elderly patients with myasthenia. In 12 such individuals, Olanow and associates reported complete remission in 9 and clinical improvement in the remainder. But generally, the improvement in older patients is less convincing than it is in

the younger group, in part because the thymus is atrophic. Nonetheless, some of our patients over age 60 have benefited.

Removal of the thymus gland is also indicated in practically all patients in whom *thymoma* is detected by CT scanning of the chest. The tumor can be locally invasive but rarely metastasizes. The operative approach is through the anterior thorax, with adequate exposure to remove all the tumor tissue. If the tumor cannot be removed completely, the remaining tissue should be treated with focused radiation. Local spread and lymph node invasion has been treated with combinations of chemotherapy including cisplatin. Park and colleagues have concluded from a large retrospective study of metastatic cases that chemotherapy offers some benefit in terms of survival, but this remains a controversial issue.

Myasthenic Crisis A rapid and severe deterioration of the myasthenia itself, termed *myasthenic crisis*, can bring the patient to the brink of respiratory failure and quadripareisis in a matter of hours. A respiratory infection or excessive use of sedative medications or drugs with a potential for blocking neuromuscular transmission may precede the myasthenic crisis. We have encountered numerous cases in which oropharyngeal weakness has led to aspiration pneumonia, which, in turn, precipitated a crisis. Just as often, a precipitating event is not evident. Rarely, a respiratory arrest is the first manifestation of crisis. Such events may occur at any time after the diagnosis of myasthenia, but about half of them are evident within 12 to 18 months. In an experience with 53 patients in myasthenic crisis at the Columbia-Presbyterian Medical Center, infection, usually pneumonia, was the most frequent precipitating event, but no cause could be determined in almost one-third (Thomas et al).

Incipient respiratory failure is usually marked by a reduction of vital capacity, often accompanied by restlessness, anxiety, diaphoresis, or tremor. Once the diaphragm fails, movements of the chest wall and abdomen become paradoxical (the abdomen moves inward during inspiration) or there may be shallow excursions of the chest, alternating with paradoxical movements. In an emergency, after clearing of the airway, such a patient can be supported briefly by a tight-fitting face mask and manual bag (Ambu) breathing. The chest wall will be found to be very compliant as a result of muscular weakness.

Treatment of Myasthenic Crisis Management of the crisis entails timely and careful intubation followed by mechanical ventilation in a critical care unit that is equipped to attend to the medical and neurologic needs of such patients. Respiratory failure in a few patients can be managed by the use of bilevel positive airway pressure (BiPAP) according to Rabinstein and Wijdicks, but this has not been consistently effective in avoiding endotracheal intubation in our experience. One must cope with both the oropharyngeal weakness that endangers the airway and the diaphragmatic weakness. Anticholinergic drugs, which exacerbate secretions, are best withdrawn at the time of intubation. The use of plasma exchange as described earlier appears to hasten improvement and weaning from the ventilator. Intravenous gamma globulin may be a useful alternative but has not been studied extensively. Some of our colleagues have used high-dose corticosteroid infusions, but this measure has not been particularly successful in our unit and, in the short run, carries the risk of inducing worsening of the weakness (Panegyres et al). Patients may respond to plasma exchange or immunoglobulin infusions in 1 or 2 days, but more often a week or more is required for recovery. It is generally best to wait 2 or 3 weeks before committing a patient to tracheostomy.

When weaning from the ventilator is anticipated, anticholinesterase agents are reintroduced slowly, and treatment with corticosteroids can be instituted if necessary. *Oral doses of 60 mg pyridostigmine or 15 mg neostigmine are roughly equivalent to 0.5 to 1 mg neostigmine intravenously and 1.5 to 2 mg intramuscularly*, as noted in Table 53-1. The management of the critically ill patient with myasthenia has been reviewed in the monograph by Ropper and colleagues.

Most patients with myasthenic crisis will take several weeks to recover, and a few of our patients have remained ventilator-dependent for months. In the extensive experience from Columbia-Presbyterian, half of patients could be safely extubated within 2 weeks and three-quarters by a month (Thomas et al). There were 7 deaths among 53 patients, reflecting the gravity of this syndrome even in the modern era of intensive care. Atelectasis, severe anemia, congestive heart failure, and clostridial diarrhea (associated with antibiotic use) portend a prolonged period of generalized weakness and intubation. From time to time one encounters a patient in whom respiration and ambulation do not improve for many months after a myasthenic crisis. In our experience, these have been middle-aged or older patients, usually women, in whom an element of hyperthyroidism or hypothyroidism may have been operative. They become wasted as the proximal limb and axial muscles, including the diaphragm, fail to recover their power, even though the ocular and oropharyngeal muscles improve. The role of corticosteroids in producing a concomitant proximal myopathy is a frequent question that can be solved by careful EMG examination.

The only recourse in cases of long-standing and severe myasthenia is to continue an average dose of corticosteroids and anticholinesterase medications with intermittent trials of immune globulin or plasma exchanges. This is also a situation in which high-dose cyclophosphamide followed by granulocyte-stimulating factor as mentioned earlier may result in slow improvement.

Management of Anesthesia and Pregnancy These represent special problems. Surgical procedures of any type are often sufficiently stressful to produce decompensation of the disease. If the patient is unable to take medications orally, anticholinesterase agents may be given intramuscularly (one-thirtieth of the oral dose of pyridostigmine and one-tenth the oral dose of neostigmine). If corticosteroids were being used, they may be continued and the dose generally left unchanged; large “stress” doses are generally not necessary. Neuromuscular blocking agents of the noncompetitive type may have a very prolonged effect and should be avoided as part of the anesthetic regimen. If they are necessary for some reason, a period of mechanical ventilation should be anticipated. In contrast, the dose of succinylcholine (which is not recommended) required to produce muscle relaxation may be larger than usual. Any drug, the use of which is contemplated in anesthetic and postsurgical management, should be checked against the list of agents that are capable of exaggerating myasthenic weakness (see later).

Pregnancy is usually uncomplicated in patients with myasthenia, but some women who are partially treated for myasthenia and have generalized weakness may have difficulty in assisting with vaginal delivery. However, the use of intravenous cholinesterase inhibitors is contraindicated because of the possibility of inducing uterine contractions, and cytotoxic drugs are generally avoided because of the potential for fetal abnormalities. Also, magnesium is not recommended for the treatment of eclampsia because of its neuromuscular blocking effects. Delivery usually proceeds

normally, and breast-feeding is not thought to be a problem with regard to the transmission of AChR antibodies. The issues of neonatal myasthenia and of reduced intrauterine movements are considered later.

OTHER DISORDERS OF NEUROMUSCULAR TRANSMISSION (Table 53-2)

Considered here are several disorders of neuromuscular transmission characterized clinically by muscular weakness and fatigability but differing in mechanism from autoimmune myasthenia gravis. The Lambert-Eaton myasthenic syndrome, neonatal myasthenia, the congenital myasthenic syndromes, and the myasthenic syndromes induced by drugs and toxins are the main disorders in this group. Two additional important members—botulism and organophosphate poisoning—are described elsewhere in the book (pages 1032 and 1037, respectively).

The Myasthenic-Myopathic Syndrome of Lambert-Eaton (Lambert-Eaton Syndrome, LEMS)

This special form of myasthenia, observed most often in patients with oat-cell carcinoma of the lung, was first described by Lambert, Eaton, and Rooke in 1956 and further by Eaton and Lambert in 1957. Unlike classic myasthenia gravis, the muscles of the trunk, shoulder girdle, pelvic girdle, and lower extremities are the ones that become weak and fatigable. Characteristic EMG findings and poor response to anticholinesterase drugs also serve to differentiate it from myasthenia gravis. Often the first symptoms are difficulty in arising from a chair, climbing stairs, and walking; the shoulder muscles are affected later. While ptosis, diplopia, dysarthria, and dysphagia may occur, presentation with these symptoms is distinctly unusual. Increasing weakness after exertion stamps the condition as myasthenic, but in direct contrast to myasthenia gravis, *there may be a temporary increase in muscle power during the first few contractions*. The tendon reflexes are often diminished, but complete abolition of the reflexes should raise the question of an associated carcinomatous polyneuropathy. Fasciculations are not seen.

One of the most instructive reviews of this disease is that of O’Neill and colleagues; in 50 well-studied and fully developed cases they describe proximal leg weakness in all, arm weakness in 39, diplopia in 25, ptosis in 21, and dysarthria in 12. Other complaints were paresthesias, aching pain (suggesting arthritis), and a number of autonomic disturbances, such as dryness of the mouth, constipation, difficult micturition, and impotence. One should not be surprised to find other neurologic manifestations of neoplasia (e.g., polyneuropathy, polymyositis or dermatomyositis, multifocal leukoencephalopathy, cerebellar degeneration, as discussed in Chap. 31).

The onset of weakness is usually subacute and the course variably progressive. Males are affected more often than females (5:1). The myasthenia may precede discovery of the tumor by months or years. About 60 percent of cases are associated with small-cell lung cancer, but small numbers have also occurred with carcinoma of the breast, prostate, stomach, and rectum and with lymphomas. However, in about one-third of patients, no tumor is found; some of these cases are associated with other autoimmune diseases, but most are idiopathic. The condition may occur in chil-

Table 53-2**Major disorders of the neuromuscular junction**

MYASTHENIC SYNDROMES	CAUSAL AGENT OR GENE DEFECT	ONSET DECADE	TREATMENT	CLINICAL FEATURES
Acquired Myasthenic Syndromes				
Presynaptic				
Botulism (Chap. 43)	Peptide toxin from <i>Clostridium botulinum</i>	Any	Supportive; ventilation	Blurred vision, dysphagia, limb weakness
Lambert-Eaton myasthenic syndrome	Autoimmune reduction in calcium-mediated quantal release	Mid-life	3,4-DAP Possibly IVIG	Truncal weakness, dysautonomic features Two-thirds have cancer
Synaptic				
Insecticides (Chap. 43)	Organophosphates (inhibits AChE)	Any	Remove toxins Atropine	Miosis, diarrhea, cramps, weakness Delayed sensorimotor neuropathy
Postsynaptic				
Myasthenia gravis	Autoimmune attack on postsynaptic membrane Antibodies to AChR or MuSK protein	Adult	AChE inhibitors, IVIG Other immunosuppressants	Diplopia, ptosis Limb weakness with exertion
Snake venom toxins (Chap. 43)	Multiple peptide toxins that lyse muscle, bind Na channels, K channels (acting both post- and presynaptically)	Any	Supportive Possibly AChE inhibitors	Acute weakness
Hereditary and Congenital Myasthenic Syndromes				
Presynaptic				
Episodic apnea	Choline acetyltransferase	1st	AChE inhibitors Apnea monitor	Mild episodes of weakness; recurrent apnea Ptosis common
Paucity of synaptic vesicles	Unknown	1st	AChE inhibitors	Recurrent, sometimes pronounced weakness
Synaptic				
AChE deficiency	AChE Collagen tail for AChE	1st	None Avoid AChE inhibitors	Diffuse weakness, ptosis
Postsynaptic				
Slow channel syndrome	AChR subunits	1st–6th	Quinidine, AChE inhibitors Avoid 3,4-DAP	Ptosis, diffuse weakness, delayed motor milestones Often show atrophy of dorsal forearms
Fast channel syndrome	AChR subunits	1st	3,4-DAP	Ptosis, recurrent weakness, motor development delays
Primary AChR deficiency	AChR subunits	1st	AChE inhibitors, 3,4-DAP	Ptosis, recurrent weakness, motor development delays
Rapsyn deficiency	Rapsyn	1st	AChE inhibitors, 3,4-DAP	Ptosis, recurrent weakness
Plectin deficiency	Plectin	1st	3,4-DAP	Myasthenic features, epidermolysis bullosa

AChE, acetylcholine esterase; AChR, acetylcholine receptor; MuSK, muscle-specific kinase; IVIG, intravenous immune globulin; DAP, diaminopyridine.

dren, usually with no relation to tumor. In the tumor cases, death usually occurs in a few months or years from the effect of the tumor itself; the idiopathic ones fluctuate over years.

As mentioned above, the response to neostigmine and pyridostigmine is poor or at least unpredictable. In contrast, *d*-tubocurarine, suxamethonium chloride, gallamine, and other muscle relaxants have a deleterious effect. Just as in myasthenia gravis, when given during anesthesia, they increase the weakness and even lead to fatality.

Conventional electrodiagnostic studies have shown no abnor-

mality in the peripheral nerves. A single stimulus of nerve may evoke a low-amplitude muscle action potential (in contrast to myasthenia gravis, in which it is normal or nearly so), whereas at fast rates of stimulation (50 per second as shown in Fig. 45-5B) or with strong voluntary contraction (for 15 s or longer), there is a marked increase in the amplitude of action potentials (incrementing response). Single-fiber recordings show an increase in “jitter,” as in myasthenia gravis (page 1106).

In the Lambert-Eaton syndrome, there is an increased representation of HLA-B8 and -DR3 haplotypes, as occurs in other au-

toimmune diseases. Elmquist and Lambert, from a series of studies of excised muscle, deduced that there is a defect in the release of ACh quanta from the *presynaptic* nerve terminals, akin to the effects of botulinum toxin, magnesium excess, and neomycin (see further on). The presynaptic vesicles themselves appear to be normal in electron micrographs. Also in contrast to myasthenia gravis, the extent of the receptor surface in this syndrome is actually increased (A. G. Engel).

The physiologic mechanism in Lambert-Eaton myasthenic syndrome is not fully delineated; however, a fundamental defect is a loss of voltage-sensitive calcium channels on the presynaptic motor nerve terminal. The calcium channels become cross-linked and aggregated by IgG autoantibodies, ultimately reducing the number of functioning channels (Fukunaga et al). In other words there are antibodies against a specific component of the *presynaptic* membrane that have the effect of reducing the presynaptic release of ACh, virtually the opposite of myasthenia gravis. A serologic test for these antibodies is available and is performed to confirm the diagnosis. Even in patients without detectable antibodies against voltage-gated calcium channels, passive transfer indicates the presence of a circulating factor with similar activity. Muscle biopsy is normal or shows only the same slight, nonspecific changes as in myasthenia gravis. The thymus is, of course, normal.

Recognition of the Lambert-Eaton syndrome should lead to a search for an occult tumor, particularly of the lung. A PET scan of the body may be useful in this regard, although CT of the lungs is usually adequate. If found, it should of course be treated; this alone may result in improvement in the neurologic syndrome. If none is found, the search should be repeated at regular intervals, since the tumors at first are small and may be inapparent even at autopsy.

Treatment Most patients with this disease benefit from administration of 3,4-diaminopyridine (3,4-DAP), an agent that blocks potassium channels in the distal motor terminal, thus prolonging depolarizations and enhancing the release of ACh vesicles. The drug is given as 20 mg, up to 5 times a day either alone or in conjunction with pyridostigmine (Lundh et al). This has largely replaced the use of guanidine hydrochloride (20 to 30 mg/kg/day in divided doses), which had proved to be more effective in increasing strength than neostigmine or pyridostigmine but had significant hematologic and renal toxicity with long-term use. With regard to more long-term relief, numerous regimens have been tried and favored by different groups. Streib and Rothner were able to achieve long-term improvement with prednisone. Dau and Denys have claimed the best results in nontumor cases with repeated courses of plasmapheresis in combination with prednisone and azathioprine. Intravenous immune globulin has also been effective in a few reported cases. Bain and coworkers indicate that the benefit is due to reduction in calcium channel autoantibodies, but the precise mechanism whereby intravenous immune globulin produces this effect could not be established. Because of the unpredictable side effects of these drugs, many clinicians prefer alternate-day administration of prednisone and azathioprine—prednisone 25 to 60 mg/day, and azathioprine 2 to 3 mg/kg body weight daily—supplemented intermittently as needed by intravenous immune globulin. The response to treatment tends to be slow, over a period of months and sometimes up to a year. Some patients recover fully; in others, restoration of power is incomplete.

Diagnosis A syndrome of symmetrical weakness and fatigability of proximal muscles—coupled with dry mouth, sphincter distur-

bances, aching muscles, and diminished reflexes—should be diagnostic. The illnesses with which it might be confused are myasthenia gravis, inclusion body myopathy, and polymyositis. There is a superficial resemblance to hysterical paralysis, where the patient may do better with encouragement on making a succession of voluntary contractions, and arthritis, where pain hampers the first movements more than the successive ones. Then the electrodiagnostic and specific serologic tests are of value.

Neonatal Myasthenia Gravis

An estimated 12 to 20 percent of babies born to mothers with myasthenia show transient signs of myasthenia (hypotonia, weak cry and suck). This transitory phenomenon is apparent at birth and has a mean duration of about 2 to 5 weeks; recovery is usually complete within 2 months of birth (rarely longer), without later relapse. Uncommonly, the mother with myasthenia reports reduced intrauterine movements, suggesting a dangerous degree of myasthenia in the fetus. A few of these children will be born with arthrogryposis, the result of a sustained period of intrauterine immobility, and this complication then tends to recur in subsequent births.

It has long been assumed that neonatal myasthenia is due to the passive transplacental transfer of anti-AChR antibodies. This explanation is not entirely satisfactory, insofar as maternal AChR antibodies are transferred from mother to fetus in all AChR antibody-positive pregnancies and the incidence and severity of the neonatal myasthenia gravis does not correlate with the severity or duration of the mother's illness or with the serum level of the maternal AChR antibody. In fact, neonatal myasthenia may occur when the mother is in remission.

Administration of plasma exchange and anticholinesterase drugs to the infant may be useful in hastening recovery from neonatal myasthenia.

Congenital Myasthenic Syndromes

(See Table 53-2)

Sporadically in the medical literature, there have appeared reports of a benign congenital myopathy in which myasthenic features could be recognized in the neonatal period or soon thereafter. The affected infants had been born to mothers who did not have myasthenia and were in the past described under headings such as "Myasthenia Gravis in the Newborn" and "Familial Infantile Myasthenia" (Greer and Schotland; Robertson et al) to distinguish the condition from passively transmitted neonatal myasthenia.

In the 1970s and 1980s, after the autoimmune basis of myasthenia gravis was established and its morphologic and physiologic features defined, the differences between this disease and the familial infantile forms became evident. Since then, at least eight distinct and rare congenital myasthenic syndromes have been delineated on the basis of their electrophysiologic and ultrastructural features, and a number of others have been partially characterized.

As indicated in Table 53-2, the congenital myasthenic syndromes are inherited defects in components of the presynaptic, synaptic, or postsynaptic junctional apparatus. Broadly speaking, the defects involve resynthesis or packaging of ACh or a paucity of synaptic vesicles (presynaptic); a deficiency of end-plate ACh esterase (synaptic); or kinetic abnormalities in the AChR channels, or AChR deficiency (postsynaptic). It has been estimated that in three-fourths of the cases the defect is postsynaptic.

Clinically, these disorders are distinguished by neonatal onset, fluctuating and sometimes progressive weakness that may be quite severe, sometimes pronounced muscle hypotrophy, persistent ptosis, and seronegativity for anti-AChR and anti-MuSK antibodies. Moreover, heritability (typically autosomal recessively) is suggested by familial occurrence of the disorders among siblings. In the neonate, the most important clue to the disease is an increase in ptosis and in bulbar and respiratory weakness with crying. Later in infancy these symptoms, as well as fluctuating ocular palsies and abnormal fatigability, are brought out by other types of sustained activity. Motor milestones may be delayed. In some cases, the myasthenic weakness and fatigability do not become evident until the second and third decades of life. The intravenous edrophonium test is inconsistently positive in a few forms of congenital myasthenia, but it usually is negative.

Both the *fast channel syndrome* and the *slow channel syndrome* are consequences of mutations in AChR subunits that respectively accelerate (fast channel) and slow (slow channel) the kinetics of gating of receptor channel (Croxen et al). Another well-characterized type of congenital myasthenia, usually causing arthrogryposis and recurrent apneic spells, but occasionally having a late onset (as late as 48 years), has been traced to mutations in the "rapsyn" gene. The rapsyn protein is believed to play a role in maintaining the integrity of the postsynaptic membrane (see Burke et al). Some of the congenital syndromes have special implications for therapy: drugs that are beneficial for one may be contraindicated in another. Deficiency of the enzyme required to synthesize and package ACh in vesicles (choline acetyl-transferase) causes a congenital myopathy with episodes of stress-induced apnea. In another type, the synaptic vesicles form poorly and are reduced in number. Being largely presynaptic defects, both of these disorders respond to ACh-esterase (AChE) inhibitors. In comparison, children with congenital myasthenia due to deficiency of AChE deteriorate markedly if given AChE inhibitors. Three disorders affecting post-synaptic structures (the fast channel syndrome, AChR deficiency, and the myasthenic syndromes associated with deficiencies of rapsyn and plectin) also respond to AChE inhibition and 3,4-DAP, while both agents are hazardous in individuals with the slow channel syndrome.

The studies of A. G. Engel have systematically defined and classified these disorders in a series of extensive investigations of more than 100 cases. A detailed and current account of this work can be found in his chapter on the subject in his monograph *Myasthenia Gravis and Myasthenic Disorders*.

Myasthenic Weakness due to Antibiotics and Other Drugs and to Natural

Environmental Toxins (See Chap. 43 and

Table 53-2)

Many drugs may cause a myasthenic syndrome or a worsening of myasthenia gravis by their action on pre- or postsynaptic structures. In the case of a nonmyasthenic patient, this is most likely to happen in the presence of hepatic or renal disease that allows excessive accumulation of the causative agent. The myasthenic state in these conditions is acute and lasts hours or days, with full recovery provided that the patient does not succumb to respiratory failure. The ocular, facial, and bulbar muscles are involved, just as in native myasthenia, as well as other muscles. The treatment in all instances

is to provide respiratory support, discontinue the offending drug, and attempt to reverse the block at the end plate by infusions of calcium gluconate, potassium supplements, and the administration of anticholinesterases along the lines suggested by Argov and Mastaglia.

There are more than 30 drugs in current clinical use (other than anesthetic agents) that may, under certain circumstances, interfere with neuromuscular transmission in otherwise normal individuals. Of these, the most important are the aminoglycoside and quinolone antibiotics. Myasthenic weakness has been reported with 18 different antibiotics but particularly neomycin, kanamycin (less so with gentamicin), colistin, streptomycin, polymyxin B, and certain tetracyclines (McQuillen et al; Pittinger et al). It has been shown that these drugs impair transmitter release by interfering with calcium-ion fluxes at nerve terminals. The fluorinated quinolones (fluoroquinolones) group, typified by ciprofloxacin, affect both pre- and postsynaptic activity. They are especially hazardous when given to patients with myasthenia, but they may be used if necessary in such patients who are already receiving ventilatory support. Also, several of the immunosuppressant drugs—adrenocorticotropic hormone (ACTH), prednisone, and possibly azathioprine—worsen myasthenia temporarily by depolarizing nerve terminals or impairing release of ACh.

Other drugs—such as anticholinesterase agents, particularly the insecticides and nerve gases—cause paralysis by binding to cholinesterase and blocking the hydrolysis of ACh. The end plate remains depolarized and is refractory to neural stimuli. The most notable of these are: (1) botulinum toxin, which binds to cholinergic motor endings, blocking quantal release of ACh; (2) black widow spider venom, which causes a massive release of ACh, resulting in muscular contraction and then paralysis from a lack of ACh; (3) *d*-tubocurarine, which binds to AChR; (4) suxamethonium and decamethonium, which also bind to AChR; (5) organophosphates, which bind irreversibly to AChE; and (6) malaathion and parathion, which inhibit AChE. The actions of all these agents except for the organophosphate "nerve gases" are transitory.

The administration of *d*-penicillamine has also caused an unusual type of myasthenia. The weakness is typical in that rest increases strength—as do neostigmine and edrophonium—and the electrophysiologic findings are also the same. In such cases, Vincent and others found anti-AChR antibodies in the serum; hence, one must assume that this is a form of induced autoimmune myasthenia gravis. In these respects it differs from the weakness caused by aminoglycosides (see review by Swift). Rarely, typical autoimmune myasthenia gravis develops as part of a chronic graft-versus-host disease in long-term (2- to 3-year) survivors of allogeneic marrow transplants.

A large group of naturally occurring environmental neurotoxins are known to act at the neuromuscular junction and to induce muscle paralysis of a pattern like that of myasthenia gravis. Venoms of certain snakes, spiders, and ticks are common and well-known animal poisons, as are ciguatera and related toxins (from fish that have ingested certain dinoflagellates), curare (from plants), and *Clostridium botulinum*—all of which are discussed in other parts of this book (see especially Chap. 43). Poisoning by these natural neurotoxins constitutes an important public health hazard in many parts of the world but particularly in the tropics. This class of disorders of neuromuscular transmission has been reviewed by Senanayake and Roman.

CHAPTER 54

THE PERIODIC PARALYSES AND HEREDITARY, NONDYSTROPHIC MYOTONIAS (ION CHANNEL DISORDERS)

This chapter considers a category of disorders that is characterized by disturbances of the electrical excitability of the skeletal muscle membrane. The main manifestations are episodes of generalized paralysis and myotonia. The myotonias have been historically categorized as a special group of muscle diseases unified by the clinical sign of myotonia and were aligned in some older classifications with the muscular dystrophies. This view was based on myotonia as it was understood in the classic form of myotonic dystrophy, a subject discussed in Chap. 50. Similarly, before fundamental knowledge of their mechanism was revealed, the periodic paralyses (better called *episodic paralysis*) were considered to be metabolic diseases of muscle. However, in the last decades, it has become evident that most diseases that feature prominent myotonia and the collection of processes that cause episodic muscular paralysis are neither degenerative nor dystrophic. Careful clinical and electrophysiologic studies show that myotonia is an elemental feature of many nondystrophic conditions, foremost among them, the hyperkalemic form of periodic paralysis and myotonia congenita. All these diseases are now known to be caused by mutations in genes that code for chloride, sodium, calcium, or potassium ion channels in the muscle fiber membrane, and they are referred to as *ion channel diseases*, or, colloquially, as “channelopathies.” Within this group there are also instances of muscle conditions that have no myotonia but only periodic paralysis.

Given that these are disorders of muscle membrane excitability, it is not surprising that the primary defects are in voltage-dependent ion channels. By analogy, it was anticipated that ion channelopathies would be implicated in two other categories of disease in which there is altered membrane excitability, namely the epilepsies and cardiac arrhythmias, and indeed this has proven to be the case (see discussion in Chap. 16 on the epilepsies). The biology of the ion channels and their disease-related mutations are reviewed by Ackerman and Clapham, by Hanna and colleagues, and by Cannon. Molecular studies, notably those of Rüdel, Lehmann-Horn, and Ricker and their associates, have identified the fundamental defects in the myotonias and episodic paralyses and clarified their relationships. In the process, several new forms of nondystrophic myotonia have been defined.

The main features of the ion channel diseases affecting muscle are summarized in Table 54-1 and the individual members of the group are described as follows.

CHLORIDE CHANNEL DISEASES

Myotonia Congenita (Thomsen Disease)

This is an uncommon disease of skeletal muscle that begins in early life and is characterized by myotonia, muscular hypertrophy, non-progressive course, and dominant inheritance. It is distinctly dif-

ferent from myotonic dystrophy, which is characterized by a progressive degeneration of muscle fibers and has a different genetic basis (see page 1221).

History The disorder was first brought to the attention of the medical profession in 1876 by Julius Thomsen, a Danish physician who himself suffered from the disease, as did 20 other members of his family over four generations. His designation of *ataxia muscularis* was not correct, but his description left no doubt as to the nature of the condition in that it featured “tonic cramps in voluntary muscles associated with an inherited psychical indisposition.” The latter aspect of the condition was not borne out by subsequent studies and is now thought to be his erroneous speculation as to causality. Strümpell in 1881 assigned the name *myotonia congenita* to the disease, and Westphal in 1883 referred to it as *Thomsen disease*. Erb provided the first description of its pathology and called attention to two additional unique features, muscular hyperexcitability and hypertrophy. In 1923, Nissen, Thomsen’s great-nephew, extended the original genealogy to 35 cases in seven generations. In 1948, Thomasen updated the subject in a monograph that is still a useful clinical reference.

Thomsen disease is caused by one of several inherited molecular defects in the voltage-dependent chloride channel gene (CLCN1), as first demonstrated by Jentsch and associates (see Koch). It is interesting that some mutations behave as dominant traits while others have either a dominant or recessive pattern of inheritance (see Table 54-1). The physiologic mechanism whereby these mutations alter ion fluxes across the muscle membrane and cause myotonia is described further on.

Clinical Features Myotonia, a tonic spasm of muscle after forceful voluntary contraction, stands as the cardinal feature of the disease. As emphasized on page 1104, this phenomenon reflects electrical hyperexcitability of the muscle membrane. It is most pronounced after a period of inactivity. Repeated contractions “wear it out,” so to speak, and the later movements in a series become more swift and effective. Rarely the converse is observed—where only the later movements of a series induce myotonia (*myotonia paradoxica*); but usually this is a feature of another condition, cold-induced paramyotonia congenita (see further on). Unlike cramp, the myotonic spasm is painless, but after prolonged activity, nocturnal myalgia—a pinching-aching sensation in the overactive muscles—may develop and prove distressing. Close observation reveals a softness of the muscles during rest, and the initial contraction appears not to be significantly slowed.

The disease is usually inherited as a dominant trait so that, most often, other members of the family have been affected. Its congenital nature may be evident even in the crib, where the infant’s eyes are noted to open slowly after it has been crying or sneezing, and its legs are conspicuously stiff as the child tries to

Table 54-1
The main inherited myotonias and periodic paroxysms (the channelopathies)

CHANNEL AFFECTED	CHLORIDE	CHLORIDE	SODIUM	SODIUM	CALCIUM	POTASSIUM
Disease	Myotonia congenita (Thomsen)	Generalized myotonia (Becker)	Hypertkalemic periodic paralysis	Paramyotonia congenita (Eulenburg)	Hypokalemic periodic paralysis	Malignant hyperthermia

take its first steps. In other cases, the myotonia becomes evident only later in the first or second decade. The muscles are generously proportioned and may become hypertrophied, but seldom to the degree observed in the recessive form of the disease described further on under "Generalized Myotonia." Despite their muscular appearance, these patients are inept in athletic pursuits.

When severe, the myotonia tends to affect all skeletal muscles but is especially prominent in the lower limbs. Attempts to walk and run are sometimes impeded to the extent that the patient stumbles and falls. Other limb and trunk muscles are also thrown into spasm, as are those of the face and upper limbs. One of the characteristic features is grip myotonia in which the patient is unable to release a handshake and must slowly open the fingers one at a time. Occasionally a sudden noise or fright may cause generalized stiffness and falling. Small, gentle movements such as blinking or elicitation of a tendon reflex do not initiate myotonia, whereas strong closure of the eyelids, as in a sneeze, sets up a spasm that may prevent complete opening of the eyes for many seconds. Spasms of extraocular muscles occur in some instances, leading to strabismus. If the patient has not spoken for a time, there is sometimes a striking dysarthria. Arising at night, the patient cannot walk without first moving the legs for a few minutes. After a period of rest, the patient may have difficulty in arising from a chair or climbing stairs. Loosening of one set of muscles after a succession of contractions does not prevent the appearance of myotonia in another area, nor in the same ones if used in another pattern of movement. Smooth and cardiac muscles are not affected and intelligence is normal. Lacking also are the narrow face, frontal balding, cataracts, and endocrine changes typical of myotonic dystrophy (page 1221). Myotonia that is evident in infancy is far more likely to represent myotonia congenita than myotonic dystrophy, in which myotonia rarely has its onset in the first few years of life.

Myotonia can also be induced in most cases by tapping a muscle belly with a percussion hammer (percussion myotonia). Unlike the lump or ridge produced in hypothyroid or cachectic muscle (myoedema), the myotonic contraction involves an entire fasciculus or an entire muscle and, unlike the phenomenon of idiomuscular irritability (contraction of a fascicle in response to striking the muscle), it persists for several seconds. If tapped, the tongue shows a similar reaction. An electrical stimulus delivered to the motor point in a muscle induces a prolonged contraction (Erb's myotonic reaction). In Thomsen disease, as in virtually all forms of myotonia, the stiffness is somewhat exaggerated in cold. On a cold day, affected individuals may have a prolonged grimace with closed eyes after a sneeze. We have encountered two brothers with this disorder who describe diving into a cool swimming pool on a hot summer day and having to lie nearly motionless at the bottom of the pool for several seconds until the muscle stiffness abated enough to allow them to swim to the top. Prominent cold-induced myotonia, however, is more characteristic of paramyotonia congenita (see later).

Biopsy reveals no abnormality other than enlargement of muscle fibers, and this change occurs only in hypertrophied muscles. As often happens in fibers of increased volume, central nucleation is somewhat more frequent than it is in normal muscle. The large fibers contain increased numbers of normally structured myofibrils. In well-fixed biopsy material examined under the electron microscope, Schroeder and Adams were unable to discern any significant morphologic changes. There are no changes in the peripheral or central nervous system.

Myotonia Levior This was the name applied by DeJong to a dominantly inherited form of myotonia congenita in which the symptoms are of milder expression and later onset than those of Thomsen disease. In two patients of a myotonia levior family, Lehmann-Horn and coworkers identified a mutation of the same chloride ion channel (CLCN1) that is implicated in Thomsen disease. Thus it appears that myotonia levior is simply a mild form of Thomsen disease.

Diagnosis In patients who complain of spasms, cramping, and stiffness, myotonia must be distinguished from several of the disorders described in Chap. 55—myokymia, persistent muscle activity and the cramp-fasciculation syndromes, periodic hyperkalemic paralysis, Schwartz-Jampel syndrome, pathologic cramp syndrome, contracture of phosphorylase or phosphofructose kinase deficiency, and perhaps most of all, "stiff-man" syndrome. In none of these disorders is there percussion myotonia or the typical electromyogram (EMG) abnormality of myotonic discharge. The only possible exception is the Schwartz-Jampel syndrome of hereditary stiffness combined with short stature and muscle hypertrophy discussed in the next chapter. The regional nature and spontaneous activity of dystonia only superficially resembles myotonia.

Some uncertainty may arise in those patients who later prove to have myotonic dystrophy when only myotonia is noted in early life. The myotonia in these cases is usually mild, and in several families that we have followed, some degree of weakness and the typical facies of myotonic dystrophy could be appreciated even in early childhood. In paramyotonia congenita (see further on), there is also myotonia of early onset, but again it tends to be mild, involving mainly the orbicularis oculi, levator palpebrae, and tongue; the diagnosis or paramyotonia is seldom in doubt because of the worsening with continued activity and prominent cold-induced episodes of paralysis.

In patients with very large muscles, one must consider not only myotonia congenita but also familial hyperdevelopment, hypothyroid polymyopathy, the Bruck-DeLange syndrome (congenital hypertrophy of muscles, mental retardation, and extrapyramidal movement disorder), and hypertrophic polymyopathy (hypertrophy musculorum vera). [This last disease is of current interest because the protein (myostatin) and gene defect have recently been characterized.] Muscle hypertrophy is not, of course, a feature of myotonic dystrophy. The demonstration of myotonia by percussion and EMG study usually resolves the problem, although it should be noted that in exceptional cases of Thomsen disease, the persistence of contraction may be difficult to demonstrate. In hypothyroidism, the EMG may show bizarre high-frequency (pseudomyotonic) discharges (page 1105). However, true myotonia does not occur, myoedema is prominent, and—along with other signs of thyroid deficiency—there is slowing of contraction and relaxation of tendon reflexes not seen in myotonia congenita.

Treatment Quinidine sulfate, 0.3 to 0.6 g; procainamide, 250 to 500 mg qid; and mexiletine, 100 to 300 mg tid, are beneficial in relieving the myotonia. Phenytoin, 100 mg tid, has also been useful in some cases. The cardiac antiarrhythmic drug tocainide (1200 mg daily) has also proved effective, but it sometimes causes agranulocytosis and is no longer recommended.

Generalized Myotonia (Becker Disease)

This is a second form of myotonia congenita, inherited as an autosomal recessive trait. Like the dominant Thomsen form, it is

caused by an allelic mutation of the gene encoding the chloride ion channel of the muscle fiber membrane. The clinical features of the dominant and recessive types are similar except that myotonia in the recessive type does not become manifest until 10 to 14 years of age or even later and tends to be more severe than the myotonia of the dominant type. The myotonia appears first in the lower limbs and spreads to the trunk, arms, and face. Hypertrophy is invariably present. There may be an associated mild distal weakness and atrophy; this was found in the forearms in 28 percent of Becker's 148 patients and in the sternocleidomastoids in 19 percent. Dorsiflexion of the feet was limited and fibrous contractures were common. Weakness may also be present in the proximal leg and arm muscles. The most troublesome aspect of the disease is the transient weakness that follows initial muscle contraction after a period of inactivity. Progression of the disease continues to about 30 years of age, and according to Sun and Streib, the course of the illness thereafter remains unchanged. In contrast to Thomsen disease, the creatine kinase (CK) may be elevated. Testicular atrophy, cardiac abnormality, frontal baldness, and cataracts—the features that characterize myotonic dystrophy—are conspicuously absent.

DISEASES OF THE SODIUM CHANNEL

The main diseases in this category are *hyperkalemic periodic paralysis* and *paramyotonia congenita*. The derivative disorders *normokalemic periodic paralysis*, *acetazolamide-responsive myotonia*, *myotonia fluctuans*, and *myotonia permanens* are variants of hyperkalemic periodic paralysis. All of them are due to mutations in the gene encoding the alpha subunit of the sodium channel in skeletal muscle (SCN4A).

Hyperkalemic Periodic Paralysis

The essential features of this disease are episodic generalized weakness of fairly rapid onset and a rise in serum potassium during attacks. Weakness appearing after a period of rest that follows exercise is particularly characteristic. This type of periodic paralysis was first described and distinguished from the more common (hypokalemic) form by Tyler and colleagues in 1951. Five years later, Gamstorp described two additional families with this disorder and named it *adynamia episodica hereditaria*. As further examples were reported, it was noted that in many of them there were minor degrees of myotonia, which brought the condition into relation with paramyotonia congenita (see further on). Hyperkalemic periodic paralysis was associated with a defect in the alpha subunit of the sodium channel gene (Fontaine et al); confirmation that it was a sodium channel disorder followed shortly thereafter. It is now appreciated that there are distinct variants of hyperkalemic periodic paralysis that breed true. All are associated with membrane hyperexcitability because of imperfections in the process of sodium channel inactivation following membrane depolarization as discussed later.

Clinical Manifestations The pattern of inheritance is autosomal dominant. Onset is usually in infancy and childhood. Characteristically, the attacks of weakness occur before breakfast and later in the day, particularly when resting following exercise. In the latter case, the weakness appears after 20 to 30 min of becoming sedentary. The patient notes difficulty that begins in the legs, thighs, and lower back and spreads to the hands, forearms, and shoulders

over minutes or more. Only in the severest attacks are the neck and cranial muscles involved. Respiratory muscles are usually spared. As the muscles become inexcitable, tendon reflexes are diminished or lost. Attacks usually last 15 to 60 min, and recovery can be hastened by mild exercise. After an attack, mild weakness may persist for a day or two. In severe cases, the attacks may occur every day; during late adolescence and the adult years, when the patient becomes more sedentary, the attacks may diminish and even cease entirely. In certain muscle groups, if myotonia coexists, it is difficult to separate the effects of paresis from those of myotonia. Indeed, when an attack of paresis is prevented by continuous movement, firm, painful lumps may form in the calf muscles. Some patients with repeated attacks may be left with a permanent weakness and wasting of the proximal limb muscles.

During the attack of weakness, serum K rises, often but not always up to 5 to 6 mmol/L. This is associated with an increased amplitude of T waves in the electrocardiogram (ECG) and a fall in the serum Na level (due to entry of Na into muscle). With increased urinary excretion of K, the serum K falls and the attack terminates. Between attacks, serum K is usually normal or only slightly elevated.

The attacks of paralysis are alike in all clinical variants of the disease. Usually the presence of myotonia can only be detected electromyographically. In the paramyotonic form discussed below, the attacks are associated with paradoxical myotonia—that is, myotonia induced by exercise and also by cold.

The *provocative test*, undertaken when the patient is functioning normally, consists of the oral administration of 2 g of KCl in a sugar-free liquid repeated every 2 h for four doses, if that many are necessary to provoke an attack. The test is given in the fasting state, ideally just after exercise. The weakness typically has a latency of 1 to 2 h after the administration of K. The patient must be carefully monitored by ECG and frequent serum K estimations. The test should never be undertaken in the presence of an attack of weakness or reduced renal function or in those with diabetes requiring insulin.

The *treatment* of this syndrome is the same as that for paramyotonia congenita, described further on.

Normokalemic Periodic Paralysis This form of episodic paralysis resembles the hyperkalemic form in practically all respects except that serum potassium does not increase out of the normal range, even during the most severe attacks. However, some patients with normokalemic periodic paralysis are sensitive to potassium loading (Poskanzer and Kerr); other kindreds are not (Meyers et al). The disorder is also transmitted as an autosomal dominant trait, and the basic defect has proved to stem from the same mutation as that of hyperkalemic periodic paralysis of which it may be considered a variant.

Paramyotonia Congenita (Eulenburg Disease)

In this disease, attacks of periodic paralysis are associated with myotonia, which may be paradoxical in type—that is, developing during exercise and worsening as the exercise continues. In addition, a widespread myotonia, often coupled with weakness, is induced by exposure to cold. In some patients the myotonia can be elicited even in a warm environment. The weakness may be diffuse, as in hyperkalemic periodic paralysis, or limited to the part of the body that is cooled. As commented in the earlier section on hyperkalemic paralysis, cold exaggerates many types of myotonia to

some extent, but this property is most characteristic of paramyotonia and it is in this condition that cold-induced weakness persists for up to several hours once started, even after the body is rewarmed. Percussion myotonia can be evoked in the tongue and thenar eminence. According to Haass and colleagues, myotonia that is constantly present in a warm environment diminishes with repeated contraction, whereas myotonia induced by cold increases with repeated contraction (paradoxical myotonia).

Like hyperkalemic periodic paralysis, paramyotonia congenita is transmitted in an autosomal dominant manner, and both diseases have been linked to the same gene (*SCN4A*), which encodes the alpha subunit of the muscle membrane sodium channel; the two diseases are caused by allelic mutations.

Laboratory Findings In both hyperkalemic periodic paralysis and paramyotonia congenita, the serum K is usually above the normal range during bouts of weakness, but paralysis has been observed at levels of 5 meq/L or even lower. Each patient appears to have a critical level of serum K, which, if exceeded, will be associated with weakness. (This has led some authors to term the periodic paralysis as *potassium dependent*.) The administration of KCl, raising serum K to above 7 meq/L, a level that has no effect on normal individuals, invariably induces an attack. As mentioned earlier, the ECG must be monitored during such provocative testing. The EMG shows myotonic discharge in all muscles, even at normal temperatures. The CK may be elevated.

In vitro studies of muscle from patients with cold-induced stiffness and weakness have shown that as temperature is reduced, the muscle membrane is progressively depolarized to the point where the fibers are inexcitable (Lehmann-Horn et al). A sodium channel blocker (tetrodotoxin) prevents the cold-induced depolarization. In patients with paramyotonia—but not in those with hyperkalemic periodic paralysis—Subramony and colleagues have observed a diminution of the compound muscle action potential in response to the cooling of muscle, settling the argument as to whether the two syndromes (hyperkalemic paralysis and paramyotonia) are the same or different.

Some patients with paramyotonia, like those with certain other forms of periodic paralysis, may in later life slowly develop a myopathy that causes persistent weakness. In some cases this is sufficiently severe that it mimics the pattern of late-onset limb girdle muscular dystrophy. However, in the case of paramyotonia there are relatively few histologic changes, primarily vacuoles in some of the muscle fibers and minimal evidence of myofiber degeneration.

Treatment Most patients with hyperkalemic periodic paralysis and its variants benefit from prophylactic use of the carbonic anhydrase inhibitor acetazolamide, 125 to 250 mg two or three times a day. Acetazolamide reduces the frequency of attacks and may provide some relief from myotonia. There are no controlled studies of acetazolamide in these disorders, but a rigorous trial of the related carbonic anhydrase inhibitor dichlorphenamide demonstrated a reduced frequency of paralytic spells in both hyper- and hypokalemic forms of periodic paralysis (Tawil et al). In contrast, many attacks of primary hyperkalemic paralysis and of paramyotonia congenita are too infrequent, too brief, or too mild to require continuous treatment.

The continuous use of conventional diuretics such as hydrochlorothiazide (about 0.5 g daily), keeping the serum K below 5 meq/L, also prevents attacks but risks inducing dangerous degrees

of hypokalemia. When the myotonia is more troublesome than the weakness, mexiletine 200 mg tid is perhaps the best alternative, since it prevents both cold- and exercise-induced myotonia, but it does not influence frequency of acute attacks. Some additional benefit may be gained by adding beta-adrenergic agonists such as albuterol or salbutamol. Some studies suggest that clenbuterol may have a direct effect in blocking the sodium channel, independent of its activation of adrenergic receptors. Procainamide or the lidocaine derivative tocainide, in doses of 400 to 1200 mg daily, are also useful for the myotonia (the last carries a small risk of agranulocytosis).

For the treatment of an acute and severe episode, intravenous calcium gluconate (1 to 2 g) often restores power. If, after a few minutes, this treatment is unsuccessful, intravenous glucose or glucose and insulin and hydrochlorothiazide should be tried in order to reduce serum potassium concentration.

Other Sodium Channel Disorders Several other clinical presentations of hereditary periodic paralysis have been linked to mutations of the gene encoding the alpha subunit of the skeletal muscle sodium channel and probably represent variants of the disease just described. One of these, described by Ricker and colleagues, has been designated *myotonia fluctuans*, because muscle stiffness fluctuated in severity from day to day. In other respects the clinical features resembled those of myotonia congenita, including provocation of attacks of myotonia by exercise. The muscle stiffness was only slightly sensitive to cold but was markedly aggravated by the ingestion of potassium and, interestingly, never progressed to muscular weakness or paralysis. *Myotonia permanens* is the name given to a severe, persistent myotonia and marked hypertrophy of muscles, particularly of the neck and shoulders. The EMG discloses continuous muscle activity. This disease was discovered in the course of genotyping a patient who earlier had been reported by Spaans and associates as an example of “myogenic” Schwartz-Jampel syndrome, but it affects the same chloride channel as in hyperkalemic periodic paralysis.

Trudell and colleagues studied 14 patients from a large kindred with autosomal dominant myotonia, the main feature of which was periodic worsening of myotonia accompanied by muscle pain and stiffness, most severe in the face and hands. The symptoms were enhanced by cold (suggesting paramyotonia), and severe stiffness and palpable rigidity followed within 15 min of the ingestion of potassium. Neither of these measures provoked muscle weakness. Muscle biopsy disclosed a normal ratio of types 1, 2A, and 2B fibers, further distinguishing this disorder from typical myotonia congenita, where 2B fibers may be reduced in number. All patients in this family who were treated with the carbonic anhydrase inhibitor acetazolamide had a dramatic resolution of symptoms within 24 h—hence the name *acetazolamide-responsive myotonia*. This disorder has now been linked to the same molecular alteration of the sodium channel gene as occurs in hyperkalemic periodic paralysis (Ptáček et al).

Rosenfeld and coworkers have described yet another form of *painful congenital myotonia* attributable to a novel mutation in the sodium channel alpha-subunit gene (*SCN4A*). Affected members of this family experienced debilitating pain, particularly severe in the intercostal muscles. Also, the pain was resistant to treatment with acetazolamide and other antimyotonic drugs (mexiletine and tocainamide) and could not be provoked by ingestion of potassium-rich foods—differing in these ways from the patients described by Trudell and Ptáček and their associates.

Finally, in regard to disorders of the sodium channel, it should be mentioned that the marine toxins (ciguatoxin, tetrodotoxin, saxitoxin), discussed in Chap. 43, produce their effects on the peripheral and central nerves by blocking sodium channels, but they have little obvious effect on muscle function.

Pathophysiology of Myotonia and Hyperkalemic Periodic Paralysis

In both myotonia congenita and hyperkalemic periodic paralysis, the absence of major morphologic changes and the prominence of the myotonic phenomenon in individual muscle fibers point to the existence of a physiologic aberration in the sarcolemma or some other part of the electrical conducting apparatus of the muscle fibers. This is consistent with the observation that myotonia persists after the administration of curare, thereby exonerating neural input as the source of myofiber hyperexcitability.

The electromyographic pattern of a myotonic muscle reveals highly characteristic discharges that persist following the cessation of voluntary contraction. The tension of the myotonic muscle fibers is slow to diminish as a result of these greatly prolonged trains of muscle action potentials (see Fig. 45-8). Some of these afterdischarge potentials are the size of fibrillations but others are as large as normal motor units. Thus myotonia can be distinguished electrophysiologically from contracture (e.g., that encountered in McArdle disease, in which the muscle is electrically silent). In classic experiments conducted in the 1940s, Denny-Brown and Foley, stimulating single muscle fibers directly, found that myotonic discharges could be elicited only by a volley of stimuli and not by a single stimulus. They also noted that the series of myotonic potentials progressively diminished in size. Percussion elicits myotonia by imparting a brief but relatively intense repetitive excitation of the muscle membrane.

The biophysical basis of myotonia is now well understood in terms of the functioning of chloride and sodium channels. The correspondence between mathematical models of the electrical properties of the muscle membrane and the clinical features of the myotonic and periodic paralyses is quite remarkable. During the normal action potential in all neural and muscular tissue, membrane depolarization is terminated by two events: the depolarization-induced inactivation of the sodium channel (which ends the inward sodium current) and the subsequent action of the outward potassium current. In muscle, the termination of an action potential requires an additional factor. Because of its large size, excitation of the muscle fiber involves depolarization that propagates not only along the cell surface but also radially into the center of the muscle cell through the transverse tubules (T tubules). The tubules are very narrow structures whose internal spaces are in continuity with the extracellular space. When the repolarizing outward potassium current is activated, potassium ions flood into the tubules from the muscle cytoplasm. By itself, this tubular K⁺ accumulation would depolarize the muscle membrane and prolong excitation. Normally, this does not occur because there is a large opposing chloride conductance in the tubules that counteracts the influence of potassium accumulation.

The first clues to the importance of the chloride channel in this electrical stabilizing process were obtained by Bryant who performed *in vitro* studies of myotonic goat muscle and found a reduced chloride conductance in the transverse tubular system. Subsequent studies of muscle from patients with myotonia congenita by Lipicky and Bryant demonstrated a similarly low chloride conductance. That a mutation in a muscle chloride channel could pro-

duce myotonia was confirmed in a mouse model by Jentsch and Steinmeyer and colleagues (see Koch et al), who subsequently also described the first human chloride channel (CLCN1) mutations.

As indicated, an essential event for normal repolarization of an excitable membrane is the rapid inactivation of the inward sodium current. This process of rapid, complete sodium channel inactivation is impaired by the sodium channel mutations implicated in hyperkalemic periodic paralysis. The sodium channel mutations cause imperfect inactivation of the channel and lead to aberrant and early reopenings. Repolarization is then incomplete, rendering the muscle cell more readily re-excited; it is this hyperexcitability that causes the myotonia of hyperkalemic periodic paralysis. The physiologic problem becomes self-reinforcing because, as the membrane fails to repolarize fully, its electrolytic inactivation becomes increasingly less effective. If this process is not aborted, the result is such excessive depolarization to a degree that the muscle cell ultimately becomes unexcitable—a state that corresponds to the paralytic phase of hyperkalemic periodic paralysis. These features are evident in hyperkalemic muscle *in vitro* (Cannon) and can be recapitulated in computer simulations. Presumably, over several hours, a variety of compensatory mechanisms [e.g., activation of Na-K adenosine triphosphatase (ATPase) pumps] restores the baseline excitability of the muscle membrane.

DISEASES OF THE CALCIUM CHANNEL

Hypokalemic Periodic Paralysis

This is the best-known form of periodic paralysis. The history of the disease is difficult to trace, but the first unmistakable account was probably that of Hartwig in 1874, followed by the accounts of Westphal (1885) and Oppenheim (1891). Goldflam (in 1895) first called attention to the remarkable vacuolization of the muscle fibers that is characteristic of the process. In 1937, Aitken and associates described the occurrence of low serum potassium during attacks of paralysis and reversal of the paralysis by the administration of potassium, thus setting the stage for subsequent differentiation of the hyperkalemic forms of periodic paralysis. For English-speaking readers, Talbott's monograph serves as the best historical review of the subject and includes all cases that had been reported prior to 1941; the more recent reviews by Layzer and by Lehmann-Horn and Engel and their associates bring the subject largely up to date.

The usual pattern of inheritance is autosomal dominant with reduced penetrance in women (male-to-female ratio of 3 or 4 to 1). Fontaine and Ptáček and their coworkers have localized the disease to chromosome 1q in a region containing the gene that encodes the alpha subunit of the calcium channel of skeletal muscle. The subunit, which is part of the dihydropyridine receptor complex, is located in the transverse tubular system. This region is believed to act both as a voltage sensor that controls calcium release from the sarcoplasmic reticulum, thus mediating muscle excitation-contraction coupling, and as a calcium-conducting pore. How the reduced calcium channel function relates to hypokalemia-induced attacks of muscle weakness is not known.

Clinical Manifestations In our experience, this disease has become clinically apparent after adolescence and has been much more severe in males. We note, however, that in Talbott's review of 152 cases, there were 40 in which symptoms began before the 10th year of life and 92 before the 16th year. The typical attack comes on during the second half of the night or the early morning hours, after

a day of unusually strenuous exercise; a meal rich in carbohydrates favors its development. Excessive hunger or thirst, dry mouth, palpitation, sweating, diarrhea, nervousness, and a sense of weariness or fatigue are mentioned as prodromata but do not necessarily precede an attack. Usually the patient awakens to discover a mild or severe weakness of the limbs. However, diurnal attacks also occur, especially after a nap that follows a large meal. The attack evolves over minutes to several hours; at its peak, it may render the patient so helpless as to be unable to call for assistance. Once established, the weakness lasts a few hours if mild or several days if severe.

The distribution of the paralysis varies. Limbs are affected earlier and often more severely than trunk muscles, and proximal muscles are possibly more susceptible than distal ones. The legs are often weakened before the arms, but exceptionally the order is reversed. The muscles most likely to escape are those of the eyes, face, tongue, pharynx, larynx, diaphragm, and sphincters, but on occasion even these may be involved. When the attack is at its peak, tendon reflexes are reduced or abolished and cutaneous reflexes may also disappear. Sensation is preserved. As the attack subsides, strength generally returns first to the muscles that were last to be affected. Headache, exhaustion, diuresis, and occasionally diarrhea may follow the attack. Myotonia is not seen; indeed, clinical or EMG evidence of myotonia essentially excludes the diagnosis of hypokalemic periodic paralysis.

Attacks of paralysis tend to occur every few weeks and tend to lessen in frequency with advancing age. Rarely, death may occur from respiratory paralysis or derangements of the conducting system of the heart. Mainly, such fatal cases were reported in the era before modern intensive care.

Atypical forms include weakness of one limb or certain groups of muscles, bibrachial palsy (inability to lift one's arms or to comb one's hair), and transient weakness during accustomed activities. Earlier descriptions in the literature of daily brief attacks, some associated with exposure to cold or coupled with muscular hypertrophy or exophthalmic goiter, preceded recognition of the other types of periodic paralysis and cannot be evaluated. Some of our patients had a talipes deformity from early life. During middle adult life, a number of patients have developed a slowly progressive proximal myopathy, with vacuolated and degenerated fibers and myopathic action potentials, in some instances long after attacks of periodic paralysis had ceased.

Laboratory Findings The attacks are accompanied by reduction in serum K levels, as low as 1.8 meq/L, but usually at levels that would not be associated with muscle weakness in normal subjects. The fall in serum K is associated with little or no increase in urinary K excretion. Presumably, large quantities of K enter the muscle fibers during an attack, but this explanation may not be complete. Some episodes occur with near-normal levels of K, and weakness persists for a time after the serum level has been restored. The serum K levels return to normal during recovery. Although the shifts in K are of undoubted importance in the pathogenesis of muscle weakness, the marked sensitivity to small reductions of serum K suggests that other factors are also operative and that the fall in K may be a secondary phenomenon.

As in hyperkalemic paralysis, the muscular weakness in this disease is associated with a decrease in the amplitude, and eventual loss, of muscle action potentials and there is failure of excitation by supramaximal stimulation of peripheral nerve or by strong voluntary effort. A decline in strength precedes loss of motor unit potentials and the failure of propagation of action potentials over the surface of the fiber. The polarization potentials of muscle fibers

measured by intracellular recordings are initially normal despite the failure of impulse propagation by the sarcolemma. One would expect the muscle fiber to be hyperpolarized as K moves into it, but it actually becomes depolarized. Rüdel and associates attribute the latter change to an increased Na conductance. The ECG changes also begin at levels of K that are slightly below normal (about 3 meq/L); they consist of prolonged PR, QRS, and QT intervals and flattening of T waves.

Diagnosis at a time when the patient is normal may be facilitated by *provocative tests*. With the patient carefully monitored, including the use of an ECG, the oral administration of 50 to 100 g of glucose or loading with 2 g of NaCl every hour for seven doses, followed by vigorous exercise, brings on an attack, which then can be terminated by 2 to 4 g of oral KCl (the opposite of what pertains in hyperkalemic periodic paralysis).

Pathologic Changes The nervous system is entirely normal. The muscle fibers are uniformly somewhat large, but the most striking change, particularly in the late degenerative phases of the disease, is vacuolization of the sarcoplasm. The myofibrils are separated by round or oval vacuoles containing clear fluid, presumably water, and a few PAS-positive granules. There are pathologic changes in myofibrils and mitochondria as well and focal increases in muscle glycogen. Isolated muscle fibers may undergo segmental degeneration. Electron microscopic studies have shown that the vacuoles arise as a result of proliferation and degeneration of membranous organelles within the sarcoplasmic reticulum and transverse tubules (A. G. Engel).

Treatment A low-sodium diet (160 meq/day), avoidance of large meals and exposure to cold, and acetazolamide 250 mg three times daily may be helpful in preventing attacks. That acetazolamide reduces attacks is somewhat surprising since it is kaluretic, but it may work through the production of acidosis; a few patients have worsened with the drug. Patients who are unresponsive to acetazolamide may be treated with the more potent carbonic anhydrase inhibitor, dichlorphenamide, 50 to 150 mg per day or with the potassium-sparing diuretics spironolactone or triamterine (both in doses of 25 to 100 mg/day) but caution must then be exercised with the simultaneous administration of oral potassium supplements. The daily administration of 5 to 10 g of KCl orally in an unsweetened aqueous solution prevents attacks in many patients, and apparently this program can be maintained indefinitely. If this approach fails, a low-carbohydrate, low-salt, high-K diet combined with a slow-release K preparation may be effective.

For an acute attack, 0.25 meq KCl/kg should be given orally or, if this is not tolerated, some other K salt may be tried. This dose may be insufficient, and if there is no improvement in 1 or 2 h, KCl may have to be given intravenously—0.05 to 0.1 meq/kg intravenously initially in a bolus at a safe rate, followed by 20 to 40 meq KCl in 5% mannitol, avoiding glucose or NaCl as the carrier solution. For the late progressive polymyopathy that follows many severe attacks of periodic paralysis, Dalakas and Engel report successful restoration of strength by the long-term administration of the carbonic anhydrase inhibitor dichlorphenamide. Regular exercise (not too strenuous) to keep the patient fit is desirable.

Secondary Kalemic Periodic Paralyses

In addition to the hereditary kalemic paralyses described earlier, transitory episodes of weakness are known to be associated with a number of acquired derangements of potassium metabolism

(mainly hypokalemia), such as thyrotoxicosis, aldosteronism, 17 α -hydroxylase deficiency (Yazaki et al), barium poisoning (Levi and Bar-Khayim), glycyrrhetic acid ingestion (a substance in licorice that has mineralocorticoid activity), and abuse of thyroid hormone (Layzer). Other forms of secondary hypokalemic weakness have been observed in patients suffering from chronic renal and adrenal insufficiency or disorders due to a loss of potassium, as occurs with excessive use of diuretics or laxatives (the most common cause in practice). Renal failure with hyperkalemia can also induce paralysis.

Thyrotoxicosis with Periodic Paralysis This is another and special form of secondary hypokalemic periodic paralysis and occurs mainly in young adult males (despite the higher incidence of thyrotoxicosis in women), with a strong predilection for those of Japanese and Chinese extraction. In Japan, Okinaka and associates found that 8.9 percent of males with thyrotoxicosis had periodic paralysis but this was the case in only 0.4 percent of females; in China, the corresponding figures were 13.0 and 0.17 percent (McFadzean and Yeung). The paralytic disorder is unrelated to the severity of the hyperthyroidism. In patients with the familial forms of periodic paralysis, the induction of hyperthyroidism is said not to increase the frequency or intensity of attacks. Therefore, it seems likely that thyrotoxicosis has unmasked another type of hereditary periodic paralysis, although a familial occurrence in the thyrotoxic cases is exceptional. Clinically, the attacks of paralysis are much the same as those of familial hypokalemic type except for a greater liability to cardiac irregularity. As in the familial form, the paralyzed muscles are inexcitable. Potassium chloride restores power in paralytic attacks, and treatment of the hyperthyroidism prevents their recurrence (see page 1236).

Hypokalemic Weakness in Primary Aldosteronism Hypokalemic weakness due to hypersecretion of the major adrenal mineralocorticoid aldosterone was first described by Conn and associates in 1955. In *primary aldosteronism*, the cause of the hypersecretion is in the adrenal gland itself—usually an adrenal cortical adenoma, less often adrenal cortical hyperplasia. The disorder is not common (occurring in about 1 percent of unselected hypertensive patients), but its recognition is essential, since it can be treated effectively. Persistent aldosteronism is frequently associated with hypernatremia, polyuria, and alkalosis, which predispose the patient to attacks of tetany as well as to hypokalemic weakness. Conn and associates (1964), in an analysis of 145 patients with primary aldosteronism, found that persistent muscular weakness was a major complaint in 73 percent; intermittent attacks of paralysis occurred in 21 percent; and tetany in 21 percent. These manifestations were much more frequent in women than in men, in contrast to the preponderance of men among patients with hypokalemic periodic paralysis of familial type. Rarely, as already noted, primary aldosteronism is produced by the chronic ingestion of licorice; this is due to its content of glycyrrhetic acid, a potent mineralocorticoid (Conn et al, 1968).

The muscle fibers of patients with primary aldosteronism show necrosis and vacuolation. Ultrastructurally, the necrotic areas are characterized by a dissolution of myofilaments with degenerative vacuoles; nonnecrotic fibers contain membrane-bound vacuoles and show dilatation of the sarcoplasmic reticulum and abnormalities of the transverse tubular system, suggesting that a vulnerability of the latter structures may be responsible for the muscle fiber necrosis (Atsumi et al).

Malignant Hyperthermia

This dramatic syndrome is observed during general anesthesia in susceptible individuals. It is characterized by rapidly rising body temperature, extreme muscular rigidity, and a high mortality rate. Since the original report by Denborough and Lovell in 1960, as larger experience was gained with this entity, it proved to be a metabolic polymyopathy inherited as a dominant trait, rendering the individual vulnerable to any potent volatile anesthetic agent, particularly halothane, and to the muscle relaxant succinylcholine. The fundamental cause in a large proportion of cases is an aberration in a component of the calcium channel. Malignant hyperthermia has been estimated to occur approximately once in the course of every 50,000 administrations of general anesthesia.

The full clinical picture is striking but anesthesiologists have become adept at detecting its earliest stages. As halothane or a similar inhalational anesthesia is induced or succinylcholine is given for muscular relaxation, the jaw muscles unexpectedly become tense rather than relaxed, and soon the rigidity extends to all of the muscles. Thereafter, the body temperature rises to 42°F or 43°F (5.5°C or 6.1°C) with tachypnea and tachycardia. Arterial CO₂ may exceed 100 mmHg, and blood pH may fall to 7.00 or below. There may be gross myoglobinuria, and serum CK often reaches extraordinarily high levels. Circulatory collapse and death may ensue in approximately 10 percent of cases, or the patient may survive with gradual recovery. In some cases there is the same sequence of events (increased temperature and acidosis) without muscular spasm. With the patient's early death, the muscle may appear normal by light microscopy. In case of survival for several days, samples of muscle reveal scattered segmental necrosis and phagocytosis of sarcoplasm without inflammation. Regenerative activity is in progress. Multicores, which are characteristic of a particular congenital polymyopathy, may be found in the muscle of patients who have had such episodes.

Pathophysiology The pathogenesis of this reaction has been the subject of a number of investigations. During the rigor phase, oxygen consumption in muscle increases threefold and serum lactate, 15- to 20-fold. Muscle from most affected individuals is abnormally sensitive to caffeine, which induces contracture in vitro. It has been postulated that halothane acts in a manner similar to caffeine—that is, to release calcium from the sarcoplasmic reticulum and prevent its reaccumulation, thus interfering with relaxation of the muscle. There is a breed of pigs, inbred for muscular development, in which muscle spasm (true contracture) and hyperthermia follow the administration of anesthetic agents. These swine have an inherited defect in the ryanodine receptor, a protein component of the calcium channel of the sarcoplasm that is sensitive to both caffeine and ryanodine. However, one of several similar defects in ryanodine is found in somewhat fewer than 20 percent of human beings. It is presumed that other yet unidentified allelic mutations of this receptor protein or another that controls the structure of the calcium channel account for the remainder of cases. The essential physiologic change is one of increased intracellular calcium. The cause of the high fever is not known; it is probably due to the muscle spasm, but an effect of the anesthetic on heat-regulating centers cannot be excluded.

Clues as to which patients are at risk for this condition come from several sources. Other members of the family may have collapsed or died during anesthesia. Some of the susceptible individuals exhibit certain myopathic and musculoskeletal abnormalities

(Isaacs and Barlow). One constellation consists of short stature, ptosis, strabismus, highly arched palate, dislocated patellae, and kyphoscoliosis, which has been noted in some families (King-Denborough syndrome). As mentioned in Chap. 52 on the congenital polymyopathies, central core (multicore) myopathy (page 1247) is frequently complicated by malignant hyperthermia. This is understandable insofar as both disorders have been linked to the gene encoding the ryanodine receptor; the two diseases are due to allelic variations (Quane et al). It has been pointed out that another rare muscle disease—Evans myopathy (named after the affected family)—may be a common predisposing condition. It is inherited as an autosomal trait and may be asymptomatic until the anesthetic reaction, but some patients have wasting of the distal thigh muscles and an elevation of serum CK concentration (see Harriman et al).

Diagnostic Testing Various tests for susceptibility to malignant hyperthermia have undergone phases of popularity. The only currently valid test involves *in vitro* exposure of a muscle biopsy specimen to halothane and to caffeine and the detection of muscle contracture with both agents. This is performed only in a few centers, which are listed at www.mhaus.org. The review by Denborough may be consulted for further details on the testing and on the general aspects of the disease.

Treatment This consists of discontinuation of anesthesia at the first hint of masseter spasm or rise of temperature. The intravenous administration of dantrolene, which inhibits the release of calcium from the sarcoplasmic reticulum, may be lifesaving. An infusion of 1 mg/kg is given initially and increased slowly until symptoms subside, the total dosage not to exceed 10 mg/kg. Other measures should include body cooling, intravenous hydration, sodium bicarbonate infusions to correct acidosis, and mechanical hyperventilation to decrease acidosis. Halothane and other volatile anesthetic agents and succinylcholine should thereafter be avoided in such individuals, and any surgical procedures, if necessary, should be done under nitrous oxide, fentanyl, thiopental (or other barbiturate), or local anesthesia. Intravenous dantrolene, 2.5 mg/kg given slowly 1 h prior to anesthesia, prevents the syndrome.

Malignant Neuroleptic Syndrome

This state, in which hyperthermia occurs as an idiosyncratic reaction to neuroleptic drugs, is also accompanied by widespread myonecrosis. It shares some features with malignant hyperthermia but is a distinct entity as discussed in Chap. 43.

DISEASES OF THE POTASSIUM CHANNEL

The discovery of several types of seizure disorder based on inherited defects of the potassium channel has elicited considerable

interest. Only recently has it been appreciated that one form of periodic paralysis, Andersen disease, is associated with the voltage-gated potassium channel.

Andersen Disease

Andersen and coworkers first drew attention to a distinct form of potassium-sensitive periodic paralysis characterized by the triad of periodic potassium-sensitive weakness, ventricular dysrhythmias with long QT syndrome, and dysmorphic features (micrognathia, short stature, scaphocephaly, hypertelorism, broad nose, low-set ears, and short index fingers). From a study of 11 additional patients with Andersen syndrome from 5 kindreds, Sansone and colleagues point out that attacks of paralysis can be associated with hypo-, normo-, or hyperkalemia and that a prolonged QT interval is an integral feature of the disease (and sometimes the only sign in a given family). Plaster and colleagues have demonstrated that most cases of Andersen disease are a consequence of dominant negative mutations in the gene KCNJ2 that encodes a particular type of K channel. *In vitro* studies indicate that the mutation impairs the ability of preformed channels to migrate to the membrane surface and also impedes the current carrying capacity of the potassium channel system. This defect would be expected to impair repolarization of the muscle membrane, thereby making both skeletal and cardiac muscle hyperexcitable.

Morvan's Fibrillary Chorea (Chorée Fibrillaire)

This obscure and oddly named disease is included in this chapter because an abnormality of voltage-gated potassium channels has been discovered in some patients. It is characterized by continuous muscle fiber activity referred to as “neuromyotonia,” hyperhidrosis, severe weight loss, insomnia, and hallucinations. Most cases so far described have ended fatally in a matter of months, but plasma exchange has reversed the syndrome in the case described by Ligouri and colleagues. Some cases have an associated thymoma. The condition is also included in the discussion of the other forms of continuous muscle fiber activity in the following chapter.

In addition to the various seizure disorders that are attributable to disorders of ion channels, also mentioned here for completeness are the Lambert-Eaton myasthenic syndrome that results from an autoimmune attack in calcium channels (it is discussed in the previous chapter), a rare paraneoplastic encephalitis that has been attributed to antibodies against potassium channels (Thieben et al), and spinocerebellar ataxia type 6, which is due to an inherited abnormality of the α -1A voltage-dependent calcium channel (see Chap. 5).

CHAPTER 55

DISORDERS OF MUSCLE CHARACTERIZED BY CRAMP, SPASM, PAIN, AND LOCALIZED MASSES

Quite apart from spasticity and rigidity, which are due to a disinhibition of spinal motor mechanisms, there are forms of muscular stiffness and spasm that can be traced to abnormalities of the lower motor neuron and its spinal inhibitory mechanisms or to the sarcolemma of the muscle fiber and its intrinsic conducting apparatus. Thus, muscles may go into spasm because of an unstable depolarization of motor axons, which sends volleys of impulses across neuromuscular junctions—as occurs in myokymia, hypocalcemic tetany, and pseudohypoparathyroidism. In other states, discussed in the preceding chapter, the innervation of muscle may be normal but contraction persists despite attempts at relaxation (myotonia). Or, after one or a series of contractions, the muscle may be slow in decontracting, as occurs in paradoxical myotonia and hypothyroidism; in the contracture of McArdle phosphorylase deficiency and phosphofructokinase deficiency, muscle, once contracted, may lack the energy to relax.

Each of these conditions evokes the complaint of cramp or spasm, which is variably painful and interferes with free and effective voluntary activity. Each condition has its own identifying clinical and electromyographic (EMG) characteristics, and most of them respond favorably to therapy. A premium is therefore attached to the clinical differentiation of these phenomena.

Muscle Cramp

This subject has already been introduced in Chap. 48, where it was pointed out that everyone at some time or other experiences muscle cramps. Usually they occur during the night, after a day of unusually strenuous activity; less often they occur during the day, either during a period of relaxation or occasionally after a strong voluntary contraction or postural adjustment. A random restless or stretching movement will induce a hard contraction of a single muscle (most frequently of the foot or leg) that cannot be voluntarily relaxed. The muscle is visibly and palpably taut and painful, and the condition is readily distinguished from an illusory cramp, in which the sensation of cramp is experienced with little or no contraction of muscle. The latter phenomenon may occur in normal persons as well as in those with certain peripheral nerve diseases. Massage and vigorous stretch of the cramped muscle will cause the spasm to yield, though for a time the muscle remains excitable and subject to recurrent cramps. Visible fasciculations may precede and follow the cramp, indicating an excessive excitability of the terminal branches of motor neurons supplying the muscle. Sometimes the cramp is so strong that the muscle appears to have been injured; it remains sore to touch and painful upon use for a day or longer. Cramps of precordial chest muscles or diaphragm may arouse fear of heart or lung disease. In the EMG, the cramp is marked by bursts of high-frequency, high-voltage action potentials, and the precramp

phase by runs of activity in motor units. Why cramps should be painful is not known; probably the demands of the overactive muscle exceed metabolic supply, causing a relative ischemia and accumulation of metabolites. Overwork of muscle with or without impairment of circulation is also painful. Between cramps, the muscles are normal clinically and electromyographically.

Cramps are known to increase in frequency under certain conditions and with certain diseases. They are frequent during pregnancy for reasons not fully understood. Dehydration and sweating predispose to cramping and are a constant threat to athletes, who try to prevent them by ingesting electrolyte solutions. Exertional cramps are frequent in motor system disease and hypothyroidism and less so in chronic polyneuropathies. Patients undergoing hemodialysis are subject to cramps, which can be suppressed by intravenous hypertonic saline or hypertonic glucose. Rapid rehydration after dehydration is another provocative factor. Focal cramping occurs after partial nerve or root injury and with diseases involving anterior horn cells. In one such condition, the calf muscle on one side is subject to severe recurrent cramps after decompression of the S1 root in lumbar disc disease; in extreme cases, the muscle hypertrophies.

The mechanism of muscle cramping is obscure. In a number of cases with exercise-induced stiffness and muscle pain, sometimes progressing to cramp, below-normal levels of myoadenylate deaminase have been found. The significance of this observation is uncertain. This enzyme, which is present in high concentration in muscle, is thought to function primarily during aerobic exercise and facilitate the regeneration of adenosine triphosphate from adenosine diphosphate through the action of adenylate kinase. Others assert that low levels of this enzyme are not specific, occurring in such unrelated disorders as hypokalemic periodic paralysis and spinal muscular atrophy (see Layzer for details).

Quinine sulfate—300 mg at bedtime and repeated in 4 h if necessary, or 300 mg tid for diurnal cramping—is an effective medication; diphenhydramine hydrochloride (Benadryl) 50 mg or procainamide 0.5 to 1.0 g can be substituted if quinine is not tolerated. Phenytoin, carbamazepine, propoxyphene, and sometimes clonazepam are even more useful in alleviating repeated daytime cramping.

Tetany, Pseudotetany, and Related Cramp Syndromes

As pointed out on page 1096, a reduction in ionizable calcium and magnesium is associated with involuntary cramplike spasms; in their mildest form they appear as distal carpopedal spasms, but they may involve any of the muscles except the extraocular ones. Stimulation of a muscle through its nerve at certain frequencies (15 to

20 times per second) characteristically reproduces the spasms, and hyperventilation and ischemia increase the tendency. Indeed, the Trousseau sign—carpal spasms with occlusion of the blood supply to the arm—takes advantage of the latter phenomenon. That hypocalcemic tetany is attributable to an unstable depolarization of the axonal membrane of the nerve fiber is shown by (1) the sensitivity of nerve to percussion (tapping over the facial nerve near its foramen of exit induces a facial twitch, or Chvostek sign), (2) the appearance of fast-frequency doublets and triplets of motor unit potentials in the EMG, (3) evocation of spasm by application of a tourniquet to proximal parts of a limb (causing ischemia of segments of nerve beneath the tourniquet), and (4) the regular association of tingling, prickling paresthesias from excitation of sensory nerve fibers. Hypocalcemia also causes a lesser change in the muscle fibers themselves; hence nerve block does not completely eradicate tetany.

A condition resembling tetany but without measurable hypocalcemia is the aforementioned benign cramp syndrome (*pseudotetany*). In the most severe forms, all skeletal muscles are intermittently locked in spasm, and almost any strong postural or voluntary movement leads to cramp. When this phenomenon is repeated again and again, the overly active muscles begin to hypertrophy. In about half of the authors' cases, stimulation of nerve at 15 or more per second produced cramp discharges, as in tetany. Biopsies have disclosed no abnormalities of the muscle fibers except for a few ringbinden (circumferential bands of myofibrils encircling a normal core of longitudinally oriented myofibrils). Calcium and diazepam are of no therapeutic value, but some patients respond to phenytoin, quinine, procainamide, or chlorpromazine.

A familial (autosomal dominant) form of the benign cramp syndrome has been reported by Jusic and coworkers; the cramps affected the distal limb muscles, began in childhood and adolescence, and persisted throughout life. Another such family with cramps beginning somewhat later in life and affecting the anterior neck, arm, and abdominal muscles as well as those of the thigh and calf has been described by Ricker and Moxley. Also, as mentioned in Chap. 50, a familial myalgic-cramp syndrome has been associated with deletion of part of the dystrophin gene (but with little or no dystrophic weakness). A tendency to cramp and pain has also been noted in a number of the congenital myopathies and in some families with Duchenne and Becker dystrophies.

Satoyoshi Syndrome Satoyoshi has described a group of patients who, in addition to widespread severe cramping of muscle, showed universal alopecia, amenorrhea, intestinal malabsorption, and sometimes epiphyseal destruction and retarded growth. Most Japanese patients described by Satoyoshi were under 20 years old, but the cases we have observed have been older. The serum calcium in these patients is normal, and the EMG shows only high-frequency discharges that are characteristic of cramps. A male patient of ours with this condition had decades of chronic diarrhea, alopecia, and continuous and extremely painful calf cramps that looked, from the surface, like fasciculations. This triad virtually identifies the disease. The cause of the disorder is entirely obscure but tentatively presumed to be autoimmune. Glucocorticoids, particularly in high doses over short periods, have been tried with some success; dantrolene has also been used, and we had the impression that plasma exchange may have been helpful in one case.

States of Persistent Fasciculation, Myokymia, Continuous Muscle Fiber Activity, Neuromyotonia, "Stiff-Man" Syndrome, and Schwartz-Jampel Syndrome

This is a confusing group of clinical states, all characterized by some degree of regional continuous muscular activity, that in some cases cannot be fully differentiated from one another. From a clinical perspective we have found it is useful to categorize them in groups that are caused by (1) hyperexcitability of the peripheral motor nerves, (2) centrally mediated hyperexcitability of motor output, (3) nonmyotonic hyperexcitability of muscle, and (4) disorders of extracellular matrix proteins that alter muscle membrane excitability.

Hyperexcitability of Peripheral Nerve

This term comprises a set of disorders in which peripheral motor nerve activity is augmented, such that there are excessive, sometimes sustained contractions of the motor unit. Its mildest manifestation is benign fasciculation. In more severe forms, the result is a group of disorders that includes cramp-fasciculation syndrome, neuromyotonia, Isaacs disease, and a variant of the latter in which there is also involvement of the central nervous system (Morvan disease), a disease of potassium-gated ion channels (page 1273). They are not generally familial but several lines of investigation argue that many of these disorders are of an acquired autoimmune nature (Newsom-Davis). For example, all but benign fasciculations are associated more often than might be expected with other autoimmune diseases such as myasthenia gravis and many respond to anti-immune therapies such as plasmapheresis. And, in some of these disorders, the patient's sera possess antibodies to either voltage-gated potassium channels as mentioned or, less frequently, nicotinic acetylcholine (ACh) receptors (Vernino and Lennon).

Persistent Benign Fasciculations A few random fasciculations in the muscles of the calf, small muscles of the hand or of the face, or elsewhere are seen in most normal individuals. They are of no significance but can be a source of worry to physicians and nurses who have heard or read that fasciculations are an early sign of amyotrophic lateral sclerosis. A simple clinical rule is that fasciculations in relaxed muscle are not indicative of motor system disease unless there is associated weakness, atrophy, or reflex change.

Frequently a healthy individual experiences intermittent twitching of a muscle (or even part of a muscle), such as one of the muscles of the thenar eminence, eyelids, calves, or orbicularis oculi. It may continue for days. Lay persons refer to it as "live flesh." Also, penicillin may destabilize the polarization of distal motor endings and cause twitching. Electromyographically, these benign fasciculations tend to be more constant in location and more frequent and rhythmic than the ominous fasciculations of amyotrophic lateral sclerosis, but such distinctions are not entirely reliable. Quantitative study of the motor unit size may be helpful in these circumstances by demonstrating normally modeled units in the benign form and abnormally large units due to reinnervation in the case of motor neuron disease (see page 1105).

Occasionally, benign fasciculations are widespread and may

last for months or even years. In several of our patients they have recurred in bouts separated by months and lasting several weeks. No reflex changes, sensory loss, nerve conduction, EMG abnormality (other than fasciculations), or increase in serum muscle enzymes are found. Low energy and fatigability in some of these patients may suggest an endogenous depressive illness, yet the fasciculations are not explained by this mechanism. Commonly, patients report a sense that the muscles affected by the twitching are weak but this cannot be confirmed by testing, and several of our patients, curiously the majority of whom were physicians, have complained of equally troubling migratory zones of paresthesias (Romero et al). Pain, of aching or burning type, may increase after activity and cease during rest. Fatigue and a sense of weakness are frequent complaints. We suspect that this fasciculatory state reflects a disease of the terminal motor nerves, for a few of our patients have shown slowing of distal latencies, and Cöers and associates have found degeneration and regeneration of motor nerve terminals. However, the majority of these cases are of a benign nature and settle down in a matter of weeks or months. In the cases reported by Hudson and colleagues, the condition, even after years, did not progress to spinal muscular atrophy, a polyneuropathy, or amyotrophic lateral sclerosis. Eventual recovery can be expected. This conforms to our experience and to that reported from the Mayo Clinic where 121 patients with benign fasciculations, followed in some cases for more than 30 years, showed no progression of symptoms and did not acquire motor neuron disease or neuropathy (Blexrud et al). It should be acknowledged, however, that there are infrequent patients with seemingly benign fasciculations in whom the EMG shows some abnormal features (e.g., rare fibrillations) in numerous muscles and who later develop the other features of motor neuron disease. Carbamazepine, and to a lesser extent phenytoin, has been helpful in reducing the fasciculations and sensations of weakness.

Cramp-Fasciculation Syndrome This is a variant of the aforementioned entity in which fasciculations are conjoined with cramps, stiffness, and systemic features such as exercise intolerance, fatigability, and muscle aches. Although affected individuals may be to some degree disabled by these symptoms, the prognosis is good. The salient finding on physiologic studies is that stimulation of peripheral nerves results in sustained muscle firing due to prolonged trains of action potentials in the distal motor nerve. This may be brought out in special electrophysiologic testing as described by Tahmoush and colleagues. In effect, this is a mild form of neuromyotonia (see later). In a small number of patients with cramp-fasciculation syndrome it is possible to demonstrate the presence of autoantibodies directed against voltage-gated axonal potassium channels. Carbamazepine or gabapentin may be beneficial.

There are, in addition to the aforementioned benign states, several syndromes of abnormal muscle activity. The main ones are *myokymia*, a state of successive contractions of motor units imparting an almost continuous undulation or rippling of the overlying body surface, and several syndromes of *continuous muscle fiber activity*.

Myokymia This state of abnormal rippling muscle activity, as defined earlier, may be generalized or limited to one part of the body, such as the muscles of the shoulders or of the lower extremities. It is observed most often with regeneration of peripheral nerve following injury, as in the facial palsy of Guillain-Barré syndrome,

and thus it is most often neuropathic in nature. In the EMG, myokymic discharges consist of groups of 2 to 10 potentials, firing at 5 to 60 Hz and recurring regularly at 0.2- to 10-s intervals. They arise in the most peripheral parts of the axon of chronically damaged nerves. In some patients, cramping is associated and, indeed, muscles about to cramp may twitch or show spontaneous rippling contractions; the cramping may be associated with sweating. Thus, myokymia, fasciculation, and cramping are closely related but not clinically identical conditions.

Continuous Muscle Fiber Activity (Isaacs Syndrome) The relation of myokymia to the state called *continuous muscle fiber activity* is ambiguous. Sporadically, in the neurologic literature, there have been described patients whose muscles at some point begin to "work" continuously (see Isaacs). Terms such as *neuromyotonia* and *widespread myokymia with delayed muscle relaxation* are additional names that have been applied to what is essentially the same condition. At the moment, there is little reason to distinguish one from another except in gradations of severity. In each case the excessive and spontaneous activity can be attributed to hyperexcitability of terminal parts of motor nerve fiber, possibly as a result of a partial loss of motor innervation and compensatory collateral sprouting of surviving axons (Cöers et al, Valli et al). Twitching, spasms, and rippling of muscles (myokymia) are evident, the latter being the main clinical sign. In advanced cases there is generalized muscle stiffness and a sense of weakness. Complaints of muscle aching are usual, but severe myalgia is uncommon. The tendon reflexes may be reduced or abolished. Any muscle group may be affected. The stiffness and slowness of movement make walking laborious ("armadillo" syndrome); in extreme cases, all voluntary movement is blocked. The muscle activity persists throughout sleep. The continuous visible and painful cramps of Satoyoshi disease are difficult to distinguish from myokymia.

General and spinal anesthesia do not always suppress the muscular activity, but curare does; nerve block usually has no effect or may reduce the activity, as in the case described by Lütschig and colleagues. The EMG findings are much the same as those described earlier.

This syndrome arises in childhood or adult life, sometimes in association either with a polyneuropathy or with an inherited type of episodic ataxia that is variably responsive to acetazolamide or remits spontaneously. An inherited form of continuous muscle fiber activity has been traced to a gene mutation on chromosome 12 and is attributed to a peripheral nerve K channel abnormality (Gutmann and Gutmann). In addition to the association with polyneuropathy, a state of continuous muscular activity has also been described with lung cancer and thymoma, with or without myasthenia, in which cases an immune mechanism has been inferred (see reviews by Thompson and by Newsom-Davis and Mills). An association of continuous muscle fiber activity with psychosis or a severe sleep disorder was described by Morvan under the name *chorée fibrillaire* as discussed in the previous chapter (see also page 1273, Serratrice and Azalay). Most cases appear to be idiopathic, however.

Treatment Phenytoin or carbamazepine often abolishes the continuous muscular activity and causes a return of reflexes. Acetazolamide has been helpful in some other cases (Celebisoy et al). Many of the idiopathic cases, as already noted, will improve spontaneously after several years, but plasma exchange may be tried if the symptoms are intractable.

Centrally Mediated Motor Hyperexcitability

Stiff-Man Syndrome This is a condition of persistent spasms, particularly of the proximal lower limbs and lumbar paraspinal muscles, forcing the patient eventually to lie helplessly in bed with the feet in equinus position and the legs extended. It was originally described by Moersch and Wolman in 1956 as stiff-man syndrome. Since then, many examples have been reported all over the world and the term *stiff-person syndrome* has been used to indicate its occurrence also in women.

The onset is insidious, usually in middle life, and men and women are affected equally. No genetic predisposition is known. At first the stiffness and spasms are intermittent; then, gradually, they become more or less continuously active in the proximal limb and axial trunk muscles and increasingly painful. The spasms impart a robotic appearance to walking and an exaggerated lumbar lordosis. Attempts to move an affected part passively yield an almost rock-like immobility, perceptibly different from spasticity, paratonia, or extrapyramidal rigidity. Muscles of respiration and swallowing and those of the face may be involved in the more advanced cases, but trismus, a common feature of tetanus, does not occur. We have observed brief periods of cyanosis and respiratory arrest during episodes of intense spasm, and one of our patients died during such an episode. Eye muscles are rarely affected. Any noise or other sensory stimulus or attempted passive or voluntary movement may precipitate severely painful spasms of all the involved musculature. The tendon reflexes are normal if they can be tested. The affected muscles, particularly the lumbar paraspinals and glutei are extremely taut when palpated. It is this axial spasm that is most characteristic of the disease and gives rise to a characteristic lumbar lordosis over time.

A similar stiffness of one limb ("stiff-limb" syndrome) has been differentiated from the generalized variety by Barker and colleagues and others (see Saiz et al; Brown et al), but it seems to us to be part of the same illness, especially since most of the localized cases have antibodies to glutamic acid decarboxylase, as described below. There is, however, no axial spasm or exaggerated lordosis; the condition begins in one leg and spreads to its opposite but remains isolated to the lower extremities. This limited form of spasm is similar to localized tetanus.

A central origin of the muscle spasms is indicated by their disappearance during sleep, during general anesthesia, and with proximal nerve block. The electrophysiologic features differ from those of myokymia and continuous muscle fiber activity syndrome in that the EMG in stiff-man syndrome consists entirely of normal motor units, with no evidence of distal motor nerve disturbance.

Of interest is the finding that most of the cases of stiff-man syndrome display circulating autoantibodies that are reactive with glutamic acid decarboxylase (GAD), the synthesizing enzyme for gamma-aminobutyric acid (GABA) (Solimena et al). These findings suggest an imbalance between the spinal inhibitory (GABA-nergic) input and the excitatory input to alpha motor neurons. This interpretation is supported by the fact that the spasms worsen under the influence of drugs that enhance aminergic activity, facilitating long-latency spinal reflexes, or that inhibit catecholaminergic or GABA-nergic transmitters. An autoimmune mechanism is further suggested by the high incidence of insulin-dependent diabetes (present in almost all the cases under our care) with detectable

antibodies to islet cells; a few patients have thyroiditis, pernicious anemia, or immune-mediated vitiligo.

There is a rare paraneoplastic variety of stiff-man syndrome, mostly accompanying breast cancer and associated sometimes with antibodies against amphiphysin or gephyrin, proteins associated with synaptic GABA receptors. Some of the cases related to the antiampiphysin antibodies also display more conventional types of paraneoplastic neurologic disorder such as encephalopathy or opsclonus (see Chap. 31).

Treatment In the stiff-man syndrome, diazepam in doses of up to 50 to 250 mg/day, increased gradually, is most effective; clonazepam, vigabatrin, or baclofen are sometimes effective as well. In keeping with the presumed autoimmune mechanism, plasma exchange, high-dose corticosteroids, or intravenous gamma globulin are helpful in some patients, albeit for only several weeks or months. Several of our patients have required infusions of gamma globulin for several years at intervals of 6 to 12 weeks but nevertheless became disabled if the dose of diazepam was reduced below 200 mg/day. A small randomized trial of intravenous immune globulin conducted by Dalakas and colleagues had demonstrated the efficacy of this treatment; in their study, the benefits varied in duration from 6 weeks to 1 year.

Clinically, the stiff-man syndrome must be distinguished from tetanus (page 1030 and further on), the Isaacs syndrome (see earlier), and the rare syndrome of subacute myoclonic spinal neuronitis, described on page 1066. In both the stiff-man syndrome and myoclonic spinal neuronitis, the intense spasms and stiffness of muscles are due to disinhibition of interneurons (possibly via GABA-nergic Renshaw cells) in the gray matter of the spinal cord. These syndromes of continuous muscle activity, except perhaps the stiff-man syndrome, are, as a rule, usually distinguishable clinically and electromyographically from extrapyramidal and corticospinal abnormalities such as dystonia, dyskinesia, and rigidity; there is only a superficial resemblance to spastic paraparesis.

Congenital Neonatal Rigidity A "stiff-infant" syndrome, observed by Dudley and colleagues in four families of mixed heritage, should probably be included in this general category. The condition came to medical attention because of respiratory distress due to a generalized muscular rigidity beginning at about 2 months of age. The rigidity spread slowly from cervical muscles to those of the trunk and limbs, and, as it persisted, slight hypertrophy developed. The use of respiratory aid and a feeding gastrostomy enabled the infants to survive. The rigidity slowly diminished in the second year of life. The clinical course was unlike that of tetanus. In fatal cases there were zones of fiber loss, with fibrosis in skeletal and cardiac muscles, and a greater than normal variation in fiber size. Altered Z lines were observed electron microscopically in some fibers.

Primary Hyperexcitability of Muscle

At least two varieties of primary muscle disorder are known, not myotonic in nature, that produce continuous muscle acitivity. The first described below is due to a defect in the muscle membrane; the second has been found to be a disease of the extracellular matrix of muscle.

Rippling Muscle Disease Ricker and Burns and their associates have described a rare familial disorder (autosomal dominant) in which muscles display an unusual sensitivity to stretch, manifest

by rippling waves of muscle contraction. Percussion of muscles yields a pronounced and painful local mounding. Similar familial and sporadic cases have been traced to a defect in caveolin, a protein otherwise implicated in one of the muscular dystrophies (Vorgerd). An autoimmune process has been implicated in some other cases (Muley and Day). The EMG discloses neither myotonic discharges nor the action potentials of cramp, indicating that the basic abnormality is in the muscle membrane.

Schwartz-Jampel Syndrome A syndrome characterized by continuous muscle fiber activity with stiffness and blepharospasm, accompanied by obvious dysmorphic features (dwarfism, pinched face with low-set ears, blepharophimosis, high-arched palate, receding chin, diffuse metaphyseal and epiphyseal bone dysplasia with flattened vertebrae), was crystallized by Schwartz and Jampel in 1962. It has also been reported under other names including *myotonic chondrodyrophy*. Intelligence is usually preserved. There may be percussion myotonia. The stiff muscles disturb gait.

The muscle stiffness is the result of frequent, almost continuous muscle activity with a combination of normal motor units as well as high-frequency discharges and afterdischarges similar to those seen in Isaacs syndrome. The discharges can be demonstrated to arise from muscle fibers themselves since the activity is not obliterated by curare. Agents such as procainamide, which block sodium channels in muscle, inhibit the discharges, just as they do in some other myotonic disorders. However, Spaans and associates, who have reviewed the clinical, EMG, and histologic features of 30 cases of this syndrome, report a diminished chloride conductance by the sarcolemma, which can be suppressed by procainamide or even better by mexiletine.

The disorder is usually inherited as an autosomal recessive trait that is caused by mutations in perlecan, a heparin-sulfate proteoglycan that is bound to the basement membranes of skeletal muscle and cartilage. Loss of function of the protein perturbs the organization of the basement membrane leading to an altered clustering of ACh esterase and abnormal expression of ion channels. Electron microscopic studies of muscle have yielded inconsistent findings: dilated T system, Z-band streaming, and dilatation of mitochondria; in addition, in the patient reported by Fariello and colleagues, muscle biopsy disclosed signs of denervation (group atrophy). In the latter case, treatment with procainamide, phenytoin, diazepam, and barbiturates was ineffective.

The condition described by Aberfeld and coworkers, of two siblings in whom myotonia was combined with dwarfism, diffuse bone disease, and unusual ocular and facial abnormalities and thought by them to represent a unique disorder, is probably a variant of the Schwartz-Jampel syndrome.

Muscle Contracture, Pseudomyotonia, Tetanus, and Related States

Physiologic Contracture Due to Phosphorylase Deficiency (McArdle) and Phosphofructokinase Deficiency (Tarui) These are examples of an entirely different type of painful shortening and hardness of muscle. In both these diseases, an otherwise healthy child, adolescent, or adult begins to complain of weakness and stiffness and sometimes pain on using the limbs. Muscle contraction and relaxation are normal when the patient is in repose, but strenuous activity, especially under conditions of ischemia, causes the muscles to shorten gradually, due to a failure of relaxation. The contracted muscles in these disorders—unlike muscles in cramp,

continuous muscular activity syndromes, or myotonia and other involuntary spasms—no longer use energy. During contracture, the muscles are almost silent electrically in the EMG. This condition is spoken of as *pharmacologic* or *physiologic contracture*. McArdle and Tarui diseases are discussed more fully beginning on page 1232.

Pseudomyotonia This phenomenon is observed in *hypothyroidism*, where the muscle fibers contract and relax slowly. This response is readily demonstrated in eliciting tendon reflexes, particularly the Achilles reflex. The muscles are large and subject to myoedema; when used, they may show waves of slow contraction. The basis of this disorder appears to be a slowness in the reaccumulation of calcium ions in the endoplasmic reticulum and in the disengagement of thin actin and thick myosin filaments. The EMG may show afterpotentials following voluntary contraction, but they do not resemble the typical waning discharges ("myotonic runs") of true myotonia.

A closely related syndrome, wherein painless contracture is induced by exercise, has been described by Lambert and Goldstein, and by Brody. Whereas muscle contraction is normal, the relaxation phase becomes increasingly slow during exercise. Lambert and coworkers referred to it as an unusual type of myotonia, and Brody, as a decrease of relaxing factor. The slow relaxation of muscles has also been attributed to a decreased uptake of calcium by the sarcoplasmic reticulum. In some cases, the disease is transmitted as a recessive trait; the gene defects are mutations that impair the function of a sarcoplasmic reticular calcium adenosine triphosphatase (ATPase; Odermatt et al). In other instances, the disease is transmitted as a dominant trait that is not genetically linked to the calcium ATPase.

Tetanus (See page 1030) This disorder is characterized by persistent spasms of skeletal muscles, owing to the effect of the tetanus toxin on spinal neurons (Renshaw and other cells), the natural function of which is to inhibit the motor neurons. As the condition develops, activities that normally excite the neurons (i.e., voluntary contraction and startle from visual and auditory stimulation) all evoke involuntary spasms. Sleep tends to quiet them, and they are suppressed by spinal anesthesia and curare. The EMG shows the expected interference pattern of action potentials. Once the muscle is involved in persistent contraction, it is said that the shortened state is not abolished by procaine block or severance of nerve (in animals), but this so-called *myostatic contracture* has not been demonstrated in humans.

The effect on the inhibitory neurons is analogous to that of strychnine. There is also an action of the tetanus toxin at the neuromuscular junction, which has been more difficult to evaluate in the face of its powerful central action. Having injected this toxin locally in animals, Price and associates have demonstrated its localization at motor end plates. It binds with ganglioside in the axon membrane and is transported by retrograde flow to the spinal cord, where it induces local tetanus effects. Neurons that innervate slow-twitch type 1 muscle fibers are more sensitive than those supplying fast-twitch type 2 fibers. Presynaptic vesicles increase, ACh is blocked, and terminal axon injury may paralyze muscle fibers. Fibrillation potentials and axonal sprouting follow. The similarities to stiff-man syndrome have already been mentioned.

Black Widow Spider Bite The toxin produced by this spider, within a few minutes of the bite, leads to a striking syndrome of

cramps and spasms and then a painful rigidity of abdominal, trunk, and leg muscles. The spasms are followed by weakness. There is also vasoconstriction, hypertension, and autonomic hyperactivity. If death does not occur in the first 24 to 48 h, recovery is complete.

The spider venom has a presynaptic localization and rapidly releases quanta of ACh. The vesicles are depleted. There is some evidence that the venom prevents endocytosis of the vesicles by inserting itself into the presynaptic membranes, causing a disturbance of ionic conductance channels (Swift).

Treatment, which is more or less empiric, consists of calcium gluconate infusions. Intravenous magnesium sulfate also helps to reduce the release of ACh and control the convulsions that sometimes occur. There is a reconstituted antiserum that is available in regions where such envenomation is frequent.

Malignant Hyperthermia (See page 1272) This condition is also characterized by an acute onset of generalized muscular rigidity accompanied by a rapid rise in body temperature, metabolic acidosis, and myoglobinuria. It is invariably induced by anesthetic agents and other drugs.

Myalgie States

Many of the muscle diseases described in the preceding pages are associated with aching and discomfort. These are particularly prominent in conditions that are accompanied by cramp and biochemical contracture (phosphorylase and phosphofructokinase deficiency). Ischemia of muscle—that is, intermittent claudication—is also painful, as is dystonia in some cases. Muscle weakness that imposes persistent abnormal postures on the limbs may cause stretch injury of muscles and tendons. This is observed in a number of the congenital myopathies and dystrophies. In all these conditions, clinical study will usually disclose the source or sources of the pain.

Diffuse muscle pain, which merges with malaise, is a frequent expression of a large variety of systemic infections—e.g., influenza, brucellosis, dengue, Colorado tick fever, glanders, measles, malaria, relapsing fever, rheumatic fever (“growing pains”), salmonellosis, toxoplasmosis, trichinosis, tularemia, and Weil disease. When the pain is intense, especially if it is localized to one side of the lower chest and abdomen, the most likely diagnostic possibility is epidemic myalgia (also designated as *pleurodynia*, “devil’s grip,” and *Bornholm disease*, due to Coxsackie virus infection). Poliomyelitis may be accompanied by intense pain at the onset of neurologic involvement, and later the paralyzed muscles may ache. This is true also of the Guillain-Barré syndrome, in which the pain may precede weakness by several days. Little is known about the pathologic basis of the muscular pain in these diseases; it is not due to muscle inflammation. Mild muscle pain is a frequent but not a necessary accompaniment of polymyositis and dermatomyositis.

Polymyalgia Rheumatica The major consideration in elderly and middle-aged patients with pain in proximal muscles of the limbs is polymyalgia rheumatica. This subject is mentioned briefly in other sections of this book in relation to back and extremity pain (page 189) and to temporal arteritis, to which it is closely connected (page 159). The muscular soreness may be diffuse or asymmetrical, particularly in the proximal arms and shoulders. Every movement is reported as stiff and painful. The periarticular tissues and their muscular attachments are affected primarily and may be tender, but

this is difficult to interpret, since it may be found in otherwise healthy individuals. The sedimentation rate is greatly elevated in the majority of patients, and a 48-h trial of prednisone, by alleviating muscle pain, confirms the diagnosis. In the context of muscle pain, systemic symptoms such as weight loss, headache, and fatigue, as well as mild anemia, are particularly suggestive of polymyalgia rheumatica.

Fibromyalgia This would appear, by definition, to represent an inflammation of the fibrous tissues of the muscles, fascia, aponeuroses, and possibly nerves as well. Unfortunately, the pathologic basis of this state remains obscure. Only some clinical facts are at hand. During the first movements after a period of inactivity, a muscle or group of muscles may become painful and tender, particularly after exposure to cold, dampness, or minor trauma, but often for no reason that can be discerned. One looks in vain for signs of tendinous or arthritic disease. The neck and shoulders are the most common sites. Sometimes firm, tender areas, up to several centimeters in diameter, can be palpated within the muscles (“fibrositic nodules”), and active contraction or passive stretching of the involved muscles increases the pain—points said to be of diagnostic value, but still disputed. Often, symptoms such as mental and physical fatigue, insomnia, and headache are associated and raise the suspicion of an anxiety state or depression. In a few instances the condition clears up in a few weeks; local heat and massage and local injections of anesthetics or steroids are found to give comfort while symptoms are present, but most often it becomes a chronic condition.

The chronic form of fibromyalgia presents far greater problems, usually disabling the patient and causing a change in accustomed habits and employment. It has become one of the prime diagnoses made by rheumatologists and physiatrists, but the patient may first come to the attention of a neurologist. Muscle pain is the primary symptom, with fatigue and the other aforementioned complaints added as an afterthought by the patient, or the muscular symptoms are elicited in exploring a case of the equally vexing condition now called “chronic fatigue syndrome” (pages 190 and 435). There is a great preponderance of women among these patients, and in the majority the illness is not predicated by any particular factor, although a few have a viral prodrome or recently preceding trauma.

Most definitions of the syndrome have been circular or somewhat arbitrary. Those now in general use are similar to the one proposed by a committee of the American College of Rheumatology. The basis for diagnosis is the presence of widespread pain including focal areas of pain (trigger points) that can be produced by 4 kg of digital pressure in 11 of 18 typical locations over muscles, tendons, or bone—these are concentrated around the shoulders and paraspinal regions—and there is no requirement for the presence of the several common systemic complaints that accompany the illness in most patients (fatigue, difficulty concentrating, sleeping difficulty, or anxiety). There is said to be a knot or fibrous band at the site of tenderness, but this is difficult to verify.

There is, to say the least, controversy regarding the nature of these pressure points and the validity of methods used to elicit them, since mechanical dolorimetry often suggests that these patients have a reduced tolerance to pain at all sites. But there is also uncertainty regarding the relationship of the symptoms to underlying depression. In the past, similar pains were associated with cases of irritable bowel or irritable bladder syndromes, dysmenorrhea, chronic headache, and cold intolerance. Depending upon

how broad a definition one allows for the widespread pain and painful trigger points, most or all patients in our experience manifest many of the same complaints as those with the chronic fatigue syndrome, which is discussed in Chap. 24. Authorities on the subject, however, have claimed that in the majority of patients, formal assessment by modern criteria fails to confirm the presence of depression and that, when depression does coexist with the muscular complaints, the two are discordant temporally and in severity. While we acknowledge that antidepressants often give disappointing results and that in our practice there have been several young women with fibromyalgia who appeared to be psychologically stable and lacked depression, these are the exceptions. The literature eschews the use of corticosteroids for treatment of the pain, but we have had occasion to see two patients whose symptoms were relieved when these medications were used for other purposes.

It can be said in conclusion that fibromyalgia remains a problematic illness, defined by a pattern of pain that justifies its name. Despite attempts to objectify the physical symptoms, psychiatric factors should not be overlooked. This condition is a “favorite” illness with physiotherapists, who claim that their physical measures are helpful, as they may well be. Rarely, a similar syndrome is the forerunner of what proves, after some days, with the onset of neurologic signs, to be a radiculitis, brachial neuritis, or outbreak of herpes zoster (see Goldenberg).

Other Myalgie States An impressive polymyalgia is the common one that follows excessive exercise. Often the patient observes that aching pain occurs not at the time of activity but some hours or even a day or two later, resembling the discomfort following the excessive use of unconditioned muscles. The muscles are sore and there is an intolerance of exercise and physical exertion. This is a natural phenomenon and is self-limiting. When such a state persists indefinitely and a program of conditioning exercises does not alleviate the pain, it represents a special category of disease. In a few instances an increased sedimentation rate or other laboratory aids may clarify the diagnosis, and muscle biopsy may reveal a non-specific interstitial nodular myositis or the giant-cell arteritis associated with polymyalgia rheumatica. A few individuals go on to have the features of the previously described fibromyalgic syndrome. However, this cluster of symptoms most often occurs without explanation, and one can only suspect an obscure infection or a subtle aberration of muscle metabolism, presently impossible to demonstrate. Reference was made earlier to the finding of a *myoadenylate deaminase deficiency* in some of these cases. Sometimes a rapid and excessive rise of creatine kinase (CK) after strenuous exercise will provide a clue (a slight to moderate elevation of CK is to be expected after heavy or prolonged exercise). There is also a group of patients who have idiopathic leg pain during rest after activity. Some families afflicted in this way are forced to live a sedentary existence. The condition does not respond to analgesics. In two cases, a deficiency of calcium-ATPase was found and reportedly alleviated by a calcium channel blocker such as verapamil, 120 mg qid (Walton; Taylor et al). It must be distinguished from Fabry disease (page 1159), from the syndromes of painful legs and moving toes, and from the restless leg syndrome (page 339).

The problem of a muscular pain-fasciculation syndrome was discussed earlier. In thin, asthenic adults who exhibit rather vague polymyalgia without other abnormalities, with or without cramps and fasciculations, the authors have found it difficult to exclude hysteria or other neurosis and depression. Before concluding that the condition has a psychiatric basis, it is important in every such

individual to search for evidence of a rheumatic disease or the myopathy that may accompany hypothyroidism, hyperparathyroidism and renal tubular acidosis, hypophosphatemia, hypoglycemia, and the intrinsic phosphorylase or phosphofructokinase defect. Patients with these latter diseases often complain of soreness, stiffness, and lameness after strenuous muscular effort. According to Mills and Edwards, *the most valuable screening tests are the sedimentation rate and serum CK concentration*. Other patients probably have an obscure metabolic myopathy, presently undiagnosable. In every reported series, such as that of Serrati and coworkers, about half of the cases with diffuse myalgia are undiagnosable. This coincides with our own experience.

LOCALIZED MUSCLE MASSES

Masses may be found in one or many muscles in a variety of clinical settings, and the clinical findings in each one have a different significance.

Muscle rupture is usually caused by a violent strain attended by an audible snap and then a bulge, which appears when the muscle contracts. A weakening in contractile power and mild discomfort are usually noted by the patient. The biceps brachii and soleus muscles are most often affected. Treatment is by surgical repair; if that is delayed, little can be done for the condition.

Hemorrhage into muscle may occur as a consequence of trauma, as a complication of the use of anticoagulants, in hematologic diseases, in severe myotonia, or after a minor trauma in a patient with Zenker degeneration of muscle who is convalescing from typhoid fever or some other infection. Runners may acquire painful localized hematomas in leg muscles.

Tumors include *desmoid tumor* (a benign massive growth of fibrous tissue observed most often in parturient women and after surgery), *rhabdomyosarcoma* (a highly malignant tumor with strong liability to local recurrence and metastasis), *liposarcoma*, and *angioma*. Large neurofibromas or neurofibrosarcomas beneath large muscles such as the hamstring may be difficult to differentiate by physical examination or magnetic resonance imaging (MRI) from masses within the muscle. *Pseudotumorous* growths, sometimes massive, may follow injury of a muscle. Interlacing regenerating muscle fibers and fibroblasts compose the mass. Excision of the entire muscle had been undertaken in several cases in the belief that the growth was a rhabdomyosarcoma, whereas it is actually a benign reaction to trauma (Kakulas and Adams).

Thrombosis of arteries or, more often, of *veins* causes congestion and infarction of muscle. A special type of *muscle infarction* occurs in patients with complicated and poorly controlled diabetes mellitus (Banker and Chester). Usually the infarction involves the anterior thigh, and occasionally other muscles of the lower limb. The major symptoms are the sudden onset of pain and swelling of the thigh, with or without the formation of a tender, palpable mass. Recurrent infarction of the same or opposite thigh is characteristic. The stereotypical clinical picture and the striking MRI appearance obviate the need for diagnostic muscle biopsy. The extensive infarction of muscle is due to the occlusion of many medium-sized muscular arteries and arterioles, most likely the result of embolization of atherosomatous material from eroded plaques in the aorta or iliac arteries. Recognition of this complication and immobilization of the limb are of prime practical importance, since muscle biopsy and early ambulation may cause serious hemorrhage into the infarcted tissue.

The *pretibial syndrome*, also well recognized, follows direct

trauma or excessive activity (marching, exercising of unconditioned muscles). There is swelling of the extensor hallucis longus, extensor digitorum longus, and anterior tibial muscles. Being tightly enclosed by the bones and pretibial fascia, the swelling leads to ischemic necrosis and myoglobinuria. Permanent weakness of this group of muscles can be prevented by incising the pretibial fascia and thereby decompressing the affected muscles.

Myositis Ossificans This condition involves the deposition of bone within the substance of a muscle. Two types are recognized. One is a localized form that appears in a single muscle or group of muscles after trauma, and the other is a progressive, widespread ossifying process, entirely unrelated to trauma, in many muscles of the body.

Localized (Traumatic) Myositis Ossificans After a muscle tear, a single blow to the muscle, or repeated minor trauma, a painful area develops in the muscle. It is gradually replaced by a mass of cartilaginous consistency, and within 4 to 7 weeks' time a solid mass of bone can be felt and seen in radiographs. As would be expected, this most frequently happens in vigorous adult men; the inner thigh muscles (in those who ride horses) and to a lesser extent the pectoralis major and biceps brachii are the most common sites of the abnormality. The mass tends to subside after several months if the patient desists from the activity that produced the trauma.

Generalized Myositis Ossificans (Fibrodysplasia Ossificans Progressiva) This disease, first described by Munchmeyer in 1869, has since been referred to by his name or as *myositis ossificans progressiva*. It is rare, although Lutwak, in 1964, was able to collect 264 cases from the literature. The cause is unknown, but the disease is probably inherited as an autosomal dominant trait. It consists of widespread bone formation along the fascial planes of muscles and has its onset in infancy and childhood in 90 percent of cases. Biopsies of early indurated swellings have revealed extensive proliferation of interstitial connective tissue in which little inflammatory cell reaction is found. Within a few weeks, the connective tissue becomes less cellular and retracts, compressing the adjacent muscle fibers. Osteoid and cartilage formation occur at a later stage, developing in the connective tissue and enclosing relatively intact muscle fibers.

Nearly 75 percent of all reported cases have been associated with congenital anomalies, the most frequent of which is a failure of development of the great toes or thumbs and less often other digits. Less frequently, there is hypogenitalism, deafness, and an absence of upper incisors. The first symptom is often a firm swelling and tenderness in a paravertebral or cervical muscle. There is, in addition, a mild discomfort during muscle contraction, and the

overlying skin may be reddened and slightly swollen. Trauma may be recalled as the initiating factor, but as the months pass, other muscles not injured in any recognizable way become similarly involved. At first, radiographs reveal no important changes, but within 6 to 12 months, calcium deposits are observed, and one can feel stony-hard masses within the muscles. As the disease advances, limitation of movement and deformities become increasingly evident. Calcified bridges between adjacent muscles and across joints lead to rigidity of the spine, jaw, and limbs; scoliosis; and limited expansion of the thorax. Ultimately, the patient is virtually "changed to stone."

The principal problem in diagnosis is to differentiate generalized myositis ossificans from *calcinosis universalis*. The latter usually occurs in relation to scleroderma or polymyositis and is characterized by calcium deposits in the skin, subcutaneous tissues, and connective tissue sheaths around the muscles; in myositis ossificans, there is actual bone formation within the muscles. The pathologic data are often too meager to justify this sharp distinction. The prolonged ingestion of large doses of vitamin D may also result in the deposition of masses of calcium salts around muscles, joints, and subcutaneous tissue. Calcific deposits, perhaps true ossification, may occur in the soft tissues around the hips and knees of paraplegics and rarely following a hemiplegia ("paralytic myositis ossificans").

Myositis ossificans may undergo spontaneous remissions and may stabilize for many years, during which the patient is capable of adequate function. In other cases, progression leads to marked debilitation and respiratory embarrassment, the final illness often being a terminal pneumonia or other infection.

The molecular basis for myositis ossificans is not known, but it has been suggested that one causative defect is the overexpression of bone morphogenic protein. In mice, the forced expression of this protein induces heterotopic bone formation. It is likely that the primary problem arises either because of inappropriate expression of one element of the protein or of excessive binding between signaling proteins and their receptors (Glaser et al).

Treatment The administration of a diphosphonate [ethane-1-hydroxy-1,1-diphosphate (EHDP), 10 to 20 mg/kg orally], a compound that inhibits the deposition of calcium phosphate, has been said to cause regression of new swellings and to prevent calcification (Russell et al). Some of the calcium deposits in calcinosis universalis have receded in response to prednisone, and because of the unclear relationship of this disease to generalized myositis ossificans, it is probably advisable to try this form of therapy as well. Excision of bony deposits may be undertaken if it is certain that they are the cause of particular disabilities.

PART 6

PSYCHIATRIC DISORDERS

To understand mental disorders, one must know something of how the brain functions, comprehend the basics of human psychology and how life's circumstances affect behavior, and at the same time, the effective physician must always be sensitive to the psychological needs of his patients and express a sincere desire to help them. The first two of these objectives require special study; the latter ones are more innate qualities, found in all good physicians. Indeed, the societal recognition awarded our profession is the result of sympathy for the sick and the willingness to put the patient's welfare ahead of our own—attributes that meet their greatest challenge in dealing with the mentally ill.

Mental disorders pose a number of special problems not met in other fields of medicine. First, there are such wide variations in personality, character, and behavior that the point where normal ends and abnormal begins is sometimes difficult to determine. Second, most of the methods of studying mental illness are quite subjective, derived mainly from the physician's perceptions of the inner thoughts and purposes of the patient and from the patient's powers of narration in revealing his symptoms. The patients' capacities to provide this information vary with intelligence, personality, education, and cerebral function. Only with some knowledge of the patient's natural endowment, education, premorbid personality, cultural background, and stability of emotional control, can such differences be understood. Third, and most unusual for the neurologist, it is easily appreciated that the classic mental diseases are not due to obvious lesions in one part of the brain, or even in one ensemble of physiologically or neurochemically related systems of the brain. Finally, the clinical entities of mental disease presented in the following chapters are not easily verifiable by laboratory tests or postmortem examination.

In attempting to study psychiatric disorders, one must be aware of another, more abstruse and essentially theoretical problem. Here, physicians find that there are two different and seemingly antithetical approaches to disordered nervous function—one proceeding along strictly medical or neurologic lines, the other, psychologically based. These two types of data, one drawn from observations of the patient's behavior, the other from the patient's introspections are acknowledged and incorporated. It must be emphasized that the terms *neurologic* and *psychologic* in this context do not necessarily refer to the activities of neurologists and psychiatrists. They are merely convenient terms for two distinct approaches to mental disorders.

This brings us face to face with a theoretical problem that is posed by more complex psychiatric diseases of the brain. The neurologic approach begins with the premise that all clinical manifestations of a nervous disorder are expressions of a pathologic process (disease) within the nervous system. This process may be obvious (such as a tumor or cerebral infarct), or it may be impossible to detect with the light and electron microscope (such as delirium tremens). Admittedly, brain processes such as perceiving, thinking, remembering, symbolization, are deranged but not readily reduceable to a coherent biological system.

The mode of approach to disordered mental function and behavior, which one may term the *psychologic*, or *psychodynamic*, has as its main premise that the disordered function has its roots in and is understandable largely in terms of previous or present life experiences. Certain abnormalities of behavior, emotional immaturity, and inability to adjust to the challenges and opportunities of everyday life are thought to stem from an inadequate development of personality, distressing experiences in early life, or both. Some of these experiences are remembered (i.e., "conscious"); others are said to be suppressed or forgotten (i.e., "subconscious or unconscious," according to psychoanalytic theory) and recalled only with difficulty or by questioning or through the free-association method of psychoanalysis. The principal method is to construct a kind of psychologic autobiography of the individual, with particular emphasis on early life experiences, and to search it for the roots of the present psychologic difficulty. Psychiatrists of this persuasion have formulated a number of psychologic mechanisms whereby symptoms are produced, and they speak of them in a language rather unfamiliar to most physicians—e.g., conflict, repression, conversion, projection, displacement of affect, conditioning, and arrest or fixation of libido. The purpose of this approach is not only to determine causality but also to understand the patient's current behavior in the light of past experiences and to use this under-

standing to effect change. By frank discussion and guidance, the physician endeavors to demonstrate the relationship of the patient's symptoms to abnormal behavior patterns and reactions, and, by a kind of reeducation, i.e., psychotherapy, to assist in bringing about an understanding of the problems and improved ways of coping with them. As an intellectual enterprise, however, the psychologic method alone, although yielding interesting data concerning the patient's background and the evolution of their particular symptoms in their form and content, does not provide a complete explanation of disease.

The two methodologies of neurologic and psychiatric medicine are both valid but have different roles. In diagnosis, one begins always with a classic medical approach, assuming every symptom to be an expression of disease. This method is relevant also to a theoretical formulation of disease processes. In reference to therapy and management, the psychiatric approach is sometimes the only rational (and available) methodology. In other circumstances, the spheres of the two methodologies tend to overlap. The two methods operate at different levels and are of principal use in different types of nervous aberrations. In the diagnosis and management of difficulties in adjusting to life's circumstances and in certain disorders of personality and character, which constitute such a large and important part of medicine and psychiatry, the psychologic approach achieves maximal credence. The psychiatric approach has been highly successful at focusing on the interaction between an individual's traits and his or her complex environment and is not easily framed in neurologic terms. This unitary view of mental disease also allows for the possibility that changes in the environment and even in the patient's mental state can cause changes in the functioning of the brain. It is fair to say that this apparent clash of views between mentalism on the one hand and *on the other hand* the mind as a property of the physical brain has been settled in favor of the neurologic view. It is supported to some extent by the observations that every known psychiatric symptom can be reproduced by well-defined cerebral diseases, and every major neurologic disease of the cerebrum may be attended by symptoms of psychiatric disease. Every disorder of function must have a structural or physiologic basis unless one adheres to a purely psychic view in which human behavior is not considered to be a product of brain function. This is the position of the mind-body problem most acceptable to neurologists. This concept of "disorders of mind arising in brain" is also subscribed to by most modern psychiatrists (Andreasen). Admittedly, neuropsychiatric monism has not had universal acceptance. Western philosophers, from Plato in ancient times through Descartes, James, and, more recently, Sherrington and Eccles, broadly speaking have been dualists, holding that body and mind are independent systems, each susceptible to its own disorders.

This brings us to another of the crucial problems in neurology and psychiatry—that of defining a disease of the nervous system and distinguishing it from a social or psychologic maladjustment. Failure to do this has resulted in confusion as to the legitimate spheres of medical activity and has been an obstacle to research. The present authors define a disease of the nervous system as any condition in which there is a visible, physiologic, biochemical, or other subcellular lesion or in which there is reasonable evidence of its existence on the basis of stereotypy of clinical expression and of genetic and collateral laboratory data. Goodwin and Guze offer a slightly different definition of psychiatric disease—as any cluster of symptoms and signs that occur with such consistency as to permit the prediction of their outcome. In contrast, an abnormal psychologic reaction is defined as a disorder of psychic function and behavior caused by a maladjustment in social relations or a disordered response to life's difficulties not based directly on a known disease process or lesion.

Certain mental abnormalities have an uncertain status vis-à-vis this division and are subject to double interpretations, depending on one's premises. For example, persistent anxiety state without obvious cause in a previously healthy adult would be viewed by some psychiatrists as a reaction of fear of some unconscious threat. Others would consider it the manifestation of a genetic disease in which some biochemical disturbance, as mysterious as was hyperthyroidism a century ago, developed de novo. Further challenging our current conceptions is how to interpret the co-opting of basic mechanisms of the limbic

system by thought processes to produce affective states such as depression. Is a susceptibility to trigger such mechanisms a disease, a genetic proclivity, or does it reflect a normal spectrum of activity? Since the nature of the condition is unsettled, it is treated by physicians using both psychologic methods and drugs. Anyone who proposes to investigate it should do so with a completely open mind and be prepared to review critically any reasonable hypothesis as to its cause.

When the clinical specialties of psychiatry and neurology are viewed in terms of these theories about disease and psychosocial reactions, it is obvious that they overlap. Diseases such as schizophrenia and manic-depressive psychosis, which are cerebral diseases and of interest to neurologists, will for the near future remain in the province of psychiatrists. The latter specialists have the training in psychotherapeutic methods and expertise in neuropsychiatry that is needed in the care of such patients. Examples of the intersection of interests between specialties occur regularly in dealing with diseases such as dementia, and in temporal lobe epilepsy, where behavioral and cognitive changes are equally distressing to the patient and family and where drug usage must be supplemented by guidance and explanation of the illness. Finally, and of utmost importance, the psychiatrist must stand as the spokesperson for the medical position on the countless ills related to social and behavioral maladjustments in modern life.

Psychosomatic Medicine It is difficult to appreciate the evolution of psychiatry, particularly in America, without mentioning the impact of psychosomatic medicine on theoretical thinking. Beginning in the 1930s there was great interest in a large category of disease referred to for decades by this term. Included at one time or another were peptic ulcer, mucous and ulcerative colitis, hay fever, asthma, urticaria, angioneurotic edema, essential hypertension, hyperthyroidism, rheumatoid arthritis, amenorrhea, and migraine—diseases in which a stressful life situation or emotional upset appeared to be associated with their development, exacerbation, or prolongation. By extension, certain personality traits were thought to be prevalent in patients who later developed brain diseases, such as Parkinson disease. More than 70 years have passed since these ideas were first promulgated and expressed, an enormous literature followed, but with the establishment of pathetically few unassailable facts for each of them. It became clear that the so-called psychosomatic diseases are not neuroses and, in most instances, a demonstrable pathologic basis has been discovered. Even peptic ulcer, an old psychosomatic favorite, has been traced to a bacterial infection. No proof of psychic causation of any of the psychosomatic diseases has been found. Treatment has been concerned mainly with the relief of physical symptoms and has been directed for the most part by nonpsychiatric specialists. There was never firm evidence that the therapeutic results obtained by psychiatrists were better than those of a competent internist or simply of the passage of time.

This extended application of the concept of psychosomatic disorders is still prevalent. The current societal preoccupation with “stress” as a cause or trigger for all manner of medical and neurologic disease, including disordered function of the immune system (*psychoneuroimmunology*), is an extension of this tenuous concept.

Interestingly, the terms *psychosomatic* and *psychophysiologic* are not listed in the fourth edition of the American Psychiatric Association's official diagnostic manual, the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. A few of the disorders originally called *psychosomatic* now appear under the categories of *somatoform disorders* or *psychological factors affecting physical conditions*; these are discussed in subsequent chapters. The reader seeking further information as to the status of psychosomatic or psychophysiologic disorders is referred to the review by Rogers, Fricchione, and Reich.

PLAN OF PSYCHIATRY SECTION

In the chapters that follow there will be a consideration of the neuroses, the affective disorders, the sociopathies, the schizophrenias, and the paranoid states. The magnitude of these disorders and their clinical and social importance can hardly be overestimated. Some 20 to 30 percent of all individuals will at some period of their lives experience psychiatric

symptoms and seek medical help for them. The headings that guide our exposition of neuropsychiatric illnesses might be questioned, but the justification for their selection is that each can be diagnosed by a competent physician and each diagnosis, once made, can be validated by follow-up studies and treatment based on proper diagnosis can be prescribed. All physicians should know something about these categories of psychiatric disease. Neurologists in particular need to be familiar with them, if only for the purposes of differentiating them from other neurologic diseases and initiating intelligent management but also to discuss intelligently the operation of the diseased brain.

Emphasis throughout these chapters will be on the biologic characteristics and the diagnosis of each state. This approach is in keeping with a significant change in American psychiatry, namely, the development in the 1960s through 1980 of rigorous criteria for the diagnosis of psychiatric disorders. The stimulus for this development can be traced largely to the studies of Mandel Cohen and Paul McHugh and the Washington University group in St. Louis (Feighner, Robins, Guze, and their colleagues and expressed in the monographs of Goodwin and Guze and of Rakoff et al). Many of the diagnostic formulations proposed by these clinicians were adopted, in 1980, by DSM-III (and its several subsequently revised forms). The prevention of suicide, the choice of appropriate therapy, communication with the patient's family and physician, predictions about the course of the illness (prognosis)—all begin with accurate diagnosis. In addition to their practical clinical value, strict diagnostic criteria are important in psychiatric research.

In forwarding the structural bias of neurologic medicine, we by no means wish to depreciate the importance of psychologic medicine or of psychiatry. Our position on this matter has been fully stated in the preceding pages and needs no further elaboration. Theoretic aspects of personality and psychopathology and symptom formation will be given little space because of our uncertainty about the status of such psychologic mechanisms.

CHAPTER 56

THE NEUROSES AND PERSONALITY DISORDERS

From time immemorial, in every society, it has been realized that there are many troubled individuals who are neither insane nor mentally retarded. They differ from other people in being plagued by feelings of inferiority or self-doubt, suspicion about the motives of others, low energy, inexplicable fatigue, shyness, irritability, moodiness, sense of guilt, and unreasonable worries and fears. They suffer as a result of these feelings or they behave in ways that are upsetting to those around them and to society at large. Yet none of these conditions precludes partaking in the everyday affairs of life, such as attending school, working, marrying, and rearing a family. As these conditions were more carefully documented, the ones that caused an individual much personal distress came to be called *psychoneuroses* and, later, *neuroses*, and those that created societal difficulties were called *psychopathies* and, more recently, *sociopathies*.

The question of the purity and homogeneity of these mental states has excited a lively polemic in psychiatry for a century. The neuroses as a group appeared to be so diverse as to require subdivision in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, DSM-IV into no less than seven different types, as elaborated further on. Originally, Freud referred to the neuroses as psychoneuroses, and the subject became enmeshed in psychoanalytic theory. The assumption was that an undercurrent of anxiety arising from unconscious conflict explained all the different types of neuroses as well as the psychopathies. Later, psychiatrists uncommitted to psychoanalytic theory attributed these states to social forces leading to maladaptive behavior from childhood. These notions were not acceptable to biologically oriented psychiatrists, with the result that the term *psychoneurosis* was expunged from later editions of the DSM and even *neurosis* was replaced by terms such as *anxiety disorders*, *phobic states*, and *obsessive-compulsive disorder*. These terms are at present applied to any mental disorder with the following characteristics: (1) symptoms that are distressing to the affected individual and regarded by him as unacceptable or alien; (2) intactness of reality testing (the patient's evaluation of the relationship between himself and the outside world); (3) symptomatic behavior that does not seriously violate social norms, although personal functioning may be considerably impaired; (4) a disturbance that is enduring—not a transitory reaction to stress; and (5) absence of a discernible medical cause or structural disease of the brain. The foregoing definition of the anxiety and allied disorders, or neuroses, has the virtue of being descriptive without committing one to any hypothesis of causation.

The genesis of the neuroses remains elusive. It is generally conceded that such disorders do not arise *de novo* in otherwise healthy individuals. The antecedents are thought to be abnormalities in personality development, strongly influenced by genetic factors, and possibly molded by stressful events in the life of the individual (Noyes et al). Traits of this nature undoubtedly arise in several individuals from the same family. Thus an informative discussion of such disorders requires a brief digression into the origins of normal personality development and departures from it.

PERSONALITY DISORDERS

The concept of *personality* and its development were introduced in Chap. 28. There it was pointed out that the term embraces the totality of a person's physical and mental attributes, his observable behavior and reportable subjective experience—the sum of which distinguishes one individual from all others. Thus it includes elements of the individual's character, intelligence, instinctual drives, temperament, sentiments, behavior, motor control, and memories—in short, all forces from within the organism, as well as the reactions to prevailing influences of the environment that govern behavior. The term *character* is almost synonymous with personality but is less useful in medicine because of its emphasis on interpersonal and ethical aspects and moralistic connotation.

The roots of personality are multiple and deviations from the normal or the average—such as in boldness and timidity, novelty seeking and excitability, level of energy and activity, fearfulness and fearlessness, social adaptability and rigidity or stubbornness, etc.—are already evident in the first months of life. Monozygotic twins are alike (but not absolutely identical) in these respects, even when reared apart. Gesell and his colleagues, in their studies of infants (see Chap. 28), observed individual differences that are clearly innate; each of these characteristics is genetically determined, like intelligence. The personalities that result are as individualistic as fingerprints. One example of a genetic predisposition to a human personality trait, albeit to a limited degree, has been found in the expression of thrill seeking, exploration, and excitability. According to Cloninger and colleagues, pleomorphism of the dopamine receptor gene on chromosome 11 accounts in a small measure for the genetic variability of this personality type. Findings such as these, which have been reproduced by other investigators, suggest that similar polymorphisms contribute to other traits such as anxiety, obsessiveness, etc. The notion, expressed by authors such as Kandel, that genetics will explain a large part of mental function and mental illness sounds reasonable enough, but the data to establish this prediction are far from complete.

Pertinent to the subject matter of this chapter is the assumption that in approximately 15 percent of the general population, certain personality traits are so pronounced as to be distressing to the individual and disturbing to others, even though the patient is not manifestly sociopathic or psychotic. Some of these traits are seen first in infancy and become sources of difficulty during childhood in relation to eating, behavior during play, and school attendance. Psychodynamic explanations abound, but—not based on reproducible evidence—are difficult to validate. They tend to emphasize the resulting psychologic conflict and deemphasize genetic and biologic factors. Therefore, the extent to which these deviations reflect past experience or a genetically predetermined pattern is unsettled.

Another unsolved problem is whether each of the personality types accepted by the American Psychiatric Association is predictive or determinative of a particular type of neurosis or psychosis. In this regard, two broad groups of personality disorders can be recognized. In one group—comprising the paranoid, schizoid, cy-

clothymic, and obsessive-compulsive personality types—there are obvious similarities to major types of psychiatric illness. Thus, among patients who develop paranoid schizophrenia, a considerable number will have had the attributes described under “paranoid personality type.” Similarly, among patients who develop schizophrenia of another type, the history will frequently disclose a pre-existent “schizoid” personality. In fact, it may be difficult to judge where the personality disorder left off and the schizophrenic illness began. Similarly, it seems clear from several family studies that the cyclothymic personality is related to manic-depressive disease. Obsessive-compulsive personality is related not only to obsessive-compulsive neurosis, as one might expect, but also to depressive disease.

The defining features of the personality disorders fall short of meeting the diagnostic criteria for the neuroses. Yet, an understanding of these personal peculiarities and their less obtrusive traits may be of great help to the physician. This knowledge makes it possible to appreciate their role as sources of perennial complaint, self-concern, and family discord and to explain a patient’s reactions, which may have interfered with diagnostic and therapeutic procedures during a medical illness.

Personality disorders, like personality itself, are pervasive, enduring, and little influenced by the physician, although often the contacts between physician and patient over many years and repeated reassurance and explanations of how best to cope with difficulties may serve as a stabilizing force. The use of medications to influence some aspect of personality should be avoided unless there is evidence that the peculiarity of personality has developed into a full-blown neurosis. However, one should never underestimate the power of maturation to ameliorate the turmoil of adolescence and to settle the young mind.

THE NEUROSES

Though considered to be the most frequent of mental disturbances, the neuroses are among the least understood. They were established as clinical entities in the late nineteenth century, but there are still major unresolved issues with respect to their nature, classification, and etiology. Descriptively, the neurotic disorders include the following syndromes: (1) anxiety neurosis; (2) phobic neurosis, which includes phobia of illness, social phobia, and agoraphobia; (3) obsessive-compulsive neurosis; (4) hysteria; and (5) hypochondriasis. Former classifications included additional types called neurasthenia (dysthymia or depressive neurosis), which is now considered with the depressive illnesses, and “depersonalization neurosis” (dissociative disorders), which is probably a form of hysterical neurosis. Although each of these syndromes is clinically identifiable and separable when occurring in pure form, experience shows that most patients suffer from symptoms of more than one type and therefore are said to have “mixed neuroses.” In the most recent classifications, all of the neuroses have been again replaced by three broad categories: (1) *anxiety disorders* (which include panic states, with and without agoraphobia, and the phobic and obsessive-compulsive neuroses); (2) *somatiform disorders* (comprising hysterical neurosis, or conversion disorder, and hypochondriasis); and (3) *dissociative disorders*.

It is evident from these and several other attempts at classification that a single definition—one that would satisfactorily explain the attributes of all the neuroses—is still to come. Syndromes as different as hypochondriasis and panic reaction are not likely to lend themselves to a unitary explanation. If there is a central feature

of the neuroses, however, it is thought to be *anxiety*, which runs as a kind of leitmotif through all of them. Even in hysterical neurosis and sociopathy, in which patients seem indifferent to their disabilities, there is often a strong undercurrent of anxiety.

In an epidemiologic survey sponsored by the National Institute of Mental Health, it was estimated that approximately one-third of the population of the United States, at some point during their lives, have some type of mental disorder. In this survey, disorders related to chronic alcoholism were the most common, followed by anxiety, alterations in mood, and obsessive-compulsive, phobic, conversion, and so-called posttraumatic stress disorders. A different view of the relative frequency of mental disorders was provided by an analysis of 1045 consecutive psychiatric consultations at the New England Center Hospital (now New England Medical Center) during the years 1955 and 1956. In this tertiary referral hospital, the dominant psychiatric syndrome in about 20 percent of patients was an anxiety state.

Other epidemiologic studies have also disclosed a strikingly high incidence of anxiety disorders in the general population (see the review of Winokur and Coryell). Lifetime prevalence figures indicate that at least 11 percent of the population is so affected—i.e., some 25 million persons in the United States. Such information as is available suggests that the incidence of the neuroses is much the same in an urban population (midtown New York) as it is in a rural one (Stirling County, Nova Scotia) indicating that socioeconomic, racial, and cultural factors are of relatively little importance. Furthermore, in times of calamity, such as the bombing of London, the incidence of neurotic symptoms was said not to have increased. Thus one tends to dismiss as an oversimplification the notion that neuroses are merely by-products of life in civilized society or reactions to environmental stress (see also Chap. 24). The symptoms first arise in late childhood, adolescence, and early adult life. Admittedly, neurotic symptoms may be recognized for the first time after this age, but a good clinical rule is to suspect any mental illness that appears for the first time after the age of 40 years to be either a depression or a dementia that is due to degenerative or other organic disease of the brain.

ANXIETY NEUROSIS AND PANIC ATTACKS

The term *anxiety neurosis* was introduced by Freud in the latter part of the nineteenth century to describe a syndrome consisting of general irritability, anxious expectation, anxiety attacks, somatic accompaniments or equivalents of anxiety, and nightmares. In anxiety neurosis, this symptom complex constitutes the entire illness. However, as indicated earlier, parts of this constellation also appear in several other psychiatric diseases—manic-depressive psychosis, schizophrenia, hysteria, and phobic neurosis. Its closest link is with depression, which it resembles in another respect—namely, *there is a strong hereditary factor in both*, as pointed out by our colleague, Mandel Cohen in 1940. The term used in DSM-IV is *anxiety disorder*, of which phobias, obsessive-compulsive disorder, panic attacks, and so-called posttraumatic stress disorder are the important subdivisions.

Clinical Presentation

Anxiety neurosis is a chronic disease, punctuated by recurrent attacks of acute anxiety or panic. The acute attacks are the hallmark of the disease and many psychiatrists are reluctant to make a di-

agnosis of anxiety neurosis in their absence. Because of the clinical features of panic attacks and particularly their episodic nature, which simulates an acute medical condition, they are of special interest to neurologists and general physicians. Fully developed panic attacks are almost as dramatic as seizures. They begin with distressing feelings of dread and foreboding. The patient is assailed by a sense of strangeness, as though his body had changed or the surroundings were unreal (depersonalization; derealization). He is frightened, sometimes by the prospect of imminent death (*angor animi*) or of losing his mind or self-control. There may be a feeling of smothering. "I am dying," "This is the end," "Oh, my God, I'm going," or "I can't breathe" are the characteristic expressions of alarm and panic. The heart races, breathing comes in rapid gasps, pupils are dilated, and the patient sweats and trembles. The palpitation and breathing difficulties are so prominent that a cardiologist is often called. Some of our psychiatric colleagues identify breathlessness or a suffocating feeling as central to the diagnosis of panic and will not make the diagnosis without it (some of them also attribute great psychologic meaning to the symptom). The symptoms abate spontaneously after 15 to 30 min, leaving the patient shaken, tense, perplexed, and often embarrassed. There is no element of confusion, and after the episode, there is full memory of the event.

Most anxiety attacks are of lesser severity than the one previously described. The patient complains of faintness, palpitations, or a feeling of postural instability, referred to as dizziness. Breathlessness, vague chest or upper abdominal discomfort, a palpitory feeling as if the heart were beating too hard, and asthenia are other common symptoms. Over 50 years ago Cohen and White listed the following symptoms in order of frequency in the patients they observed: palpitation, 97 percent; easy fatigue, 93 percent; breathlessness, 90 percent; nervousness, 88 percent; chest pain, 85 percent; sighing, 79 percent; dizziness, 78 percent; apprehensiveness, 61 percent; headache, 58 percent; paresthesias, 58 percent; weakness, 56 percent; insomnia, 53 percent; unhappiness, 50 percent.

Many patients experience a constant uneasiness that the spells may occur in public; hence the patient may be fearful of leaving his home lest help not be available should an attack occur (agoraphobia). Except in minor details, it is notable that all the attacks are alike in any one individual. Between attacks, some patients feel relatively well, but many complain of the symptoms of anxiety and asthenia in lesser but persistent fashion.

Hyperventilation is a special though not invariable feature of the anxiety attack. Hyperventilation itself, by reducing the PCO₂, will cause giddiness, paresthesias of the fingers, tongue, and lips, and at times frank tetany. However, contrary to what is stated in some textbooks, in only a minority of patients does a 3-min period of commanded deep breathing reproduce the symptoms of an anxiety attack. This maneuver may be used to assist the patient in describing certain aspects of an attack.

Anxiety attacks may occur at infrequent intervals or several times a day. They may occur in situations where there are no easily recognizable sources of fear, as when the patient is sitting quietly at home or has just awakened from sleep. In other instances, a trying or upsetting experience induces an attack, which is nonetheless excessive for the condition that provoked it. In some patients, attacks are brought on consistently by confinement to a closed space (claustrophobia)—an elevator, for example—or by crowded surroundings, as in a church, restaurant, or theater. An anxiety state frequently follows an accident and may, according to Modlin, be

a source of ongoing disability. Similar spells of anxiety are also a prominent feature of the postconcussive syndrome (page 864).

The onset of anxiety neurosis is often insidious—feelings of tenseness, vague apprehension, fatigue, weakness, and giddiness having been present for weeks or months before the first panic attack. From the history alone, two patterns of chronic anxiety neurosis are discernible. In one, there is a nearly lifelong history of poor exercise tolerance, little stamina, inability to do heavy physical work or participate in vigorous sports, tenseness, nervousness, and intolerance of crowds, i.e., what had been called neurasthenia. These symptoms often arise during military service and had been designated, since the American Civil War, as *neurocirculatory asthenia*, "irritable heart," or "soldier's heart." In the other pattern of onset, the patient is vigorous and symptom-free before the anxiety state begins. The latter type usually has its origin in a late-life "anxious depression" that nonetheless may arise on a background of lifelong mild anxiety or obsessiveness.

Most patients with chronic symptoms first consult a physician not with a complaint of "anxiety" but with symptoms referable to the cardiorespiratory system or gastrointestinal system (dyspepsia, loss of appetite, or "irritable colon"). The physical examination between acute attacks yields relatively little of diagnostic value. The common findings, disclosed by the study of Cohen and associates, were slight tachycardia, sighing respirations, yawning, flushed face and neck, tremor of the outstretched hands, and brisk tendon jerks. The patient tends to be restless and abrupt in movement, expressive of an inner uneasiness. During a panic attack, there may be manifest agitation and a tendency to leave the current venue, and blood pressure is invariably elevated.

The onset of both acute and chronic anxiety neurosis is rare before 18 or after 35 to 40 years of age (average age of onset, 25 years). The condition in some series is twice as frequent in women as in men, and there is a high familial incidence. In one study (Wheeler et al) there was a prevalence of 49 percent among the grown children of patients with anxiety neurosis, compared with a prevalence of about 5 percent in the general population. Slater and Shields found that there was a concordance rate of 40 percent in identical twins, compared with 4 percent in dizygotic twins. Among the relatives of index cases, the mothers suffered from anxiety neurosis more often than did the fathers; in the latter, alcoholism was more frequent than in the population at large (Modlin). The pattern of inheritance has not been established, but it most closely approximates that of autosomal dominance with incomplete penetrance.

The course of anxiety neurosis is variable. The symptoms fluctuate in severity without apparent relation to environmental stress. A 20-year follow-up study by Wheeler and associates showed that symptoms of anxiety neurosis were still present in 88 percent but persisted in being moderately or severely disabling in only 15 percent. Most affected patients were able to work and to enjoy a reasonably normal family and social life. Their only liability to further psychiatric illness was to recurrent anxiety neurosis or to later anxious depression whereas so-called psychosomatic illnesses and other psychiatric illnesses did not occur more frequently than in the general population. The life span of patients with anxiety neurosis is not shortened. Those with pure, uncomplicated anxiety neurosis rarely commit suicide.

Etiology and Pathogenesis

Anxiety neurosis has been attributed to a genetic abnormality, to constitutional weakness of the nervous system, to social and psy-

chologic factors, some of which have already been discussed, and, more recently, to certain physiologic and biochemical derangements; but none of these factors provides a completely satisfactory explanation of the primary disorder. The psychodynamic theories that attempt to provide a unified explanation of these diverse neurotic states have been reviewed by Nemiah. The symptoms of an anxiety attack resemble those of fear in many ways, though nearly always the former symptoms are longer in duration and less distinct. The most important difference, however, is that the cause of fear is known to the patient, whereas that of anxiety is not.

On the physiologic and biochemical side, it has been observed that anger provokes an excessive secretion of norepinephrine, whereas fear is accompanied by increased secretion of epinephrine. Actually, fear activates the autonomic nervous system, and the increase in epinephrine is more than counterbalanced by a parasympathetic discharge. Attention has been focused on overactivity of the locus ceruleus and upper brainstem nuclei as the possible anatomic substratum of anxiety (Judd et al). Other studies have implicated serotonergic centers. Evidently, the responsiveness of the autonomic nervous system in these patients remains heightened, and a number of stimuli (cold, pain, muscular effort) may produce abnormal responses in pulse, respiration, oxygen consumption, and work performance. Another interesting abnormality (first noted by Cohen et al) is that the blood lactic acid levels in response to exercise are higher than normal. The presence of these derangements does not necessarily mean that they are causal; they are as likely secondary to other factors such as poor physical condition and apprehension associated with the syndrome. Nevertheless, some investigators have found that infusions of lactic acid can trigger panic attacks in persons with anxiety neurosis (Liebowitz et al). Subsequently, a number of other theories of causation have been proposed based on the reported provocation of panic attacks by a number of different substances—carbon dioxide, yohimbine, gamma aminobutyric acid (GABA), isoproterenol, and others. None provides a comprehensive biological explanation.

Studies correlating cerebral function and blood flow indicate that when panic is induced by an intravenous injection of sodium lactate, there is an immediate increase in blood flow to the cortex of both temporal lobes. In states of fear, the tips of the temporal lobes and the amygdaloid nuclei are known to become activated. In the relaxed period between panic attacks, the right limbic system and the parahippocampal gyrus are abnormally active in some studies. As with the aforementioned biochemical models, these seem to be more reflections of brain activity in response to the psychic experience than they are explanations. Nevertheless, parts of the limbic system are presumably involved in a germinal way in the production and perpetuation of anxiety and its related states. The most extreme but not inconceivable interpretation of anxiety is the James-Lange theory of emotion, which attributes the psychologic experience entirely to the accompanying physical symptoms.

Of potential importance is the finding of a connection between anxiety traits and certain genetic polymorphisms such as one of the serotonin transporter gene on chromosome 17 (Lesch et al). It is estimated that allelic differences on the chromosome contributes perhaps 10 percent to the overall neurotic tendency, and there is an implication that numerous additional genes may participate in a similar way. Others have not found this particular association or have found it only in patients with generalized anxiety but not those with panic attacks. Therefore the precise relationship of this and other genetic abnormalities to neurosis cannot be stated at this moment but a heritable component is undoubtedly.

Differential Diagnosis

Shorn of the psychologic components of apprehension and fear, the anxiety attack consists essentially of an excessive autonomic discharge. Some of the autonomic symptoms are duplicated by chromaffin tumors, hyperthyroidism, and the menopause. The prominence of chest discomfort and respiratory distress during an acute anxiety attack may be mistaken for myocardial ischemia, in which case the patient is often subjected to a series of studies of cardiac function. Another form of the illness—in which dizziness, a vague difficulty with visual clarity, and fear of losing consciousness are the most prominent features—may be mistaken for a neuro-otologic problem (“panic-vertigo,” page 258). In contrast, numerous other symptoms such as headache are relatively infrequent, and the diagnosis should be suspect if headache is a prominent feature. (Chronic headache may be part of chronic anxiety state or anxious depression.) Loss of consciousness, incontinence, and clonic or myoclonic movements do not occur. Other medical diseases that are brought to mind by particular elements of an anxiety state are pulmonary embolism, cardiac arrhythmias, hypoglycemia, hypoparathyroidism, alcohol, drug, and nicotine withdrawal, and especially complex partial seizures. Strict adherence to the diagnostic criteria of these disease states readily permits their differentiation from acute anxiety, but diagnosis may be difficult if the symptoms of anxiety are very brief or persist for hours or days on end.

Of greater importance is the relationship of anxiety neurosis to other psychiatric illnesses, particularly to depression. Symptoms of depression are frequently added to those of anxiety neurosis, and the majority of patients with depression have symptoms of anxiety. Indeed, some psychiatrists believe that anxiety neurosis is accounted for mainly by a variant of depression. As has been mentioned, an anxiety state appearing for the first time after the fortieth year usually proves to be primarily a depression. The uncovering of paranoid symptoms in a patient with an anxiety state should always raise the question of depression, as should the presence of symptoms such as overwhelming fatigue, self-depreciation, and feelings of hopelessness and, of course, ideas of self-destruction. As mentioned, a very small number of patients with a condition diagnosed as pure anxiety neurosis by competent psychiatrists have committed suicide.

Schizophrenia may also begin with prominent anxiety symptoms. Here the diagnosis rests on finding the characteristic thought disorder of schizophrenia, which may emerge only after several interviews. Hysteria may include anxiety symptoms, though they are seldom prominent, as do also phobic and obsessive-compulsive neuroses, but each has other distinguishing attributes.

Treatment

Certain medications, particularly anxiolytics and antidepressants, are highly effective in suppressing panic attacks and creating a sense of well-being. Among these, the benzodiazepine alprazolam (2 to 6 mg/day) is currently favored, but lorazepam and clonazepam are almost as effective and are considered slightly less likely to cause dependence. They are all effective within hours. In mild cases, the benzodiazepines may be used intermittently rather than several times daily, but they tend to be less useful once a panic attack has become established. The panic attacks tend to recur when the medications are discontinued, even after prolonged (6 to 12 months) administration. Attempts to reduce the amount of these medications should be gradual. Tricyclic antidepressants and drugs

that putatively raise serotonin concentrations in the nervous system (selective serotonin reuptake inhibitors, or SSRIs) are also effective to some degree in the prevention of panic attacks and agoraphobia but their onset of action is delayed for weeks. They become useful for symptoms of anxiety that persist for more than several months. The doses are similar to those used to treat depression (see Chap. 57). Buspirone, a specific serotonin 5-HT₂ agonist, has been promoted as effective in the treatment of anxiety and as a surrogate for benzodiazepines, but its benefit has seemed to us to be slight. *It is important to point out that during the initial weeks of administration of antidepressants, the underlying anxiety symptoms may worsen and an anxiolytic is usually required until the antidepressant becomes effective.* Propranolol, 10 to 20 mg three times daily, or a long-acting form of adrenergic blocker, reduces many of the autonomic accompaniments of anxiety and is useful to many patients, but its effects on the other symptoms are uncertain.

For true anxiety neurosis with panic attacks, psychiatric consultation is valuable. With regard to psychotherapy, behavioral therapy (progressive exposure of the patient to panic-provoking situations) is said to be beneficial, particularly if agoraphobia is a major symptom. Relaxation activities, including biofeedback and meditation, help many patients, although persistence is required in performing these at least once daily and they are less helpful once a panic attack has begun. So-called cognitive-behavioral psychotherapy, which is discussed in relation to the treatment of depression (page 1315), also appears to be useful in the treatment of panic disorder according to Andreasen and Black. A cardiac consultation and some simple tests (electrocardiogram, chest films) may be needed to reinforce the benign nature of the cardiac and respiratory symptoms and to alleviate the patient's fear of heart disease. These and other current concepts of the treatment of anxiety are discussed by Goodwin and Guze. Anxiety symptoms arising in relation to a particular threatening event in a nonneurotic individual carry the best prognosis.

PHOBIC NEUROSIS

In this state, patients are overwhelmed by an intense and irrational fear of some animal, object, social situation, or disease. Though acknowledging that there are no grounds for a particular fear (hence it is not a delusion) and that such provocative stimuli are for the most part innocuous, the patient is nonetheless powerless to suppress it. This disorder was known to Hippocrates, who drew a distinction between normal and morbid fears. Westphal in 1871 was the first to give morbid fears the status of a disease. Women are affected slightly more often than are men.

Unlike an anxiety attack, such a phobia always focuses on a specific object or situation. The patient is chronically fearful of a particular animal or situation and becomes extremely anxious or panic-stricken and incapacitated when placed in a situation that evokes the phobia. These situations are avoided at all costs. For example, it may be impossible for the patient to leave the house or neighborhood unaccompanied—or at all, mingle in a crowd, walk across a bridge, or travel by air. This fear of being in places or situations from which escape might be difficult or extremely embarrassing is spoken of as *agoraphobia*. (Agoraphobia, however, may be a secondary feature of other psychiatric disorders, the most frequent being anxiety with panic attacks as already mentioned.) The most common phobia is probably claustrophobia (the fear of being confined in a close space, such as an elevator or a magnetic resonance scanner). Other phobias, as remarked earlier, are those

of open (agoraphobia), closed, or high places, dogs, cats, insects, dirt, sprays and other contaminants, air travel, acquired immunodeficiency syndrome (AIDS), cancer, insanity, and death. Feelings of helplessness, pessimism, and despondency, the hallmarks of a depressive illness, result after years of phobic suffering. Often there are obsessive-compulsive tendencies as well, and some patients are hypochondriacal. Phobias are essentially *obsessive fears* and are somehow allied with this latter category of neurosis. The present authors have observed a number of patients whose phobic (or obsessive-compulsive) neurosis became greatly exaggerated as an endogenous depression developed. Recovery from the depression returned them to their earlier and milder phobic state. All of these features suggest a linkage between neuroses and depression.

OBSESSIVE-COMPULSIVE NEUROSIS

Like the pure phobic states, a neurosis dominated by obsessions and compulsions is relatively rare, occurring in less than 5 percent of patients seeking help in a psychiatric outpatient clinic, but they can be extremely disabling. Minor compulsions (for example, not stepping on cracks in the sidewalk), like minor phobias, are common in children, cause little or no distress, and tend to disappear in later life. A few, such as rechecking a locked door or a gas stove, may persist throughout life. Also, certain habits and rigid, obsessional ways of thinking, stubbornness, extreme punctuality, and excessive attention to detail are frequent and persistent but excite little attention medically unless they interfere with a diagnostic procedure or the treatment of a medical disease.

Obsessive-compulsive neurosis, or disorder, as it is now designated, begins, as do the other neuroses, in adolescence or early adult years, although treatment may not be sought until middle age is reached. The two sexes are equally affected. The onset is usually gradual and often cannot be accurately dated, but in some cases it is precipitated by a particular event in the patient's life, such as the death of a relative. The family history often discloses a high incidence of obsessional or phobic personality in other members. In some, but not all, instances, the obsessive-compulsive neurosis is engrafted onto a personality in which rigidity, inflexibility, and lack of adaptability are prominent. There is always a prevailing undercurrent of insecurity and anxiety.

Obsessions are defined as imperative and distressing thoughts and impulses that persist in the patient's mind despite a desire to resist and to be rid of them. They take various forms; the most common are *intellectual obsessions*, in which phrases, rhymes, ideas, or vivid images (these are often absurd, blasphemous, obscene, and sometimes frightening) constantly intrude into consciousness; *impulsive obsessions*, in which the mind is dominated by an impulse to kill oneself, to stab one's children, or to perform some other objectionable act; and *inhibiting obsessions*, in which every act must be ruminated upon and analyzed before it is carried out—a state that was cleverly called *doubting mania*. Every effort at distraction fails to rid the patient of the obsessive thought. It engulfs the mind, rendering him miserable and inefficient. Probably the most disturbing obsessions are the impulsive ones, in which patients constantly struggle with the fear that they will put some terrible thought into action. Even as they tell of the obsession, they reveal a severe underlying anxiety and seek reassurance that they will not yield to it. Fortunately, such patients rarely obey their pathologic impulses. Phobias, as mentioned earlier, are considered

by some authorities to be essentially obsessive fears and may be included in this category of neurosis.

Compulsions are acts that result from obsessions. These are single acts or a series of acts (rituals) that the patient must carry out in order to put his mind at ease. Examples are repeated checking of the gas jets or the locks on doors, adjusting articles of clothing, repeated hand washing, using a clean handkerchief to wipe objects that have been touched by others, tasting foods in specific ways, touching or arranging objects in a particular sequence, etc. In general, the most common of these obsessions and compulsions center around contamination concerns that lead to repeated hand washing or bathing. Other obsessions and compulsions can be identified as clusters that derive from the above-mentioned concern about harm to oneself or to others and consequent checking on others, or praying or requesting constant reassurance that a harmful act will not be carried out. Less common clusters involve excessive focus on symmetry, precision, and ordering, and on saving and hoarding.

Certain motor disturbances—namely, habit spasms or tics—are, in a sense, *motor compulsions*. They consist of repetitive movements of the shoulders, arms, hands, and certain of the facial muscles (see Chap. 6). One feature that separates quasivoluntary tics from involuntary movements of extrapyramidal type is the patient's feeling that the tics must be carried out to relieve an inner tension. Unlike compulsions, however, tics are not usually based directly on obsessive thoughts—except perhaps the Gilles de la Tourette syndrome, in which multiple tics are combined with compulsive utterances, often offensive ones (see later).

In all these obsessions and compulsions and in the phobias, patients recognize the irrationality of their ideas and behavior yet are powerless to control them, much as they desire to do so. It is this insight into the obsessional experience and the struggle against it that distinguish obsessions from delusions.

These patients often suffer from typical anxiety attacks. After the condition has persisted for a time, they may become depressed. Fatigue, anorexia, and general lack of interest, which are often present, are probably related to the secondary effects of anxiety and depression.

Mechanisms of Obsessive Neuroses

For many years a number of psychoanalytic conceptualizations held sway of obsessional neurosis as the product of intrapsychic conflicts. Only relatively recently has a neurobiologic model been advanced. These are largely derived from the findings of functional imaging, which have been quite consistent. Positron emission tomography has demonstrated increased metabolic activity in the orbitofrontal cortex, cingulate, and, to a lesser extent, striatum of affected patients. The orbitofrontal cortex and amygdala were reported to be shrunken in other cases. However, in a study of 13 patients who developed elements of obsessiveness and compulsive disorder after incurring focal brain lesions, Berthier et al found lesions in diverse loci, including the cingulate, frontal, and temporal cortices as well as the basal ganglia. Two of the most accurately localized lesions in their series were a hamartoma of the right parahippocampal gyrus and an infarction in the posterior putamen. The presence of brain injuries and seizure disorders in other of their patients made a precise localization more problematic.

Additional insight into acquired obsessive-compulsive disorder may be obtained from the many cases in which striatal damage is linked to this type of behavior. One such entity is a poststreptococcal tic disorder termed *PANDAS* (pediatric autoimmune psy-

chiatric disorders associated with streptococcal infections, page 96). This disorder is presumably related to another extrapyramidal condition, Sydenham chorea, in which tics and similar movement disorders as well as obsessive behavioral abnormalities have long been known to coexist. Functional imaging studies in patients with PANDAS have yielded variable findings, but generally there has been increased activity in the caudate nucleus and orbitofrontal cortex in temporal association with the patient's compulsive thoughts. The neurochemical alterations in obsessive-compulsive disorder have been studied but most of the conclusions have been based on the responses to medications, notably to the serotonin reuptake inhibitors as noted further on. These agents are found to be of therapeutic benefit, as are stereotactic neurosurgical lesions in the cingulate gyri (see further on).

The *Gilles de la Tourette syndrome* of multiple tics, including vocal ones, beginning in childhood or adolescence and lasting more than a year, also bears a resemblance to obsessive-compulsive disorder. The two conditions often appear together; more than half of Tourette patients have obsessive-compulsive disorder. Both occur in a pattern of inheritance that is close to an autosomal dominant trait with incomplete percent penetrance (Kurlan). Because dopamine antagonists are beneficial in the management of the Tourette syndrome, a number of etiologic hypotheses revolve around serotonergic and dopaminergic neurotransmitter systems (Baxter; Behar et al). More extensive comments on the Tourette syndrome are to be found on page 95.

Treatment

Treatment is best left to the psychiatrist. At least there should be a trial of therapy using behavioral modification techniques. In the case of phobic neurosis, the aim of such treatment is to reduce the patient's fear to the extent that exposure to the phobic situation can be tolerated. A popular form of therapy is *systematic desensitization*, which consists of increasing and graded exposure of the patient to the object or situation that arouses the fear. Psychotherapy, if undertaken, need not be intensive, consisting instead of repeated explanation, reassurance, and guidance in dealing with symptoms. As with phobic neurosis, several reports have indicated that compulsive rituals can often be abolished by the techniques of behavior therapy. Much in vogue is cognitive-behavioral psychotherapy alluded to earlier and discussed in the next chapter (page 1315). This too is best left to the experienced psychiatrist.

Certain medications, particularly the SSRI types such as fluoxetine, are considered to be very effective forms of therapy—abolishing or greatly reducing obsessions and compulsions in more than half the patients. The less-selective agent, clomipramine, is also highly effective, as were more commonly used tricyclic antidepressants in the past, but clomipramine is not nearly as well tolerated as are the conventional SSRI drugs (see review by Stein).

Finally, it should be mentioned that cingulotomy has produced symptomatic improvement in both phobic and obsessional neuroses and was at one time considered a reasonable procedure. This measure, if it is to be used at all, should be considered only as a last resort in exceptionally severe cases in which the patient has failed to respond to all other methods of medical and behavioral treatment and is totally disabled. Perhaps the implantation of a reversible electrical stimulating electrode in this same region is a sensible area for future investigation. This and other surgical approaches to these illnesses has been reviewed by Greenberg and colleagues. They acknowledge that few adequate trials have been conducted

and it should be pointed out that most of the surgical series they discuss took place well before the modern era of psychopharmacology.

Hysteria (Briquet Disease; Somatization Disorder)

Although hysteria has been known since ancient times, many writers credit the first description of the syndrome (on somewhat uncertain grounds) to the French physician Briquet in 1859. Later, Charcot elaborated certain manifestations of the disease, particularly those with a theatrical aspect, and interested Freud and Janet in the problem. Charcot demonstrated that the symptoms could be produced and relieved by hypnosis (mesmerism). Janet postulated a *dissociative state* of mind to account for certain features such as trances and *fugue* states, a term which has reappeared in modern psychiatry. Freud and his students conceived of hysterical symptoms as a product of "ego defense mechanisms," in which psychic energy, generated by unconscious sexual conflicts, was converted into physical symptoms. This latter concept was widely accepted, to the point where the term *conversion* became incorporated into the nomenclature of the neuroses and the terms *conversion symptoms* and *conversion reaction* came to be equated with the disease hysteria. In the present authors' opinion, the term *conversion*, if it is used at all, should refer only to certain unexplained symptoms, such as amnesia, paralysis, blindness, and aphonia, that mimic neurologic disease. We see no merit in the dichotomy, based on unsubstantiated psychodynamic theory, of a conversion type as separate from a dissociative type of hysteria, as claimed by the DSM classification. Nemiah, who is in other respects partial to the psychoanalytic interpretation, agrees. Also in our view, the term *hysteria* is best reserved for a *disease* that is practically confined to women and is characterized by a distinctive age of onset, natural history, and certain somatic symptoms and signs, which typically include "conversion symptoms," dissociative reactions, or states of "multiple personality."

In clinical neurology one encounters two types of hysteria or neurologic signs with no possible explanation in disease of the nervous system: (1) a chronic illness marked by multiple and often dramatically presented symptoms and somatic abnormalities of "classic hysteria" for which no cause is evident, almost limited to girls and women, and (2) an illness predominantly of men but also of women, who develop physical symptoms or remain inexplicably disabled for the purpose of obtaining compensation, influencing litigation, avoiding military duty or imprisonment, etc. This latter state is called *compensation neurosis*, *compensation hysteria*, or *hysteria with sociopathy*, in other words, *malingering*.

Classic Hysteria

This is a neurosis of sorts, which accounts for 1 to 2 percent of admissions to a neurologic service and a greater number of outpatient visits. It usually has its onset in the teens or early twenties, almost exclusively in young women; a very few cases begin before puberty. Once established, the diagnosis remains unchanged over many years but the symptoms recur intermittently, though with reduced frequency, throughout the adult years even to an advanced age. No doubt there are cases of lesser severity in which symptoms occur only a few times or perhaps only once, just as there are mild forms of other diseases. The patient may be seen for the first time during middle life or later, and the earlier history may not at first

be forthcoming. Careful probing almost invariably reveals that the earliest manifestations of the illness had appeared before the age of about 25 years.

Other important data are also revealed by eliciting a careful past history. During late childhood and adolescence, the normal activities of the patient, including education, had often been interrupted by periods of ill-defined illness. In the past, rheumatic fever, and in the current era, some obscure disease may have been suspected. Later in life, problems in work adjustment and marriage are frequent. Notable in many cases is a high incidence of marital incompatibility, separation, and divorce. The patient's life history is punctuated by symptoms that do not conform to recognizable patterns of medical and surgical disease. For these ailments, many forms of therapy including surgical operations will have been performed. In the past, rarely had adult life been reached without at least one abdominal operation, which was usually done because of vague abdominal pain, persistent nausea and vomiting, or an obscure gynecologic complaint. Often the indications for the surgical procedures were unclear; moreover, the same symptoms or others often recurred to complicate the convalescence. The biographies of these patients are replete with disorders that center about menstrual, sexual, and procreative functions. Menstrual periods may be painfully prostrating, irregular, or excessive. Sexual intercourse may be painful or unpleasant. Pregnancies may be difficult; the common vomiting of the first trimester may persist all through the gestational period, with weight loss and prostration; labor may be unusually difficult and prolonged, and all manner of unpredictable complications are said to have occurred during and after parturition.

Hysteria is, then, a polysymptomatic disorder, involving almost every organ system. The most frequent symptoms that were reported by Purtell and colleagues during a study of 50 unmistakable cases of hysteria (as compared with a control group of 50 healthy women) included the following: headache, blurred vision, lump in the throat, loss of voice, dyspnea, palpitation, anxiety attacks, anorexia, nausea and vomiting, abdominal pain, unusual food allergies, severe menstrual pain, urinary retention, sexual indifference, painful intercourse, paresthesias, dizzy spells, nervousness, and easy crying.

The mental examination of the patient with hysteria demonstrates a number of characteristic findings. There is a lack of precision in relating the details of the illness. Questions regarding the chief complaint usually elicit a vague reply or the narration of a series of incidents or problems, many of which prove to have little or no relevance to the question. Memory defects (amnesic gaps) are usually demonstrated while the history is being taken; the patient appears to have forgotten important segments of the history, some of which she had clearly described in the past and are part of the medical record. The description of symptoms may be dramatic and exaggerated and not in accord with the facts as elicited from other members of the family. Often, a rather casual demeanor is manifest, the patient insisting that everything in her life is quite normal and controlled, when, in fact, her medical record is checkered with instances of dramatic behavior and unexplained illness. This calm attitude toward a turbulent illness and seemingly disabling physical signs is so common that it has been singled out as an important characteristic of hysteria, *la belle indifférence*. Other patients, however, are obviously tense and anxious and report frank anxiety attacks; or the patient may appear to be putting on an act, and demanding constant attention. Emotional reactions are superficial and scenes that are disturbing to others are quickly forgotten. Claims of early-life sexual abuse are common and often prove to

be imagined, but a valid history of such abuse is frequent enough in our experience to play a role in the genesis of some cases (see further on).

There are no pathognomonic findings. Although many have commented on the rather youthful, girlish appearance and coquettish ("seductive") manner of the patients, these by no means characterize all patients. The abdomen may be diffusely and exceedingly tender but without other signs of abdominal disease. The so-called stigmata of hysteria—i.e., corneal anesthesia; absence of gag reflex; spots of pain and tenderness over the scalp, sternum, breasts, lower ribs, and ovaries—are often suggested by the examiner and are too inconsistent to be of much help in the diagnosis. The variation and pleomorphism of the physical signs are limited only by the patient's ability to produce them by voluntary effort. Accordingly, symptoms and signs that are beyond volitional control should not be accepted as manifestations of hysteria. Sometimes the patient's physical signs are an imitation of those of another member of the family ("folie à deux") or are evoked by a stressful event in the patient's personal life. However, this may not be disclosed at the time of the first examination.

Special Neurologic Syndromes of Hysterical Origin

A few hysterical syndromes occur with regularity and every physician may expect to encounter them. Most are neurologic in nature. They constitute some of the most puzzling diagnostic problems in medicine.

Hysterical Pain This may involve any part of the body; generalized or localized headache, "atypical facial pain," vague abdominal pain, and chronic back pain with camptocormia are the most frequent and troublesome. In many of these patients the response to analgesic drugs has been unusual or excessive, and some of them are addicted. The hysterical patient may respond readily to a placebo as though it were a potent drug, but it should be pointed out that this is a notoriously unreliable means of distinguishing hysterical pain from that of other diseases. A greater error is to mistake the pain of osteomyelitis or visceral tumor—before other symptoms have developed—for a manifestation of hysteria. There are several helpful diagnostic features of hysterical pain: (1) the patient's inability to give a clear, concise description of the type of pain; (2) the location of the pain does not conform to the pattern of pain in the familiar medical syndromes; (3) the dramatic elaborations of its intensity (speaking in inflated metaphors—"like a giant knife stabbing") and its effects on the body ("tearing my limb off"); (4) its persistence, either continuous or intermittent, for long periods of time; (5) the assumption of bizarre attitudes and postures; and, most important; (6) the coexistence of other clinical features or previous attacks of hysterical nature.

Hysterical Vomiting This is often combined with pain and tenderness in the lower abdomen and results in unnecessary appendectomies and removal of pelvic organs in adolescent girls and young women. The vomiting often occurs after a meal, leaving the patient hungry and ready to eat again; it may be induced by unpleasant circumstances. Some of these patients can vomit at will, regurgitating food from the stomach like a ruminant animal. Vomiting may persist for weeks with no cause being found. Weight loss may occur, but seldom to the degree anticipated. As remarked earlier, the usual first-trimester vomiting of pregnancy may continue

throughout the entire 9 months, and occasionally pregnancy will be interrupted because of it. Anorexia may be a prominent associated symptom and must be differentiated from anorexia nervosa–bulimia, another closely related disease of young women (page 1304).

Hysterical Seizures, Trances, and Fugues These conditions seem to be less frequent than in the days of Charcot, when *la grande attaque d'hystérie* was often exhibited before medical audiences. Nevertheless, such attacks do occur and must be distinguished from cerebral cortical seizures and catalepsy. To witness an attack is of great assistance in diagnosis. The lack of an aura, initiating cry, hurtful fall, or incontinence; the presence of peculiar movements such as grimacing, squirming, thrashing and flailing of the limbs, side-to-side motions of the head, and striking at or resisting those who offer assistance; the retention of consciousness during a motor seizure that involves both sides of the body; the long duration of the seizure, its abrupt termination by strong sensory stimulation, lack of postictal confusion, and failure to produce a rise in creatine kinase—are all typical of the hysterical attack. Sometimes hyperventilation will initiate an attack and is therefore a useful diagnostic maneuver. Both epilepsy, particularly of frontal-lobe type, and hysteria may occur in the same patient, a combination that invariably causes difficulty in diagnosis.

Hysterical trances or fugues, in which the patient wanders about for hours or days and carries out complex acts, may simulate temporal lobe epilepsy or any of the conditions that lead to confusional psychosis or stupor. Here the most reliable point of differentiation comes from observation of the patient, who, if hysterical, is likely to indicate a degree of alertness and promptness of response not seen in temporal lobe seizures or confusional states. Following the episode, an interview with the patient—under the influence of hypnosis, strong suggestion, or midazolam or amobarbital—will often reveal memories of what happened during the episode. This helps to exclude the possibility of an epileptic spell.

Hysterical Paralyses, Gait, Sensory Loss, and Tremors Hysterical pareses may involve an arm, a leg, one side of the body, or both legs. If the affected limb can be moved at all, muscle action is weak and tremulous. Movements are slow, tentative, and poorly sustained; often it can be demonstrated that the strength of voluntary movement is proportional to the resistance offered by the examiner, thus imparting a "give-way" character (page 52). One can detect by palpation that agonist and antagonist muscles are contracting simultaneously holding the limb in place rather than opposing the examiner, and when the resistance is suddenly withdrawn, there is no follow-through or rebound, as is normally the case. Other indicators have been devised to demonstrate inconsistencies with normal physiologic principles and a purposive lack of cooperation. These are elaborated in articles by Stone, Zeman, and Sharpe. The discrepancies are usually found by testing an agonist, antagonist, or fixator movement while the patient is focused on making an effort with another group of muscles (e.g., the Hoover sign, see page 52). Muscular tone in the affected limbs is usually normal, but slight resistance may sometimes be found. A seeming lack of effort and the absence of full compliance with the examiner's requests during the testing of muscle strength, while common in hysterical patients, is not confined to them; one encounters such findings not infrequently during the examination of suggestible but nonhysterical patients who harbor a neurologic disease.

Walking and standing may be impossible (astasia-abasia) or

the gait may be bizarre with collapsing legs that bring the patient to a squat, or there is a “skating” gait in which one foot is pushed ahead of the body, and other forms that are easily recognized as inconsistent with the makings of the nervous system in disease (page 107). Weakness and poor balance are combined elements in both the quadriparetic and hemiparetic forms. In Keane’s informative series of 60 cases of hysterical gait, the hemiparetic and monocular forms were twice as frequent as the quadriparetic. The gait disorder is sometimes difficult to describe because of its variability. Sudden falls without voluntary protective movements and inconsistencies of balance are helpful features. Other features are discussed in Chap. 7 on gait disorders. Difficulty in walking and moving the legs while seated is, of course, not unique to hysteria; it also occurs in so-called frontal lobe gait apraxia and in ataxia from midline cerebellar lesions and in hydrocephalus. In the most remarkable and recalcitrant cases, maintenance of the limbs in a rigid or dystonic posture for a long time may result in a bed-bound, crippled state with severe flexion pseudocontractures of the limbs. We have seen one such case of 18 years duration. The tendon reflexes are usually normal if they can be tested, but with hysterical rigidity and contractures, the abdominal and plantar reflexes may be suppressed.

Anesthesia or hypesthesia is almost always inadvertently suggested by the physician’s examination. Seldom is sensory loss a spontaneous complaint, although “numbness” and paresthesias are not uncommon in hysterics. The sensory loss may involve one or more limbs below a sharp line (stocking and glove distribution), or may involve precisely one half of the body, or vibratory sense may be lost over precisely one half of the skull (a test favored to demonstrate hysterical hemianesthesia). Touch, pain, taste, smell, vision, and hearing may all be affected on that side, which is an anatomic impossibility from a single lesion. Other aspects are discussed in Chap. 9.

The sometimes-stated notion that hysterical paralysis and sensory deficits are more common on the left side is probably untrue according to Stone and colleagues.

The features of hysterical tremor have been described on page 84. To be emphasized are the cessation of tremor with distracting tasks—e.g., complex finger movement patterns on the side opposite the tremor (such as touching the fourth, second, and fifth fingers in sequence rapidly), or refixation of the eyes on a target, or walking on the outside of the heels. The ability of the examiner to “chase” the tremor to proximal or distal parts of the limb by holding and immobilizing other parts is highly characteristic. Also a fairly dependable sign is worsening of a tremor with loading, that is accomplished by placing a heavy object in the patient’s hand (most basal ganglionic and cerebellar tremors are muted by this maneuver).

Hysterical Blindness (See page 219) This dramatic event may affect one eye or both and may be coupled with hemiparesis or appear in isolation. The symptoms usually develop suddenly, often after an altercation or other emotionally charged event. The patient stares straight ahead blandly when undisturbed but may squint or move the head as if straining to see when asked to view an object. Some such individuals can reduce reflexive blinking in response to a visual threat. The psychic nature of the problem may be recognized by a nurse who observes the patient reaching for a cup or for the phone. The preservation of vision is confirmed by the presence of normal pupillary reflexes and of optokinetic nystagmus, although one occasionally encounters a patient who has learned to suppress the latter response as well. A mirror passed slowly in the

patient’s central vision often engages eye movements. Other similar maneuvers are favored by different examiners. The presence of visual evoked responses also confirms the intactness of retino-occipital connections. The patient expresses little concern about her condition, which is usually short-lived. Cortical blindness and variants of the Balint syndrome (pages 404 and 406) from bioccipital infarcts are the main diagnostic considerations.

Convergence spasm, occurring as an isolated phenomenon, is practically always of hysterical nature (page 226).

A related phenomenon involves the *self-administration of mydriatic eyedrops* by health care personnel. The patient arrives on the emergency ward complaining of reduced vision (expected) or with headache and claiming to have an intracranial mass. This behavior is perhaps more sociopathic (or malingering) than hysterical.

Hysterical Amnesia Patients brought to a hospital in a state of amnesia, not knowing their own identity, are usually hysterical females, or sociopathic males involved in a crime. Usually, after a few hours or days, with encouragement, they divulge their life history. Epileptic patients or victims of a concussion, transient global amnesia, or acute confusional psychosis do not come to a hospital asking for help in establishing their identity. Moreover, the complete loss of memory for all previous life experiences by patients who are otherwise able to comport themselves normally is not observed in any other condition.

In the *Ganser syndrome* (amnesia, disturbance of consciousness, and hallucinations) patients pretend to have lost their memory or to have become insane. They may act in an absurd manner, simulating the way they believe that an insane or demented person would act, and give senseless or only approximate answers to every question asked of them (calling the color red, *blue* or answering *five* for two plus two).

Hysteria in Men (Compensation Neurosis in Men and Women)

As stated earlier, symptoms of the same nature as those in hysteria do occur in men, most often in those trying to avoid legal difficulties or military service or attempting to obtain disability or pension payments, or, compensation following injury. Sociopaths may also present with this type of illness. Unless such a motivating factor can be identified, the diagnosis of hysteria in the male should be made with caution. In compensation neurosis, as in the classic form of hysteria, multiple symptoms are reported; many of the symptoms are the same as those listed under female hysteria. Or the patient may be monosymptomatic (e.g., “seizures”) and the symptoms, particularly chronic pain, may be confined to the neck, head, arm, or low back. The description of symptoms tends to be lengthy and circumstantial, and the patient fails to give details that are necessary for diagnosis. A tangible gain from the illness may be discovered by simple questioning. This is usually in the form of monetary compensation, which, surprisingly, is sometimes less than that which the patient could earn if he returned to work. Most such patients are actively engaged in litigation when first seen. Another interesting feature is the frequency with which the patient expresses extreme dissatisfaction with the medical care given him; he is often hostile toward the physicians and nurses. Many of these patients have already been subjected to an excessive number of hospitalizations, and rather dramatic mishaps have allegedly occurred in carrying out diagnostic and therapeutic procedures. The majority have been previously suspected of malingering.

Women who suffer injury at work or are involved in auto accidents may exhibit the same symptoms and signs of compensation neurosis as men but in our experience, do so infrequently.

Etiology and Pathogenesis Psychoanalytic theory, which holds that both conversion and dissociative symptoms are based on particular psychodynamic mechanisms, is impossible to affirm or refute. While subject to some question of fabricated recall, we have been impressed at the high rate of childhood sexual abuse reported by women with severe monosymptomatic cases of hysteria or fugue states. This conforms to some extent with psychoanalytic views but may not apply in classic hysteria. Sociologic and educational factors are probably important, for it has been observed that hysterical women as a group tend to be less intelligent and less educated than nonhysterical women. A genetic causation must also be considered. Family studies have disclosed that about 20 percent of first-degree relatives of female hysterics have the same illness, an incidence 10 times that in the general population. This supports the idea that hysteria is a disease and not merely a surfacing of a basic personality disorder (see Goodwin and Guze).

Whether conversion symptoms are consciously produced by the patient or arise unconsciously, without the patient's awareness, is a question that has been debated endlessly without resolution. Babinski attributed the symptoms to *hypersuggestibility*. In fact, he defined hysteria as an illness whose symptoms could be induced (and removed) by suggestion. There is strong evidence to support this idea, since most patients can be readily hypnotized and their symptoms temporarily eliminated by this procedure, or by an interview and examination under the influence of midazolam. The present authors place great weight on the importance of hypersuggestibility, in keeping with older studies that emphasized these patients' unusual susceptibility to suggestion and hypnosis. Interesting in this regard were the observations of Charcot's students, that on their wards the patients' symptoms disappeared in his absence.

Some insights can be obtained from studies of functional imaging in hysterical paralysis (see also Chap. 3). In general, the contralateral prefrontal cortex is suppressed when the patient with hysteria attempts to move a limb, suggesting to Spence and colleagues a "choice" of an active attempt not to move the limb. However, the pattern of activation was quite different from volunteers who purposefully feigned paralysis and who did not demonstrate such reduced prefrontal activity.

As pointed out by Carothers and by Guze and colleagues, hysteria and sociopathy are closely related. Hysteria is a disease of women and sociopathy mainly of men. As restated by Cloninger and colleagues, they may constitute expressions of a single underlying variable. This relationship is also supported by family studies. First-degree male relatives of hysterical women have an increased incidence of sociopathy and alcoholism; among first-degree female relatives of convicted male felons, there is an increased prevalence of hysteria. Moreover, careful histories of sociopathic girls reveal that many of them develop the full syndrome of hysteria. Women felons often present a mixed picture of hysteria and sociopathy, according to Cloninger and Guze.

Diagnosis The characteristic age of onset; the longitudinal history of recurrent multiple complaints, as outlined earlier; the attitude of the patient and the manner of presenting her symptoms; the incongruity of affect and clinical state; the discrepancy between the neurologic deficit and the signs on examination; the impossibility

of explaining the patient's signs on an anatomic or physiologic basis; and the absence of symptoms and signs of other medical and surgical disease will permit an accurate diagnosis in the majority of cases. Certain tests designed to reveal normal functioning of a limb, of vision, and of gait have been mentioned.

There is a significant overlap of hysteria and other medical and neurologic diseases. On record are numerous studies in which patients with an initial diagnosis of hysteria by general physicians were followed for many years. Up to one third of them (less in most series) turned out eventually to have an "organic condition" which, in retrospect, explained the initial symptoms (Couplie et al). This emphasizes that the original clinical diagnosis of hysteria is often erroneous. When the diagnostic criteria in these cases are closely analyzed, it becomes apparent that the diagnosis was made solely by the "discrepancy method"—i.e., the patient's symptoms or signs were not deemed to be credible manifestations of disease, based mainly on the clinical experience of the examiner. Of course, this assumes that the examiner has a wide experience; unfortunately for the novice, many syndromes are unknown or incomprehensible.

However, when diagnosis is based on the totality of the clinical picture and not on the "discrepancy method," it can be quite accurate. The physician can be further reassured that in follow-up studies of patients with so-called conversion disorder (exclusive of pseudoseizures), virtually none develop a neurologic lesion that in retrospect was related to the initial episode as for example in the study by Stone and colleagues. It is of interest that in the series cited, most patients had persistent functional disability from their conversion symptoms, even a decade later.

So-called projective tests (the Rorschach and Thematic Apperception Tests), which for a time were popular with dynamic psychiatrists, are not helpful in diagnosis and are now used very little. The presence of extreme suggestibility and the tendency to dramatize symptoms as measured by one part of the Minnesota Multiphasic Personality Inventory and other psychometric tests is helpful in diagnosis but not pathognomonic of the disease; these traits appear under certain conditions in individuals who never develop hysteria.

Finally it should be reemphasized that single bouts of isolated hysterical paresis, blindness, and anesthesia are quite common in neurologic practice and do not presage a chronic hysterical illness. The same is true for transient neurologic signs exhibited during the course of the examination, mainly pertaining to unusual or drifting sensory loss or asthenic weakness of a limb.

Treatment of Hysteria

This may be considered from two aspects: the correction of the long-standing basic personality defect and relieving the recently acquired physical symptoms. Little or nothing can be done about the former. Psychoanalysts have attempted to modify it by long-term reeducation, but their results are uninterpretable, and there are no control studies for the few reports of therapeutic success. Many psychiatrists are inclined to regard the female with hysteria who has a lifelong history of ill health as having a severe personality disorder—i.e., sociopathy. In other, less severe cases and especially in those in whom hysterical symptoms have appeared under the pressure of a major crisis, explanatory and supportive psychotherapy appears to be helpful, and the patients have been able thereafter to resume their places in society.

The acute symptoms can usually be mitigated by persuasion

and demonstration. One tactic is to treat the patient as though she has had an illness and is now in the process of recovering. The earlier this is done after the development of symptoms, the more likely they are to be relieved. Sometimes a single symptom such as hemiparesis or tremor can be halted by a particular maneuver and this demonstration suffices to begin recovery. In chronically bedridden patients, strong pressure to get out of bed and resume function must be applied. Compensation and litigation neuroses are quite difficult to treat, and settlement of the patient's claim ("the green poultice") is usually necessary before the symptoms subside.

Several approaches to discussing the symptomatology with the patient have been suggested. At one extreme is a confrontative approach in which the patient is told the symptoms are psychologic, or "in your head." We have found this to be counterproductive and almost always to provoke an angry response that does not aid clinical improvement. On the other extreme is complete avoidance on the part of the physician, an approach that is almost as unproductive. We prefer to ask the patient if the symptoms can in some way be the result of "stress" or an upsetting recent experience. On occasion, in private we will inquire about childhood sexual abuse and often get an affirmative response from the patient, with later confirmation by a spouse or sibling. Next comes nonjudgmental but firm reassurance that there is no serious disease. We have found it very useful to list the diseases that have been excluded by examination and testing: brain tumor, stroke, amyotrophic lateral sclerosis, multiple sclerosis, etc. This often evokes an acknowledgment by the patient that one of the diseases had been a preoccupying concern. We then indicate, without using psychologic terms, that the brain may at times adopt certain patterns of behavior that do not reflect structural damage, and furthermore, these patterns can be unlearned with physical therapy and time as described below.

That the patient's response to these conversations varies widely is not surprising. One group seems not to mind and to be relieved by the expression of concern and reassurance that there is no dangerous disease at the root of the problem. They can be sent to a physical therapist and may do well in the short run. Another group is indignant and not likely to consult the physician again; several have refused to pay the doctor's bill. Some have objected to the explanation based on their own view, often derived from research on the internet and with similarly afflicted persons, that Lyme disease, chronic viral infection, environmental toxins, allergies, etc., are to blame. A few of these cases have the flavor of a delusion. All that the physician can offer here is an openness to see and reexamine the patient in several months; "cure" has no meaning in these instances and there is a great likelihood that such individuals will see a long line of doctors.

Persuasion and suggestion, both direct and indirect, should be employed as already noted. Illustratively, the patient should be repeatedly encouraged, told that she is improving, urged to resume work or other duties, and continue participation in routine activities. Medication should be withheld. Some of our best results have been obtained by indicating that the neurologic symptoms are a "constitutional" weakness that can be overcome by physical and other therapies. Once the current neurologic disorder has disappeared, it may be helpful to counsel the patient in ways to prevent its recurrence. Family members should be given the same explanation. A regimen of physical therapy should be instituted, utilizing an experienced therapist and setting simple goals for success. Every subsequent illness in such patients should be evaluated objectively,

so as not to overlook any medical or surgical disease, which may strike a hysterical patient just as it does any other person.

The success of this program over a long period is not known. The eradication of some recently acquired hysterical symptom is relatively easy. The real test is whether it enables the patient to adjust satisfactorily to family and society and to perform daily activities effectively, and whether it prevents addiction, unnecessary medical treatments, and operations. Estimates of the recurrence rate of hysterical symptoms vary widely from 12 to 80 percent. In the series reported by Gatfield and Guze and by Merskey, the recurrence of somatic symptoms of similar or of other types was as high as in sociopathies. We have seen a few patients with monosymptomatic hysteria (paraparesis, bizarre gait, crippling dystonia) that persisted for years on end regardless of treatment. The long-term poor prognosis for well-established symptoms in several series has been alluded to earlier. The use of a wheelchair for more than several days has been a bad prognostic sign in these cases.

Hypochondriasis

Hypochondriasis is the morbid preoccupation with bodily functions or physical signs and sensations, leading to the fear or belief of having serious disease. Hallmarks of this condition are the failure of repeated examinations to disclose any physical basis for the patient's symptoms and the failure of reassurance to affect either the patient's symptoms or his conviction of being sick. It is estimated that 85 percent of hypochondriasis is secondary to other mental disorders, chiefly depression, but also schizophrenia and the neuroses. In about 15 percent of cases, however, there appears to be no associated illness (*primary hypochondriasis*). Most patients in this latter category are habitués of medical outpatient clinics, who are passed from specialist to specialist, perplexing and angering doctors along the way, because their symptoms defy both satisfactory diagnosis and cure. Often referred to by house officers as "crocks," these patients seldom benefit from conventional therapy.

Related to hypochondriasis, but probably more delusional are young adults who present with a fixed somatic belief regarding a peculiar symptom such as that the tongue is swollen, the jaw is not properly aligned, or the penis is ulcerated, when in fact no such abnormalities are present. The malignant aspect of such an illness is the persistence of the symptom and disability that extends for years, all tests having been negative. Probably these patients should be treated like schizophrenic patients, which many of them probably are. What to do with patients who are less severely affected but have an unshakable belief that they have Lyme disease or environmental "allergies" depends on the context but the outcome can be almost as bad as for the worst hypochondriac patients.

The treatment of primary hypochondriasis is difficult if not impossible unless the physician keeps in mind the personality of the patient and the therapeutic goals. A psychodynamic outlook would suggest that for a variety of reasons, these patients need to retain their symptoms, so that the usual concept of "curing" is inapplicable. The presence of symptoms provides the context for a relationship with a physician. It is the continuation of this relationship, which is often the only dependable human contact in the patient's life, and is the motivation for some hypochondriac patients. Such patients are best managed by general physicians who realize that these are patients who do not necessarily want or expect a cure, and who are content with small gains and the avoidance of unnecessary surgery.

THE SOCIOPATHIES

Antisocial Personality (Sociopathy)

Of all the abnormal personality types listed in Table 56-1, the antisocial is the best defined and the one most likely to cause trouble in the family and community. It has been defined (in DSM-III) as a state in which the individual “*is always in trouble, profiting not from experience or punishment, unable to empathize with family or friends or to maintain loyalties to any person, group, or code. He is likely to be shallow, callous, and hedonistic, showing marked emotional immaturity with lack of sense of responsibility, lack of judgment, and an ability to rationalize his behavior so that it appears warranted, reasonable and justified.*”

Since Prichard, in 1835, first described this condition under the term *immoral insanity*, there have been many attempts to give it a more precise definition and to avoid using it as a psychiatric wastebasket. At the turn of the century, Koch introduced the term *psychopathic inferiority*, implying that it was a constitutionally determined deviation in personality. Later the term *psychopathic personality* came into common use. Some authors used this last term indiscriminately to embrace all forms of deviant personality. Subsequently the term came to be used in a more restricted sense to define a subgroup of antisocial or aggressive psychopaths (*antisocial personality disorder*, DSM-IV). Aubrey Lewis has given a lucid account of the history of the concept of sociopathy. By far

the best modern study of sociopathy is that of L. N. Robins, based on a 30-year follow-up study of 524 cases from a child guidance clinic and 100 controls. Other investigations of note are those of Cleckley, of McCord and McCord, and of Guze and coworkers, who studied psychiatric illness in large numbers of felons and their first-degree relatives. The descriptions that follow and the preceding quotation are taken largely from these writings and from those of Reid.

Clinical Description This condition, unlike the majority of psychiatric disorders, is manifest by the age of 12 to 15 years and frequently earlier. The manifestations of sociopathic behavior in children and adults are five to ten times more frequent in males than they are in females. It consists essentially of deviant behavior in which individuals seem driven to make trouble in everything they do. Codes imposed by family, school, religion, and society are broken. Seemingly, the sociopath acts on impulse, but after committing the unsocial act, he shows no remorse. The most frequent antisocial activities are theft, truancy, running away, associating with undesirable characters, indiscriminate sexual relations, repeated fighting, recklessness and impulsivity, lying without cause, vandalism, abuse of drugs and alcohol, and, later, inability to work steadily or keep a job. Fire setting and cruelty to animals have been added as common early features by several authors. In the study by Robins, of children or adolescents who exhibited 10

Table 56-1
Personality disorders

TYPE ^a	CHARACTERISTICS
Paranoid (16)	Chronic wariness, suspiciousness, litigiousness, hypersensitivity, jealousy, envy; lack of insight or humor, tendency to blame others; sense of self-importance and entitlement
Cyclothymic (3)	Recurring periods of depression (low energy, pessimism, hopelessness, despair) and elation (high energy, ambition, enthusiasm, optimism) not readily explained by circumstances
Schizoid (30)	Isolation, seclusiveness, secretiveness, discomfort in relationships; often eccentric and lacking in energy; few friends; detachment; inability to express ideas and feelings, especially anger
Explosive (4)	Outbursts of rage and aggression not in keeping with usual personality, often in response to minor provocation; sense of loss of control followed by regret
Obsessive-compulsive (anankastic) (21)	Chronic worries about standards; excessive concern about self-image; tension in relationships, leading to isolation; inability to relax and excessive inhibitions; overly meticulous, conscientious, and perfectionist; predisposition to depression and obsessive-compulsive neurosis
Hysterical (103)	Immaturity, histrionic behavior, excitability, emotional instability, sexualization of relationships, low frustration tolerance, and shallow interpersonal ties; dependency
Asthenic (1)	Chronic weakness, easy fatigability, sense of vulnerability, oversensitive to physically and emotionally taxing situations, little ambition or aggression; low energy level; anhedonia
Passive-aggressive (78)	Obstructive behavior, stubbornness, intentional errors or omissions; intolerance of authority with struggles over control often creating difficulties in medical settings; externalization of conflicts and blaming others for untoward events
Inadequate (17)	Chronic inability to meet ordinary life demands in the absence of mental retardation; severe dependency on others; tendency to become institutionalized or to become dependent on institutions
Antisocial (32)	Unsocialized or antisocial behavior in conflict with society; selfishness, callousness, impulsiveness, lack of loyalty, and little guilt; low frustration tolerance; tendency to blame others, long history of interpersonal and social difficulties and arrests
Passive-dependent (30)	Lack of self-confidence, indecisiveness, tendency to cling to and seek support from others
Immature (12)	Ineffectual responses to social, psychologic, and physical demands; lack of stamina; poor adaptation to ordinary situations; a “loser”
Unspecified (14)	

^a Figures in parentheses represent the number of diagnoses of each personality disorder out of a total of 361 patients with the diagnosis of personality disorder at the Psychiatric Service of the University of Iowa (Winokur and Crowe).

or more antisocial symptoms, 43 percent were categorized as sociopaths in adulthood. If only 8 or 9 of these traits were present, 29 percent were so grouped; if 6 or 7, 25 percent; and 3 to 5, only 15 percent. Conversely, not a single adult sociopath was observed who did not manifest antisocial symptoms in earlier life. Interestingly, a number of other problems of childhood and adolescence—such as enuresis, dirty appearance, sleepwalking, irritability, nail biting, oversensitivity, poor eating habits, nervousness, being withdrawn or seclusive, unhappiness, tics, and fears—were not predictive of adult sociopathy. None of Robins' patients was mentally retarded.

It should at the same time be noted that more than half the deviant children in Robins' study (even those with 10 or more antisocial manifestations) had lost most of their sociopathic traits by adulthood. This does not mean that they remained psychiatrically normal. Of those who did not become adult sociopaths, the large majority developed other adult psychiatric illnesses, particularly addiction to alcohol. Only in the group of children with less than three antisocial symptoms did a reasonable number (one third) remain entirely well from a psychiatric point of view in adult life. Because sociopathic behavior in children may terminate spontaneously or evolve into other disorders, it is advised (in DSM-IV) that the diagnosis of antisocial personality disorder be reserved for adults; the same behavior pattern in children is designated as *conduct disorder*.

Also of interest are Robins' findings that sociopaths showed an unusually high incidence of "conversion" symptoms (we would substitute "malingering," see further on), as well as depressive symptoms and anxiety, and that the neurotic symptoms are in proportion to the sociopathic ones—i.e., the larger the number of antisocial manifestations, the larger the number of neurotic symptoms or the greater the disability from them. Among women with sociopathic behavior there was a high incidence of hysterical manifestations—evidence that female hysteria may be the counterpart of male sociopathy. In Robins' series, a search for evidence of encephalitis, often postulated in the past as the basis of sociopathy, was not revealing, or was there any proof of other brain damage.

Electroencephalographic (EEG) abnormalities, taking the form of mild to moderate bilateral slowing, are more frequent in criminals and sociopaths than they are in the normal population but the meaning of this finding is unclear. Furthermore, the biologic parents of sociopaths also show a higher frequency of such EEG abnormalities than the general population. These and other findings suggest a genetic predisposition to antisocial personality. In a Danish study of criminals by Christiansen, "inappropriate nonpsychotic impulse-ridden behavior" was found five times more frequently in first-degree biologic relatives than it was in the general population. Criminality was two times more frequent in monozygotic twins than it was in dizygotic twins. His study confirmed an association between hysteria and sociopathy. More direct evidence of a genetic factor has been provided by Cadoret's studies of adoptees who were separated at birth from antisocial biologic parents. A higher incidence of antisocial behavior was present in the adoptees than were in controls. This study also suggested that excessive childhood hyperactivity and classic female hysteria were phenotypic manifestations of an antisocial personality genotype.

There is no information as to the best methods of treatment and the role of the medical profession has never been clear. Most psychiatrists have been discouraged by the results of psychotherapy, but whether behavioral therapy, psychoanalysis, or drugs have more to offer cannot be determined from available data. Medical

efforts should be directed to evaluating the patient's neurologic status, assessing his intelligence, and explaining the nature of the disorder to parents and social agencies, tasks best performed by a psychiatrist.

Malingering

This problem arises frequently in connection with both hysteria and sociopathy and the physician should know how to deal with it. It is not a medical diagnosis except under the rare circumstances in which a patient is caught in the act of producing a sign of disease or confesses to having done so. The term *malingering* refers to the *conscious and deliberate feigning of illness or disability in order to attain a desired goal*. It does not appear as an isolated phenomenon, and its occurrence must be interpreted as a sign of a serious personality disturbance, often one that prevents effective work or military service, as a means of obtaining recompense for an alleged injury, although noteworthy exceptions to this statement can be found.

In the malingerer one may observe pain, hyperesthesia, anesthesia, limping gait, tremor, contracture, paralysis, amaurosis, deafness, stuttering, mutism, amnesia, pseudoconvulsions and fugues, unexplained gastrointestinal bleeding, and unexplained skin lesions—in short, the same array of symptoms and signs, singly or in combination, as in the patients with compensation hysteria.

Certainly there is a similarity between hysteria and malingering, but the nature of the relationship is nebulous, and there may be great difficulty in establishing a clinical differentiation. As Jones and Llewellyn have observed:

Nothing . . . resembles malingering more than hysteria; nothing, hysteria more than malingering. In both alike we are confronted with the same discrepancy between fact and statement, objective sign and subjective symptom—the outward aspect of health seemingly giving the lie to all the alleged functional disabilities. We may examine the hysterical person and the malingerer, using the same tests, and get precisely the same results in one case as the other.

Most authors cite the following as the main points of difference between the two conditions: (1) The conscious or unconscious quality of the motivation, which seems more unconscious in the hysteria patient and more conscious in the malingerer. (2) The influence of persuasion, which is usually effective in hysteria and not in the malingerer. (3) The attitude of the patient. The hysteria patient appears more genuinely ill and invites examination; the malingerer seems less ill and evades examination. The tendency of the sociopath to malinger has already been mentioned. Most of the more obvious cases of malingering seen by the present authors have been in sociopaths, for which reason discussions of the two conditions have been juxtaposed.

A particular form of sociopathy or malingering, which consists essentially of systematically and specifically deceiving the medical profession, has been described as *Munchausen's syndrome*—named (not altogether aptly) after a seventeenth-century German soldier, Baron von Munchausen, who invented incredible tales of adventure and daring. Ireland and colleagues, who analyzed 59 well-documented cases (45 men, 14 women), list the following characteristic features, which will be recognized at once by all neurologists with extensive hospital experience: feigned severe illness of a dramatic and emergency nature; factitious evidence of disease, surreptitious interference with diagnostic procedures, or self-mu-

titation; a history of many hospitalizations (sometimes more than a hundred); extensive travel or visits to innumerable physicians; evidence of laparotomy scars and cranial burr holes; pathologic lying; aggressive, unruly, evasive behavior; and, finally, regular departure from the hospital against medical advice. Unlike the usual forms of compensation hysteria, an ulterior motive is not readily discernible. The psychopathology of this syndrome is obscure. It has been regarded by various experts as a form of sociopathy, malingering, and compensation hysteria, but the distinctions between them are too ambiguous to be of clinical value. Probably the medical profession has placed too great a reliance on degree of conscious awareness of deception. In such unstable and immature individuals, the terms *conscious*, *unconscious*, and *deception* are too subjective to be useful in practical work.

Intermittent Explosive Disorder

Designated by this title is an uncommon disorder, the characteristic feature of which is the occurrence of repetitive, unpredictable outbursts of violent, aggressive behavior out of all proportion to the provoking situation. This condition needs to be set apart from the uncontrollable outbursts of violent behavior that sometimes are associated with mental retardation, schizophrenia, drug addiction, or alcoholism, or those that follow serious head injuries or other brain diseases. Neurologic opinions have been solicited on our services by patients afflicted with this condition, the question often being on seizures as a cause. Some persons with intermittent explosive disorder have, from early childhood, reacted to frustration with a loss of self-control, striking out in blind rage at anyone who crossed them (*episodic dyscontrol syndrome*); as adults, they may inflict serious injury or kill. Lesser degrees are recognized as expressions of "hot temper." Sometimes such behavior appears to be a continuation of the temper tantrums of earlier childhood.

The causes of aggressive violence are poorly understood. There appears to be a heritable tendency (Cadoret et al); males predominate and a sex-linked form extending over several generations has been described. In only a very small number of patients, a seizure disorder can be identified, particularly temporal lobe epilepsy. Examples have been demonstrated in patients with temporal lobe tumors and encephalitis, raising the possibility that more cases have a pathologic basis but the majority still appear to be constitutional in nature. Adrenergic hyperactivity has been suggested and supported to some extent by these patients' response to propranolol (see Chap. 25 in the discussion on the limbic system). Most instances probably represent a variant of sociopathy. In DSM-IV, intense outbursts of anger and physical violence are also important features of a diagnostic category called *borderline personality disorder*, the other manifestations of which include "a pervasive pattern of instability of mood, interpersonal relationships, and self-image." Elliott, and Jenkins and Maruta report a beneficial effect of propranolol. Others find lithium, carbamazepine, and phenytoin to be helpful in controlling and preventing the explosive attacks. We have noted the recent increased use by psychiatrists of serotonergic antidepressants in these patients but have no way to judge their effect.

ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa is a behavioral disorder of previously healthy girls and young women living in affluent societies, mainly from

upper and middle social classes, who become emaciated as a result of voluntary starvation. It is rare in Asian and African-American women and very uncommon in males. Herzog reminds us that it was Richard Morton who first described the condition in 1649, under the title of "nervous phthisis," a "nervous consumption" resulting from "sadness and anxious cares"—a title that embodied enigmatic roots in psychologic derangements. Bulimia (literally ox-hunger), to which it is closely related, was not identified as an eating disorder until the latter part of the nineteenth century.

As a rule, anorexia nervosa begins shortly after puberty—sometimes later, but seldom after 30 years of age. Some of the patients have been overweight in childhood, especially in the pre-pubertal period. Dieting is much talked about and may have been encouraged, especially by mothers who want their daughters to become more attractive. In epochs such as the current one, where dieting and female thinness are popular, the illness seems to be more common and lesser forms of the disorder are rampant in high-school- and college-age young women. Sometimes there appears to be a precipitating event, such as leaving home, a disruption of family life, or other stress. Whatever the provocation, it leads to an obsessive refusal to eat. What is more important, the abnormal eating habits persist even when the patient has become painfully thin, and when counseled to eat normally, she will use every artifice to starve herself. Food is hidden instead of being eaten, vomiting may be provoked after a meal, or the bowel may be emptied by laxatives. No amount of persuasion will induce the patient to take adequate amounts of food. The patient shows no concern about her obvious emaciation and remains active. If left alone, these patients waste away, and about 5 percent have succumbed to some intercurrent infection or other medical complication, placing it among the most lethal of psychiatric conditions.

On physical examination, one is struck with the degree of emaciation; it exceeds that of most of the known wasting diseases. Often 30 percent or more of the body weight will have been lost by the time the patient's family insists on medical consultation. A fine lanugo covers the face, body, and limbs. The skin is thin and dry, without its normal elasticity, and the nails are brittle. The dental enamel is eroded. Pubic hair and breast tissue (except for loss of fat) are normal, and in this respect anorexia nervosa is unlike hypopituitary cachexia (Simmonds disease). There are no neurologic signs of nutritional deficiency. The patient is alert and cheerfully indifferent to her condition. Any suggestion that she is unattractively thin or seriously depleted is rejected.

Amenorrhea is practically always present and may precede the extreme weight loss. Luteinizing hormone (LH) concentrations are reduced to pubertal or prepubertal levels. Clomiphene citrate fails to stimulate a rise in LH, as it does normally. Administration of gonadotropin-releasing factor raises the LH and FSH levels, suggesting a hypothalamic disorder. The basal metabolic rate is low; T₃ and T₄ are low, while levels of physiologically inactive 3,3,5-triiodothyronine (reverse T₃) are normal or increased. Plasma thyrotropin (TSH) and growth hormone levels are normal. Serum cortisol levels are usually normal; excretion of 17-hydroxysteroids is slightly reduced. In sum, there is evidence of hypothalamic-pituitary dysfunction; probably this is not primary but is secondary to starvation as indicated by the study of Scheithauer and colleagues who found no definite changes in the pituitary gland in 12 fatal cases. These abnormalities, most of which are probably secondary effects of weight loss, are summarized in the review by Becker and colleagues. Computed tomography scanning shows slight to mod-

erate enlargement of the lateral and third ventricles, which return to normal size when the illness subsides.

The etiology of anorexia nervosa is unknown, although there is no lack of hypotheses. Holland and coworkers reported a strikingly high concordance in monozygotic twins as compared with dizygotic twins, indicating that constitutional factors are important. Earlier signs of hysterical tendencies, obsessional personality traits, and depression are mentioned as being frequent in some series but not in others. Certain polymorphisms in the serotonin transporter gene, of types different from those that have been tentatively attached to anxiety and to obsessive traits, have also been reported. These findings are difficult to interpret. A functional imaging study has shown activation of the left insula, amygdala, and cingulate when high-calorie drinks were imbibed by anorectic women (Ellison et al), but this conceivably may have reflected anxiety that the authors termed *calorie fear* rather than a specific biologic feature of the disease.

Reports concerning the percentage of first-degree relatives of anorectic patients with manic-depressive disease are also contradictory. An increased prevalence of neurosis or alcoholism has been noted in other members of the family. However, psychiatrists seem to agree that the patient does not have symptoms that conform to any of the major neuroses or psychoses. Certainly loss of appetite, lack of self-esteem and interest in personal appearance, and self-destructive behavior—common features of anorexia nervosa—are also symptoms of depressive illness, yet most of the patients do not look or admit to being dejected. Moreover, endogenous depression affects both sexes. The pathologic fear of becoming fat and the obsession with weight might be interpreted as a phobic or obsessional neurosis. A characteristic personality disorder has not been defined.

That anorexia nervosa is practically confined to females must figure in any acceptable explanation of the syndrome. Among psychiatric disorders, only hysteria has this sexual predilection. Yet most psychiatrists do not believe anorexia nervosa to be a manifestation of hysteria. Probably important is that anorexia nervosa has its onset in relation to the menarche, at a time when the female exhibits rather large fluctuations in appetite and weight. This has suggested to some an imbalance between the satiety center, believed to lie in the ventromedial hypothalamus, and the feeding center, in the lateral hypothalamus. It is as though the appetite-satiety mechanism of the female hypothalamus were unstable.

The association of *anorexia* with structural disease involving the appetite centers has not been established, though the cases reported by Lewin and colleagues and of White and Hain are suggestive. Martin and Reichlin, in citing these rare cases, attribute the anorexia and cachexia to lesions of the lateral hypothalamus. A rare disorder of infants has been described under the title of "diencephalic syndrome." Progressive and ultimately fatal emaciation ("failure to thrive"), despite normal food intake, in an otherwise alert and cheerful infant is the main clinical feature. The causative lesion has usually proved to be a low-grade astrocytoma of

the anterior hypothalamus or optic nerve region (Burr et al). See Chap. 27 for further discussion and references.

Treatment The most effective treatment consists of winning the patient's confidence, supportive psychotherapy, assignment of one individual to sit with the patient as each meal is eaten, and a gradual increase of a balanced diet (Anderson). Extreme cases require hospitalization. If the patient refuses to eat, tube feeding is the only alternative. As weight is gained over several weeks, the patient usually becomes more normal in her attitude toward eating and will continue to recover on this regimen at home. The menses will not return until considerable weight has been gained (about 10 percent above the weight at the time of the menarche). Our colleagues report better success with such a regimen when imipramine or fluoxetine is added. Others have found these drugs to be ineffective except in patients with prominent symptoms of depression.

Becker and colleagues emphasized the potentially devastating medical complications to which severely anorectic patients are prone and the need to evaluate and treat these problems at the same time that nutritional therapy is undertaken. In particular, an electrocardiogram is essential in order to exclude a prolonged QT interval—the presence of which contraindicates the use of tricyclic antidepressants and increases the risk of ventricular tachycardia.

On average, 50 percent of patients recover completely or almost completely (Steinhausen and Seidel). In the remainder, the outcome is quite unfavorable. They either relapse after an initial period of improvement or remain chronically anorectic. Many patients are said to lapse into a chronic neurotic state characterized by a persistent preoccupation with food, weight, and dieting. It is not generally appreciated that chronic anorexia nervosa significantly shortens life; after a mean follow-up period of 12 years, 11 percent of a group of 84 patients had died (Deter and Herzog), and 15 percent after 20 years (Ratnasuriya et al). Suicide is a major contributor to this high mortality rate (Sullivan).

The few adolescent boys that we have seen with this syndrome have recovered on antidepressant medication. A few cases due to tumors within the hypothalamus have been mentioned in Chap 27.

Bulimia This is a related eating disorder characterized by massive binge eating followed by the induction of vomiting or excessive use of laxatives. Insofar as the central psychologic disturbance is the pursuit of thinness at all costs, it is generally conceived as a variant of anorexia nervosa. Indeed, binge eating is a frequent manifestation of anorexia nervosa, although it also occurs as the only, or predominant, eating disorder. However, a close relationship with the menarche as well as emaciation and endocrinologic disturbances are not as evident in bulimic patients as in those with anorexia nervosa. Pope and colleagues reported considerable success in 19 of 20 bulimic patients treated with imipramine and followed for 2 years; the newer antidepressants appear to be equally effective. In general, the therapeutic benefit of these drugs is considerably greater in cases of bulimia than it is in anorexia nervosa.

CHAPTER 57

REACTIVE DEPRESSION, ENDOGENOUS DEPRESSION, AND MANIC-DEPRESSIVE DISEASE

Psychosis, in its broadest definition, refers to any major derangement in mental function in which the individual's ability to perceive and interact with the environment is impaired. Hallucinations are a frequent accompaniment but do not alone define this category of illness.

From a neurologic perspective, there are four major categories of psychosis: (1) confusional-delirious states, (2) psychoses associated with focal or multifocal cerebral lesions, (3) affective disorders (manic-depressive and depressive psychoses), and (4) schizophrenia. The first two categories are discussed in Chaps. 20 and 22. The latter two groups are the subject of this and the following chapter.

Depression is perhaps the cause of more grief and misery than any other single disease to which humankind is subject. This view, expressed by Kline almost 40 years ago, is still shared by everyone in the field of mental health. The several forms of depression taken together are the most frequent of all psychiatric illnesses. In a tertiary general referral hospital, as indicated in the previous chapter, they accounted for an estimated 50 percent of psychiatric consultations and 12 percent of all admissions to one teaching hospital. Although depression has been known for over 2000 years (melancholia is described in the writings of Hippocrates), there is still uncertainty as to its medical status as a disease state (kraepelinian concept) or as a type of psychologic reaction (meyerian concept). In other words, is it basically a biologic derangement or a response to psychosocial stress? An eclectic position is that both are correct—i.e., that there are two basic forms of depression: exogenous (an apparent cause) and endogenous (with no overt external cause) and that there may be an interplay between them.

In respect to endogenous depression and manic-depressive psychosis, genetic and neurochemical data cited further on support the kraepelinian view of a disease state. Nonetheless, a lay concept persists, perpetuated perhaps by some process-oriented psychiatrists, that events in one's life, either distant or current, underlie all types of depressive illness. An unfortunate consequence of this view is the assumption that an inability to deal with these stresses represents a personal failure of sorts and may inhibit the acceptance of psychiatric help.

Of great consequence for clinical work, depressive states are often associated with obscure physical symptoms. For this reason they are more likely to come first to the attention of general physicians and internists than are other psychiatric entities. Moreover, the physical symptoms are frequently mistakenly attributed to anemia, low blood pressure, hypothyroidism, migraine, tension headaches, chronic pain syndrome, chronic infection, emotional problems, worry, and stress. Neurologists are most likely to encounter depressed patients who complain of fatigue and weakness, chronic headache, and difficulty in thinking or remembering. When depression masquerades as a chronic pain or a fatigued state or some

other medical condition, it had been called *masked depression* or *depressive equivalent*.

Another important reason why all physicians should be knowledgeable about depressive illness in all its forms is the danger of suicide, which may be attempted and successfully accomplished before the depression is recognized. Timely diagnosis may prevent such a tragedy—one that is all the more regrettable since most depressive illnesses can be successfully treated.

Nosology and Classification

As remarked in Chap. 24, the term *depression* embraces more than a feeling of sadness and unhappiness. It stands for a complex of disturbed feelings (called *mood*, or *affective disorder*)—which may include despair, hopelessness, sense of worthlessness, and thoughts of self-harm—associated with decreased energy and libido, loss of interest in personal affairs, impaired concentration, various abnormalities of behavior and appearance, and prominent physical complaints—the most important of which are insomnia, anorexia or overeating, headache, and various types of regional pain. At one extreme are depressive symptoms of psychotic proportions (including paranoid or somatic delusions), which create chaos in the lives of the patient and those close to him. At the other extreme are the common feelings of unhappiness, anhedonia (loss of pleasurable responses), discouragement, and resentment that occur in almost everyone as a reaction to the disappointments of everyday life, such as loss of employment, a failure to gain recognition, or unsuccessful sexual or social adjustment, all of which are closely linked in their duration to the persistence of the precipitating factors.

The place in this nosology of postpartum depression has not been clear as discussed in the next chapter. In severe cases it is sometimes difficult to differentiate this condition from postpartum psychosis, a more dramatic and well-defined disorder discussed in the next chapter. Many modern authors question the existence of a primary biologic depression that is tied to the postpartum period (see summary by Brockington). This is not in accord with general experience in which varying degrees of depression are quite common in the weeks after delivery and cannot simply be attributed to psychosocial factors or sleep deprivation.

An abnormally elevated mood, or *mania*, is about one third as frequent as depression. It may develop as a relatively pure, recurrent clinical state, or it may alternate or be intertwined with depression, in which case it has been referred to as *manic-depressive disease* (*bipolar disorder* in the classification of the *Diagnostic and Statistical Manual of Mental Disorders*, or *DSM-IV*). *Hypomania* and *cyclothymic disorder* are the names given to milder forms of mania and bipolar disorder, respectively. The *DSM-IV* classification also acknowledges the existence of mixed *schizoaaf-*

fective states in which attributes of depression and schizophrenia are combined. Distinguishing these various types of depressive illness is of therapeutic as well as theoretical importance insofar as a particular type of depressive illness may respond better to one form of treatment than to another. Finally, the neurologist should always bear in mind the possibility of an incipient dementia presenting as a depression, although the reverse, a masked depression causing difficulty with thinking and memory (pseudodementia) is more common.

Reactive Depressions and Depressions with Medical and Neurologic Diseases

Patients reacting to a medical or neurologic illness seldom express feelings of sadness or despair without mentioning physical concomitants, such as easy fatigability, anxiety, tension headaches, dizziness, loss of appetite, reduced interest in life and love, trouble in falling asleep, or premature awakening. It follows that whenever these symptoms become manifest in the course of medical disease, they should arouse suspicion of a depressive reaction (Table 57-1).

Chronic pain is a particularly frequent somatic manifestation of depression. The pain may be based on an attendant disease but is prolonged, disabling, sometimes vague in nature, and recalcitrant to straightforward medical and surgical approaches. In other words, depressed mood exacerbates and prolongs pain of any type. All patients with chronic pain syndromes should be evaluated psychiatrically, as pointed out in Chap. 8.

In a number of major medical illnesses, depressive symptoms occur with such frequency as to become almost part of the disease. They constitute important diagnostic and therapeutic problems. Contrariwise, in certain chronic, occult diseases, symptoms such as lassitude and fatigue may resemble and be mistaken for a depressive reaction. Hypothyroidism, infectious mononucleosis, infectious hepatitis, carcinoma of the pancreas, lymphoma, myeloma, metastatic carcinoma, malnutrition, polymyalgia rheumatica, and frontal lobe tumors, especially meningiomas, may simulate depression for weeks or months before the diagnosis becomes evident. Sedative drugs, beta-adrenergic blocking agents, beta-interferon, and the phenothiazines may evoke a depressive reaction; corticosteroids can induce a peculiar psychiatric state in which confusion, insomnia, and either an elevation of mood or depression are combined. A depressed mood may also emerge during the tapering-off period of steroid medication or during their initial use (a hypomanic state is more common).

Of particular significance is the reactive depression that occurs on learning of a serious medical or neurologic disease. Often such an emotional reaction, which the physician may tend to ignore, is the dominant manifestation of a disease that threatens the life pattern and independence of the patient. Recognition by the patient that he has suffered a stroke or that she has cancer, multiple sclerosis, amyotrophic lateral sclerosis, or Parkinson disease is almost always followed by some degree of reactive depression, often with an element of anxiety. A prime example is the depression that follows myocardial infarction (Wishnie et al). Usually it begins toward the end of the patient's stay in the hospital and attracts little attention. Once the patient is home, fatigability that approaches exhaustion is the main complaint and interferes with accustomed activities. It may be described as weakness and falsely attributed to heart failure. Symptoms of irritability, anxiety, and despondency are next in order of frequency, followed by insomnia and feelings of aimlessness and boredom. Although most of these patients ul-

Table 57-1

Depression secondary to neurologic, medical, and surgical diseases and drugs

1. *Neurologic diseases*
 - a. Neuronal degenerations—Alzheimer, Huntington, fronto-temporal dementia, Lewy-body disease, Parkinson disease, and multiple system atrophy
 - b. Focal CNS disease—strokes, brain tumors and trauma, multiple sclerosis
2. *Metabolic and endocrine diseases*
 - a. Corticosteroids, excess or withdrawal
 - b. Hypothyroidism, rarely thyrotoxicosis
 - c. Cushing syndrome
 - d. Addison disease
 - e. Pernicious anemia (vitamin B₁₂ deficiency)
3. *Myocardial infarction, open heart surgery, and other operations*
4. *Infectious diseases*
 - a. Brucellosis
 - b. Viral hepatitis, influenza, pneumonia
 - c. Infectious mononucleosis
 - d. Whipple disease
 - e. Creutzfeldt-Jakob disease
5. *Cancer, particularly pancreatic and metastatic*
6. *Parturition*
7. *Medications*
 - a. Corticosteroids and ACTH
 - b. Interferons
 - c. Analgesics and anti-inflammatory agents (other than steroids)—indomethacin, phenacetin
 - d. Amphetamines (when withdrawn)
 - e. Antibiotics, particularly cycloserine, ethionamide, griseofulvin, isoniazid, nalidixic acid, and sulfonamide
 - f. Antihypertensive drugs—clonidine, propranolol (and certain other beta-adrenergic blockers)
 - g. Cardiac drugs—digitalis, procainamide
 - h. Disulfiram
 - i. L-Dopa
 - j. Methysergide
 - k. Oral contraceptives
8. *Alcoholism*

CNS, central nervous system; ACTH, adrenocorticotrophic hormone.

timately recover without medical assistance the depression exacts a high toll in terms of mental suffering.

An analogous depressive reaction occurs in some patients after a stroke. Some studies have indicated that patients with left anterior cerebral lesions, involving predominantly the lateral frontal cortex or basal ganglia (as detected by computed tomography scanning) and examined within several weeks of the stroke, have a greater frequency and severity of depression than do patients with lesions in other locations (Starkstein et al; Robinson). According to these authors, lesions of the right hemisphere do not show this correlation with depression but do show a higher association with pathologic cheerfulness or mania. However, House et al, in a British community-based study of stroke survivors, failed to confirm these findings, perhaps because the infarcts were small in size (more than half the patients had never been admitted to hospital) and many patients were examined for the first time only at 6 and 12 months

after their strokes. Our colleagues Levine and Finkelstein have reported the occurrence of psychotic depression with hallucinations and delusions in patients with right temporoparietal infarcts. Our own experience suggests a not surprising relationship between the degree of motor and language disability and the severity of post-stroke depression but a less predictable relationship to the location of the lesion. The possible predisposing effects of minor previous episodes of depression, family history of depressive illness, and medications have not been studied systematically.

With regard to emotional reactions in degenerative brain diseases, Parkinson disease is complicated by a depressive reaction in approximately one quarter of cases. Weakness and fatigability, the principal psychologic manifestations, are added to the bradykinesia, and the resulting therapeutic problem becomes formidable. Another hazard in Parkinson and in Lewy body disease is the tendency for L-dopa itself to provoke a depression in a limited number of patients, sometimes with suicidal tendencies, paranoid ideation, and psychotic episodes. Huntington chorea is quite often associated with depression, even before the movement disorder and dementia become conspicuous. In one series, 10 of 101 patients with Huntington disease either committed suicide or attempted it. Also, Alzheimer disease may be accompanied by depressive symptoms, in which instance it is difficult or impossible early in the illness to evaluate the relative contributions of the mood disorder and the dementia. In later stages, the overt signs of depression abate.

ENDOGENOUS DEPRESSION AND MANIC-DEPRESSIVE DISEASE

Definitions and Epidemiology

Manic-depressive disease is a disorder of mood consisting of prolonged episodes of depression, mania, or both. It was given its name by Kraepelin in 1896, and it was with him that our current clinical concept of this disorder originated. He viewed the manic and depressive attacks as opposite poles of the same underlying process and pointed out that, unlike dementia praecox (his name for schizophrenia), manic-depressive psychosis entails no intellectual deterioration with recurrent episodes. A traditional view of this disease was that of a periodic or cyclic condition in which one major mood swing was followed by an equal but opposite excursion. This is seldom the case, however. Episodes of depression are more than twice as frequent as manic ones, and according to current thinking, the most common form of the illness is characterized by episodic depression alone. Recurrence of episodes of pure mania without interspersed episodes of depression is well known but relatively uncommon. As a consequence, manic-depressive psychosis has been divided into two subtypes: the *unipolar group*, in which only an endogenous depressive illness occurs, and a *bipolar group*, in which one or more bouts of mania occur with or without depression. The bipolar variety occurs in about 10 percent of patients with affective disorder. The biologic accuracy of this classification has not been critically determined.

In addition, there are *mixed affective states*, in which symptoms of both depression and mania occur within a single episode of the illness. A so-called "rapid-cycling" form of manic-depressive disease has been recognized in which four or more circumscribed episodes occur in a year. Like other variants of the disease, it tends to have an aberrant or unpredictable response to medication. Still other patients with affective elements of depression present with atypical features; instead of anorexia, weight loss, and insomnia,

for example, they sleep and eat excessively. These patients are also less responsive to therapy. In adolescents, the latter symptoms are difficult to differentiate from the Kleine-Levin syndrome (page 344).

The prevalence of manic-depressive disease cannot be stated with precision, mainly because of varying criteria used for diagnosis. The apparent increase of the disease in the past 50 years probably reflects a growing awareness of the condition among both physicians and the laity. Studies of large groups of patients from isolated areas of Iceland and the Danish islands of Bornholm and Samsø have indicated that 5 percent of men and 9 percent of women will develop symptoms of major depression, mania, or both at some time during their lives (Goodwin and Guze). The estimate for an American urban community in 1978 (New Haven, Connecticut) was higher; 8 to 12 percent in men and twice this number in women (Weissman and Myers).

Manic-depressive disease occurs most frequently in middle and later adult years, with a peak age of onset between 55 and 65 for both sexes. However, a significant proportion of patients experience the first attack in childhood, adolescence, or early adult life. Depression is also a significant problem in the elderly. Blazer and Williams, who studied 997 persons over the age of 65 in North Carolina, found symptoms of a major depressive illness in 3.7 percent. The disease was two or three times more frequent among women. There is no known explanation for this gender difference, but some have speculated that just as many men are depressed, only they deny it or turn to alcohol. Patients in the bipolar group have an earlier age of onset, more frequent and shorter cycles of illness, and a greater prevalence of affective disorder among their relatives than do patients with unipolar depression (Winokur).

Clinical Presentation

Fully developed endogenous depression may evolve within a few days, or, more often, it emerges more gradually, on a background of vague prodromal symptoms that had been present for months. A detailed description of the symptoms and signs of depression is given in Chap. 24. Here it need only be repeated that the patient expresses feelings of sadness, unhappiness, discouragement, hopelessness, and despondency, with loss of self-esteem. Reduced energy and activity, typically expressed as mental and physical exhaustion, is almost always present, to the point of catatonia in the most severe cases. Indeed, the most common cause of symptoms relating to reduced psychic and physical energy and drive (connation) is depression. There is heightened irritability as well as a lack of interest in most activities that formerly were pleasurable. The patient tends to move slowly, sighing is frequent, and speech is reduced. The mental life of such an individual may narrow to a single-minded concern about physical or mental decline or both. In dialogue, the patient's responses become so stereotyped that the listener can soon predict exactly what is going to be said. There is a poverty of ideation and sometimes a notable absence of insight. Consciousness is clear, and though there is no evidence of a schizophrenic type of thought disorder, delusional ideas and less often hallucinations may be prominent in some patients, justifying the term *depressive psychosis*. The delusions are generally congruent with the patient's mood and are not as fixed or bizarre as those of schizophrenia or paranoia. In our experience, delusions are more common in older patients and tend to appear only after weeks or months of more typical symptoms of depression. Hallucinations, when they occur, are usually transitory, vocal, and vaguely accu-

satory; their presence should always raise the possibility of an associated structural brain disease, drug intoxication, or alcoholic auditory hallucinosis.

Frequently, agitation and irascibility rather than physical inactivity and mental slowness are the principal behavioral abnormalities. The source of the agitation is an underlying anxiety state. Pacing the floor and wringing the hands, particularly in the early morning hours, are characteristic. Such patients tend to be overly talkative and vexed in their manner of expression, irritable, short-tempered, impatient, and intolerant of minor problems—changes noted mainly by family members. Attempts at reassurance may meet with initial success, only to be dispelled in the next rush of doubts. These patients remain impervious to reason and logic with respect to their symptoms, even though they are reasonable and logical to a variable degree in other areas of their lives. At its worst the illness takes the form of a depressive stupor; the patient becomes mute, indifferent to nutritional needs, and neglectful even of bowel and bladder functions (anergic depression). The condition in this extreme form is a *catatonic depression*. Such patients must be fed and their other needs attended to until therapy [usually electroconvulsive therapy (ECT)] brings about improvement.

The most important concern in patients with mid- and late-life depression is the risk of suicide. Since many of these individuals have reputations for being sound, dependable, and stable and deny being depressed, one's inclination is to doubt the possibility of self-destruction. *Such patients should be questioned forthrightly on this subject:* Do they feel that life is not worthwhile? Have there been thoughts of suicide? Do they think themselves capable of committing suicide? Have they made such plans or made suicide attempts before? Is there a family history of suicide? Do they own a firearm? Are they fearful of dying? Are they concerned about leaving their family without support? Do they have a strongly held religious view that proscribes suicide? These questions relate to features that have been shown to put depressed individuals at risk of suicide. If, from their answers, they are judged to carry an imminent risk of suicide, they should be directed to a psychiatrist and generally admitted to a hospital.

In some depressions, hypochondriacal preoccupation with bowel and digestive functions accounts for repeated visits to the medical clinic. In one study, 21 of 120 such patients were subsequently diagnosed as being depressed. Persistent insomnia may be the major complaint of the depressed patient. Early awakening is typical, and the morning hours are then the worst period of the day. Other patients have difficulty falling asleep, especially if there is an associated anxiety state. A complaint in the male of loss of libido and impotence is another monosymptomatic presentation; only with probing inquiry about other disturbances common to depression will the diagnosis become evident.

The *manic state* is, in most ways, the opposite of the depressed state, being characterized by a flight of ideas, motor and speech hyperactivity, and an increased appetite and sex urge. When such a state is fully developed, it qualifies as a psychosis. After a minimum of sleep, the patient awakes with enthusiasm and expectation. The manic individual appears to possess great drive and confidence yet lacks the ability to carry out plans. Headstrong, impulsive, socially intrusive behavior is characteristic. Judgment may be so impaired that reckless investments are made; fortunes are spent in gambling or on extravagant shopping sprees. Setbacks do not perturb the patient, but rather act as goads to new activities. Euphoria and expansiveness sometimes bubble over into delusions of power and grandeur, which, in turn, may make the patient offensively

aggressive. Up to a point, the patient's mirth and good spirits may be contagious, and others may join in; however, if the patient is thwarted, the warmth and good humor can suddenly change to anger. Irritability rather than elation may become the prevailing mood. The threshold for paranoid thinking is low, which makes the patient sensitive and suspicious. Personal neglect may reach the point of dishevelment and poor hygiene. In its most advanced form, a condition described as "delirious mania," the patient becomes totally incoherent and altogether disorganized in behavior. At this stage visual and auditory hallucinations and paranoid delusions may be rampant; furthermore, as the term *delirium* implies, the patient may be disoriented and agitated, with a clouded sensorium. This extreme is rarely encountered. As mentioned earlier, one observes patients with repeated attacks of mania without depression at any time, but this is not common.

Hypomania represents a milder degree of the disorder, but this term is also used loosely to depict behavior in a normally functioning individual who is unusually energetic and active. In this latter sense hypomania is a personality trait found in many talented and productive persons and need not arouse concern unless it is excessive and out of character for the individual. This is best determined by questioning the family. As commented in the review by Belmaker, a number of highly creative individuals have had bipolar disorders, but full-blown mania is uniformly destructive of careers and personal relationships. He cites Shou in pointing out that such individuals are actually more creative when treated with appropriate medications.

First attacks of either depression or mania last an average of 6 months if untreated, although the duration varies greatly. With treatment, this can be reduced by more than half in most patients. Although most attacks of manic-depressive disease subside in a matter of months, a significant number, unipolar patients more than bipolar ones, remain chronically ill for long periods. According to Winokur and colleagues, 14 percent of their bipolar patients had not recovered after 2 years and 5 percent after 5 years. Comparative figures for primary unipolar patients were 19 and 12 percent, respectively. Well over one half of all depressed patients have one or more recurrences. Variables that are predictive of an unfavorable outcome are high degrees of neuroticism, strongly positive family history of a similar psychiatric illness, and presence of depression-provoking circumstances (Hirschfeld et al). Perhaps most important is the duration of illness before treatment, i.e., earlier treatment is generally associated with a more favorable prognosis.

Diagnosis

According to DSM-IV, the essential diagnostic criteria of endogenous depression ("major depressive syndrome") consist of a dysphoric mood or loss of interest or pleasure in all usual activities (including sexual activity) in combination with at least four of the following seven symptoms: (1) disturbance of appetite and change in weight; (2) sleep disorder; (3) psychomotor retardation or agitation; (4) decreased energy and fatigue; (5) self-reproach, feelings of worthlessness or guilt; (6) indecisiveness, complaints of memory loss and difficulty in concentrating; and (7) thoughts of death or suicide or actual suicide attempts. In this diagnostic scheme, each of the four diagnostic symptoms should have been present for at least 2 weeks.

Adherence to the aforementioned criteria undoubtedly facilitates diagnosis, but not infrequently a single one of these symptoms so dominates the clinical picture as to suggest the diagnosis of

another disease state and obscure the presence of an underlying depression. As mentioned earlier, depressed patients who are referred to the neurologist tend to complain inordinately of physical and cognitive symptoms and to minimize or deny the purely affective ones. Complaints of fatigue, weakness, malaise, or widespread aches and pains, for example, suggest a variety of medical diseases, such as Addison disease, hypothyroidism, chronic infection, polymyositis, or early rheumatoid arthritis. Often the fatigue state is misinterpreted as muscular weakness, and this directs a medical search for neuromuscular disease. Similarly, complaints of persistent headache may suggest the presence of intracranial disease. Complaints of poor memory, inability to concentrate, and other cognitive impairments raise the question of a dementia—until it is found, by careful examination, that mental competence belies the patient's appraisal of his own presumed defects.

A number of psychologic testing scales are used to detect and score the severity of depression. Although they are of value mainly for clinical studies, several of them can be quite helpful in clinical works, since they are sensitive to one or another aspect of depression. They do not supplant the clinical examination in determining if an individual is depressed or suicidal but they may be helpful in differentiating depression from dementia and in detecting depression in cases where physical complaints are more prominent than psychic ones. The tests most familiar to neurologists are the Hamilton and the Beck scales, but several others are as valid.

In our experience, the following are some of the common and troublesome clinical situations in which it may prove difficult to recognize an underlying depression:

1. *Patients with chronic pain.* The association of chronic pain and depression has long been appreciated. This is far from a homogeneous group. The special case of chronic headache, confronted often by neurologists, is discussed later. In some patients with chronic pain, the symptoms and signs of depression are quite apparent. If the pain has been present for less than a year and had its onset at the same time as other depressive symptoms, response to antidepressant treatment is likely to be favorable.

Far more difficult to understand, and to manage, are patients with persistent pain as the only complaint; the head, face, and lower back are the most common loci. Among the depressive pain syndromes, *intractable headaches* may be the most prominent manifestation of depression seen by neurologists. Weeks or months of unremitting daily tension-type headaches in the context of a normal examination are highly suggestive of depression at any age. If an exhaustive search for the source of the pain proves unsuccessful, the conclusion is finally reached that the pain is "psychogenic." This attribution of pain to some obscure psychologic mechanism is hardly helpful, for usually no amount of exploration will reveal its source. Nevertheless, in a small proportion of such patients, pain will be alleviated by antidepressant drugs, suggestive, at least in these cases, of a linkage of the pain and depression. In this group of patients, the problem is frequently made even more difficult by repeated surgical operations as well as dependency on analgesic drugs, which in themselves deplete energy and have other adverse effects. Such patients are to be found among those disabled after multiple operations for prolapsed intervertebral disc or arthritic hips or those with atypical facial pain.

2. *Depression and alcoholism.* These are commonly associated,

and it is important to determine which is primary and which is secondary. A depressive syndrome developing for the first time on a background of alcoholism is a common clinical occurrence. In a large series of alcoholic patients studied by Cadoret and Winokur, a secondary depression occurred in 30 of 61 females and in 41 of 112 males; moreover, once the alcoholism was established, depression became evident much earlier in the women than in the men. The opposite occurrence (i.e., the development of alcoholism on the background of a primary depression) is less common. Again, women are disproportionately affected. As mentioned earlier, these differences may be spurious; Winokur's family studies have suggested that the same genetic predisposition leads to depression in females and alcoholism and sociopathy in men.

3. *Depression in childhood and adolescence.* We have observed depressive states in children, and they have often been misdiagnosed by both pediatricians and psychiatrists. The common manifestations have been chronic headache, refusal to go to school, withdrawal from social activities, anorexia, vomiting and weight loss, and scholastic failure. Puberty is a time of onset in many cases, but we have seen depressive disease in late childhood, and it is extremely frequent in high school and college students. It is a tragic mistake not to appreciate this fact and to treat the patient for some presumed nonaffective nervous symptoms, only to have the patient commit suicide. This has happened to more than half a dozen of the children of our medical colleagues over the years.
4. *Anxiety neurosis, hypochondriasis, and pseudodementia.* These are clinical circumstances in which an underlying depressive illness may not be immediately apparent but must always be suspected. These symptoms are discussed in detail in the preceding chapter. The complaint of severe chronic fatigue without medical explanation should raise the same suspicion (Chap. 24). An elderly person with seemingly early signs of dementia may, on closer examination, turn out to have a severe depressive illness (pseudodementia, page 375).

Etiology of Depression

The following are the main theories, not mutually exclusive, that have been proposed to explain the origin of depression; for a detailed review of the subject, the reader is referred to Nestler.

Genetic Factors The capacity to experience sadness and depression is common to all people but there is no question that some individuals are more liable to depression than others who are subjected to similar psychosocial forces. It has been estimated, using various genetic techniques, that as much as 40 to 50 percent of the risk of depression is heritable. Adopted children whose biologic parents had affective disorder are at greater risk of developing this disease than adoptees whose biologic parents were not affected (Mendlewicz and Rainer; Cadoret). The frequency of these illnesses is greatly increased in the relatives of affected patients (prevalence rate of 14 to 25 percent in first-degree relatives). Similarly, the risk of depression among first-degree relatives is increased (15 percent, in comparison to 1 to 2 percent risk in the general population). If several twin studies are taken together, 72 percent of monozygotic twins are concordant for bipolar disease, compared with 14 percent of same-sex dizygotic twins; comparative figures for unipolar disease are 40 percent and 11 percent, respectively.

(see Goodwin and Guze). All of these findings indicate a strong genetic factor. The genes for manic-depressive disease remain to be discovered, and current thinking holds that several are likely to be involved. One of the first indications that specific genes may alter the susceptibility to depression has been presented by Ogilvie and colleagues; they found allelic variations in the serotonin transporter gene (the main target of the selective serotonin antidepressants) that were associated with a sevenfold increased risk of major depression. Not all studies agree on these points. This result has been reinforced by Caspi and colleagues who reported that a variant in the serotonin transporter correlates with an increase in depression in response to stress. Other hypotheses have postulated susceptibility loci on chromosomes 18, 21, and X. A single gene locus seems unlikely (see Sanders et al.).

Anatomic Correlates Several lines of study, including those employing functional magnetic resonance imaging, indicate that several regions of the brain are implicated in the pathogenesis of the complex symptomatology of depression (Drevets). Hypometabolism in the left frontal cortex is among the most consistent findings. Also prominent in many studies are metabolic changes in the cingulate and orbitofrontal cortices, related parts of the medial limbic system, and the hippocampus.

An intriguing observation, and one that does not entirely accord with the above, has been made by Bejjani et al in the course of deep brain stimulation for the treatment of Parkinson disease. One of their patients displayed transient but dramatic manifestations of depression when high-frequency stimulation was delivered to the left substantia nigra. Functional positron emission tomography imaging during stimulation showed activation in the left orbitofrontal cortex and, less consistently, in the left amygdala, globus pallidus, thalamus, and right parietal lobe. Changes of mania could not be produced but in at least two other cases with no prior psychiatric symptoms, deep brain stimulation of the subthalamic nucleus did induce a reversible manic state (Herzog et al; Kulisevsky et al). Fisher noted a hypomanic episode in the early stages of herpes encephalitis, and numerous cases of temporary secondary mania have been reported after stroke and after brain trauma, the latter affecting most often the right temporal lobe (see also pages 450 and 1309).

On histologic level, several studies have shown a depletion of and changes in the pyramidal neurons of the CA3 region of the hippocampus in both depression and stress but the meaning of these findings is unclear (Sapolsky). They are referred to later in relation to neurogenesis (the appearance in adults of new neurons) in the temporal lobe and recovery from depression. These ideas regarding neurogenesis, which are in our view still somewhat speculative as they relate to human disease, are discussed in Chap. 29. Interestingly, in a rodent model of depression, such neurogenesis was required for the beneficial effects of antidepressants to take place (Santarelli). Based in part on this observation, a relationship has been suggested between depressive illness and the later development of dementia. The reviews of Starkstein and Robinson and their colleagues, and that of Nestler mentioned earlier, may be consulted for further information on anatomic lesions and changes in affect.

Biochemical Theories It has been evident for several years that the biogenic monoamines (norepinephrine, serotonin, and dopamine) are in some way involved in the biology of depression. However, most of the neurochemical theories of depression suffer from

the weakness that they have been the result of a type of backward reasoning from the biochemical effects of antidepressants on various neurotransmitters to the putative mechanisms of the disease. Following the observations that the tricyclic antidepressants and the monoamine oxidase (MAO) inhibitors exerted their effect by increasing norepinephrine and serotonin at central adrenergic receptor sites in the limbic system and hypothalamus, and that depression-provoking drugs (such as reserpine) deplete biogenic amines at these sites, it was proposed that naturally occurring depressions might be associated with a deficiency of these substances. Furthermore, depressed patients and their first-degree relatives, as well as healthy individuals, develop a depressed mood after dietary depletion of the monoamine precursor tryptophan. Also noteworthy is the reduced concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, in the cerebrospinal fluid (CSF) of patients during endogenous depression and the elevated levels in manic states. Some neurochemical imaging studies corroborate these findings and others do not. Along similar lines, 5-hydroxyindoleacetic acid (5-HIAA), a deaminated metabolite of serotonin, is reduced in the CSF of depressed patients (Carroll et al).

Certain of the newer antidepressants act as selective serotonin reuptake inhibitors (SSRIs) and apparently produce their salutary effects by increasing the amount of serotonin that is functionally active in the synapse (they also raise the concentrations of norepinephrine). For these reasons, serotonin and its neuronal pathways are also currently implicated in the genesis of depression. However, the reader should be reminded that only a decade ago it was widely held that depletion of norepinephrine fulfilled this role. It is also not yet clear which neurochemical alterations are primary and which modulate other systems. For example, reports suggest that substance P plays an important role in the causation of depression (Kramer et al) and that blockade of substance P receptors has antidepressant effects. Why there is a delay of several weeks in the improvement of depression related to the taking of the various antidepressants is unexplained by any of the neurochemical models.

Another set of observations that has continued to capture interest for more than a decade, implicates a disorder of hypothalamic-pituitary-adrenal function as another component of depression (summarized by Schlesser et al). It had been found several decades ago that the parenteral administration of 1 to 2 mg of dexamethasone failed to suppress serum cortisol secretion while the patient was ill with endogenous depression but did so after recovery. In a comparable series of reactive depressions, there was a normal suppression of cortisol secretion. Originally the dexamethasone suppression test was believed to separate the two large groups of depressed patients and to predict the response to drug therapy. However, subsequent studies have shown that the specificity of this test was less than earlier reports had indicated (Amsterdam et al, Insel et al). Nonetheless, accumulated evidence now indicates that one half of severely depressed patients do not show suppression of cortisol secretion, and a positive test can be obtained in a significant number of patients with other psychiatric disorders.

The failure of dexamethasone suppression has been attributed to hyperactivity in the hypothalamic pituitary axis and a corresponding increase in secretion of corticotropin-releasing hormone, ACTH and glucocorticoids. Elevated levels of glucocorticoids have been theorized to impede neurogenesis in the medial temporal lobe and perhaps to explain or exaggerate the loss of hippocampal neurons demonstrated in some studies of the brains of deceased depressed patients. A proposal that ECT acts by elevating levels of

neurotrophic factors is at least consistent with this view and with the hypothesis that one component of recovery from depression is in some way associated with restoration of normal neuronal architecture in regions of the hippocampus and the hypothalamus (Chen). Although highly speculative, perhaps some of these changes explain the delay in improvement after the administration of antidepressant drugs.

At the present time, it must also be conceded that there is no reliable biologic test for depression. One must resort to clinical analysis (i.e., the interpretation of symptoms and signs) not only for diagnosis but also for the differentiation of special types of depressive reactions.

Psychosocial Theories Many experienced psychiatrists have emphasized the importance of psychosocial factors in the genesis of depressive illness. Among patients with primary depressive disorders, life events of a stressful nature were found to have occurred more frequently in the months preceding the onset of depression than in matched control groups. In the study by Thomson and Hendrie, this was equally true of patients with a positive family history of depression and those without such a history. Nor did patients with endogenous depression differ in this respect from those with reactive depression. Left unanswered is the question of why some individuals are subject to a reactive depression. Are they predisposed by psychologic or personality makeup? Perhaps the genetically transmitted factor is a heightened vulnerability to the effects of psychosocial stress. Epidemiologic data favoring one or another of these speculations are lacking. One is tempted to conclude that many depressions attributed to psychosocial stress are contaminating a group of endogenous depressions. Psychiatrists have also failed to find a consistent correlation between depressive illness and personality type or a particular psychodynamic mechanism. In our view, the adoption studies noted tend to diminish the importance of environmental factors in explaining most major depressions.

Treatment

The use of medications for depression is now so widespread that all physicians should be familiar with them. The physician untrained in psychiatry would, however, be unwise to undertake the management of manic-depressive disease or endogenous depression without the advice or assistance of a psychiatrist. If the symptoms are primarily neurologic (e.g., chronic headache, generalized weakness and fatigability) and if there is a low risk of suicide, it is appropriate for the experienced neurologist or generalist to institute treatment with antidepressant medication. If there is any suspicion of suicide, the patient should be hospitalized and, if necessary, involuntarily committed.

Antidepressant Medication In the management of bipolar and unipolar disease, five main categories of drugs are in general use—the tricyclic antidepressants, the “atypical” or nontricyclic group of compounds, the MAO inhibitors, serotonin agonists (reuptake inhibitors), and lithium. The pharmacologic properties and modes of action of these drugs have already been considered in Chap. 43 (pages 1026 to 1028). Additional points of therapeutic interest are mentioned here. It should also be stated that meta-analyses of several large studies on the therapeutic effects of antidepressants have suggested that clinical improvement attributable to the drugs themselves occurs in only about one half of patients; remarkably, an

additional improvement in up to 25 percent has been attributable to a placebo effect or to the natural course of the disease. The remainder fail to improve in a timely manner or relapse while on medication.

Most psychiatrists currently prefer to begin treatment with one of the functional serotonin agonists (SSRIs)—fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), citalopram (Celexa), and others, or one of a related group, exemplified by venlafaxine (Effexor) and nefazodone (Serzone). New ones of similar type are appearing yearly. These drugs have less sedating and anticholinergic effects than the tricyclic antidepressants discussed later. Fluoxetine has a tendency to produce insomnia and weight loss, making it particularly useful in the treatment of depressions that are characterized by overeating and hypersomnia. Some female patients have experienced an opposite effect, i.e., weight gain. Patients with anorexia, insomnia, and high levels of anxiety may do better with a more sedating medication, such as amitriptyline. In a similar vein, fluoxetine would be a reasonable choice for patients in whom lethargy is a prominent complaint. Certain side effects such as loss of libido or impotence occur in a proportion of patients and are difficult to differentiate from the signs of depression.

The tricyclic antidepressants comprise amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan), clomipramine (Anafranil), and trimipramine (Surmontil), and the closely related drugs desipramine (Norpramin), nortriptyline (Pamelor), and protriptyline (Vivactil). Among this group, most psychiatrists start with imipramine or amitriptyline because of their relative safety. In general, all of these drugs are equally effective, although an individual patient may have a better response to one than to another. The starting dose for amitriptyline or imipramine is 25 mg/day, which is then raised by 25 mg every 3 to 4 days as needed up to 150 mg/day. These drugs, taken at bedtime, are also very helpful in alleviating the insomnia that accompanies depression. The therapeutic effect of tricyclic medication is generally not evident for 2 to 4 weeks after treatment has been initiated, and it is important that this be explained to the patient and family. Common side effects are orthostatic hypotension, dry mouth, constipation, tachycardia, urinary hesitancy or retention (especially in patients with prostatic hypertrophy), tremor, and drowsiness. Closed-angle glaucoma may decompensate. Caution should be exercised in elderly patients with cardiac disorders of all types. For such patients, the serotonin drugs or one of a newer group of nontricyclic antidepressant drugs—bupropion (Wellbutrin) and trazodone (Desyrel)—may be preferable. The latter drugs appear to be as effective as the tricyclic agents in the treatment of depression without the adverse anticholinergic and cardiotoxic effects.

If one of the aforementioned drugs, given in full doses for 4 to 6 weeks, does not produce the desired effect (or if the patient is intolerant of the given drug), another one from an alternative group, e.g., an MAO inhibitor, may be tried. In the case of SSRIs, *there must be a drug-free interval of 1 to 2 weeks before instituting an MAO inhibitor*. Some studies suggest that MAO inhibitors are superior in depression with atypical features such as increased appetite. Phenelzine (Nardil), isocarboxazid (Marplan), and tranylcypromine (Parnate) are in this category, of which the first is said to be the least likely to produce serious side effects. The usual starting dose is 15 mg tid, which is gradually increased as needed to a maximum of 45 mg tid. The most serious risk of MAO inhibitors is the occurrence of a hypertensive crisis; therefore, these drugs should be dispensed with caution in patients with hypertension and with cardiovascular or cerebrovascular disease. Patients

taking these drugs should avoid foods with a high tyramine content (aged cheese, pickled herring, chicken liver, beer, wines, yeast extract) as well as medications containing sympathomimetic agents or L-dopa (decongestants, amphetamines, caffeine) and the aforementioned serotonin agonists.

Supplementation of antidepressants with the administration of an anticonvulsant is a popular approach with many psychiatrists. Valproate or gabapentin are used, but also carbamazepine or phenytoin. There are few credible studies by which to judge the value of this strategy, but these drugs may provide some additional benefit as "mood stabilizers," if only as antianxiety agents. More persuasive are the data suggesting that anticonvulsant drugs are useful in treatment of the manic state.

Since many patients are responsive to one of the tricyclic drugs, MAO inhibitors, or serotonin agonists but not to all of them, the clinician is greatly aided by information regarding which of these drugs has been most helpful in the past. This will guide one in current management. As mentioned, response to antidepressant drugs is not expected for several weeks. Treatment should then be continued for 4 to 6 months and generally should be combined with some type of psychotherapy. The dosage of medication should then be reduced slowly over a period of weeks. Rapid reduction may result in withdrawal symptoms (nausea, vomiting, malaise, and muscular pains). If depressive symptoms recur upon withdrawal, the effective dose should be gradually reinstated.

Lithium Carbonate This is the drug of choice in treating the manic phase of manic-depressive disease and it is useful in preventing relapses of depression in some patients. Hospitalization is usually required to protect the manic patient from impulsive and aggressive behavior which might cause a loss of standing in the community or jeopardize a career. Chlorpromazine (Thorazine), haloperidol (Haldol), or one of the newer antipsychosis agents discussed in the next chapter—or ECT if these drugs are ineffective—can be used to control the mania until lithium carbonate becomes effective, usually a matter of 4 or 5 days. The usual dosage of lithium is 1200 to 2400 mg daily in divided oral doses, which produces a desired serum level of 0.9 to 1.4 meq/L. The serum level of lithium must be checked frequently, both to ensure that a therapeutic dose is being taken and to guard against toxicity (see later).

The side effects of lithium are nausea and vomiting, diarrhea (especially if the dose is increased too rapidly), a feeling of mental dullness, action tremor, weakness, ataxia, slurred speech, blurred vision, dizziness, nystagmus (especially vertical or down beating), stupor, and coma. A confusional psychosis with polymyoclonus and ataxia simulating Creutzfeldt-Jakob disease (including periodic sharp waves in the electroencephalogram) may occur at toxic levels. In patients who do not tolerate lithium, carbamazepine or valproate may be substituted. A combination of lithium and a tricyclic or SSRI medication at the lowest effective level has been one of the best long-term preventive therapies for manic-depressive disease, and the same combination is useful for patients with mixed bipolar disorder in which depressive and manic manifestations occur within a single episode of illness.

Electroconvulsive Therapy (ECT) and Transcranial Magnetic Stimulation ECT continues to be a highly effective treatment for severe endogenous depression and can also be used to interrupt manic episodes. The latter often requires only two or three treatments. The technique is relatively simple and safe. The patient is

anesthetized by an intravenous injection of a short-acting barbiturate, benzodiazepine, or propofol and also medicated with a muscle relaxant (succinylcholine). An electrode is placed over each temple and an alternating current of about 400 mA and 70 to 120 V is passed between them for 0.1 to 0.5 s. The succinylcholine prevents strong and injurious muscle spasms. The patient is awake within 5 to 10 min and is up and about in 30 min. The mechanism by which ECT produces its effects is not known. Treatments are usually given every other day for 6 to 14 sessions. The only absolute contraindication is the presence of increased intracranial pressure, as may occur with a neoplasm or hematoma. Whether epilepsy is precipitated or worsened by ECT is still debated. This treatment should also be used cautiously in the presence of uncontrolled systemic hypertension or with a known sensitivity to the anesthetic agents that are used as premedication (malignant hyperthermia; page 1272).

The major drawback of ECT is the production of a transient impairment of recent memory for the period of treatment and the days that follow, the degree of impairment related to the number of treatments given. Placing both electrodes on the nondominant side (unilateral ECT) or using lower amounts of current and a pulse rather than a sine wave may produce less memory disturbance but has been somewhat less effective against the depression.

With the recognition that transcranial magnetic motor stimulation sometimes produced an elevation of mood, its use as a substitute for ECT has been suggested. The magnetic technique has the advantage of being free of any but minor physical effects, and since it produces no loss of consciousness, anesthesia and neuromuscular paralysis are not needed. Brief pulses of high-frequency stimuli are used. Few controlled studies have as yet been performed, but the initial results have been promising, and this technique could conceivably replace ECT. Whether it is as effective for severe depressions and catatonia is not yet known.

Until the advent of the antidepressant drugs, ECT was the treatment of choice for the agitated depression of middle and late life and for catatonia. Following a course of 6 to 14 treatments, close to 90 percent of patients recover within 2 months or less. Prior to the use of ECT, this type of depression might last for 2 years or longer before remission occurred. In cases of catatonia or severe psychotic depression most psychiatrists favor the initial use of a neuroleptic agent, such as haloperidol, followed by a trial of an antidepressant, before resorting to ECT. Following ECT therapy, maintenance therapy with a tricyclic compound, serotonin agonist, or lithium is necessary to prevent relapse.

Psychotherapy In all patients with manic-depressive disease, frequently repeated explanations of the patient's illness, reassurance that the illness is self-limited, and encouragement and instruction of the family are of value in helping both the patient and family to understand the illness and cope with it. As a general rule, manic-depressive illness is best managed by a physician who is willing to follow the patient over a long period of time and who is known to the family. He should be available to reevaluate the patient on suspicion of a relapse. Although the prognosis for any individual attack is relatively good, it is wise to arrange for a plan of action that will be set in operation at the first hint of a recurrence.

Tomes have been written about various psychodynamic approaches to psychotherapy and the authors are unable to comment reliably on them. A structured and problem-oriented approach to psychotherapy, utilizing "cognitive-behavioral" and "interpersonal" strategies, has gained considerable popularity since its introduction in the 1970s by Beck. It draws to a limited extent on

psychoanalytic and other psychodynamic theories and has been used in patients with depression and in those with neuroses, chronic pain, sexual dysfunction, and other disorders. According to Blen-kiron, cognitive-behavioral therapy is most effective in patients with mild to moderate (not chronic) depression, generalized anxiety and panic disorder, and obsessive-compulsive and phobic disorders. Essentially, in the short term, the therapist provides the patient with information on the nature of the illness, its common symptoms, and the active interventions that are to be undertaken to alter the specific misperceptions and the dysfunctional behaviors that spring from them. The interested reader can find discussion of this subject in the current edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry* (Sadock and Sadock, eds.). Noteworthy is the opinion of Gabbard that behavioral-cognitive psychotherapy has been shown to be no better or worse than other forms of psychotherapy.

Suicide

Some 30,000 suicides are recorded annually in the United States, and attempted suicides exceed this number by about 10 times. All psychiatrists agree that these are conservative figures. Suicide is the eighth leading cause of death among adults in the United States and the second leading cause among persons between the ages of 15 and 24 years, figures that emphasize the importance of recognizing depressions that have a high potential for self-destruction. Every physician should, therefore, be familiar with the few clues we possess to identify those patients who intend to end their lives. Some of the questions that may be broached in the interview regarding depression were listed earlier (page 1311). Physicians should also be aware that the majority of suicides are accomplished by taking an overdose of prescribed medications, for which reason caution needs to be exercised in their prescription and administration in depressed patients.

Current opinion, summarized by Mann, indicates that suicidal intent represents a special form of depression, or an important variant of it, and that certain individuals are by nature susceptible as a result of biologic factors. In other words, suicide is not simply a cognitive response to extreme stress or despondency. There is no way for the authors to judge this view, but it seems correct and proponents have pointed to particular indices of serotonin function that differ between depressed individuals who attempt suicide and those who do not. It has also been observed that the inception of modern antidepressant medications has not greatly altered the rate of suicide among depressed patients. Manic-depressive illness, endogenous depression, depression resulting from a debilitating disease (particularly Huntington disease, cancer, and AIDS), pathologic grief, and depression in an alcoholic or schizophrenic all carry the risk of suicide. In manic-depressive disease and endogenous depression, the risk of suicide over the lifetime of the patient is about 15 percent (Guze and Robins). In Robins' series of 134 pa-

tients who committed suicide, 47 percent had a known depressive illness and 25 percent were alcoholic. Other series have recorded even higher rates of depression, alcoholism, and other forms of drug abuse (see Andreasen and Black).

Most suicides are planned, not impulsive. Furthermore, the intention of committing suicide is more often than not communicated to someone significant in the patient's life. In Robins' series, 4 out of 5 patients had made medical contact in the year before death. The message may be in the form of a direct verbal statement of intent, or it may be indirect, such as giving away a treasured possession or revising a will. It is known that successful suicide is three times more common in men than in women and particularly common among men over 40 years of age. Patients with a history of suicide in either mother or father carry a higher risk than those without such a history. A previous suicide attempt adds to the risk. Experience has instructed that important deterrents to suicide are devout Catholicism or comparable religious belief (suicide is a sin), concern about the suffering it would cause the family, and fear of death sincerely expressed by the patient. However, no single one of these attributes stands out as entirely predictive of suicide. As a consequence, one is left with clinical judgment and an index of suspicion as the main guides. The only rule of thumb is that all suicidal threats are to be taken seriously and all patients who threaten to kill themselves should be evaluated by a psychiatrist.

Some physicians are reluctant to question depressed patients about the presence of suicidal thoughts on the grounds that this might upset them. More likely it is the physician who is upset by this questioning, for surely the mention of suicide will not alarm persons who are determined to end their lives or offend those with no such intention. Rather, a query of this type is apt to be appreciated by the depressed patient because it expresses the physician's concern and indicates that the patient's behavior is taken seriously. Should a patient's manner or conversation raise a suspicion of suicidal intent, the issue should be quickly taken up by the physician. If the suicidal patient refuses hospitalization, the family should be consulted, along with an intimate friend or clergyman if appropriate, to urge the patient's cooperation. Should all efforts fail, the only recourse may be commitment to a psychiatric ward. Although an action of this sort is bound to be stressful for all concerned, hard feelings engendered by a short period of enforced confinement vanish in time; but those who mourn the loss of a loved one through a preventable suicide are apt to be unforgiving.

Among patients who have been hospitalized because of a preoccupation with suicide, a particular danger attends the phase of recovery from depression, when the physician may be lulled into a false sense of security. In either case, a psychiatrist should assume the responsibility for setting up a program of therapy and arranging for transfer to a psychiatric ward if this is necessary, or for outpatient treatment. For the depressed patient with terminal disease, the authors have taken the personal position of providing comfort by all possible means but not in assisting the patient to commit suicide.

CHAPTER 58

THE SCHIZOPHENIAS AND PARANOID STATES

SCHIZOPHRENIA

Schizophrenia is among the most serious of all unsolved diseases. This was the opinion expressed 50 years ago in *Medical Research: A Mid-Century Survey*, sponsored by the American Foundation. Because of a worldwide lifetime prevalence of about 0.85 percent and particularly because of its onset early in life, its chronicity, and the associated social, vocational, and personal disabilities, the same conclusion is justified today (Carpenter and Buchanan).

Definitions Neurologists and psychiatrists currently accept the idea that schizophrenia comprises a group of closely related disorders characterized by a particular type of disordered thinking, affect, and behavior. The syndrome by which these disorders manifest themselves differ from those of delirium, confusional states, dementia, and depression in ways that will become clear in the following pages. Unfortunately, the diagnosis of schizophrenia depends on the recognition of characteristic psychologic disturbances largely unsupported by physical findings and laboratory data. This inevitably results in a certain diagnostic imprecision. In other words, any group of patients classified as schizophrenic will to some extent be “contaminated” by patients with diseases that only resemble schizophrenia, whereas variant or incomplete cases of schizophrenia may not have been included. Moreover, there is not full agreement as to whether all the conditions called schizophrenic are the expression of a single disease process. In America, for example, *paranoid schizophrenia* is usually considered to be a subtype of the common syndrome, whereas in some parts of Europe it is thought to be a separate disease.

Historical Background Present views of the disease now called schizophrenia originated with Emil Kraepelin, a Munich psychiatrist, who first clearly separated it from manic-depressive psychosis. He called it *dementia praecox* (adopting the term introduced earlier by Morel) to refer to a deterioration of mental function at an early age, from a previous level of normalcy. At first, Kraepelin believed that “catatonia” and “hebephrenia,” which had previously been described by Kahlbaum and by Hecker, respectively, as well as the paranoid form of schizophrenia, were separate diseases, but later, by 1898, he had concluded that these were all subtypes of a single disease. He emphasized an onset in adolescence or early adult life and a chronic course, often ending in marked deterioration of personality as the defining attributes of all forms of the disease. Early in the twentieth century, the Swiss psychiatrist Eugen Bleuler substituted the term *schizophrenia* for *dementia praecox*. This was an improvement insofar as the term *dementia* was already being used to specify the clinical effects of another category of disease, but unfortunately the new name implied a “split personality” or “split mind.” By the “splitting” of psychic functions, Bleuler meant the lack of correspondence between ideation and emotional display—the inappropriateness of the patient’s affect in relation to his thoughts and behavior. By contrast, in manic-depressive disease, the patient’s mood and affect accurately express

his morbid thoughts. Bleuler also introduced the terms *autism* (“thinking divorced from reality”) as an aspect of the thought disorder.

Bleuler believed that all the schizophrenic syndromes were composed of primary or basic symptoms, summarized by some authors as the “four A’s” (loose associations, flat affect, ambivalence, and *autism*), and of secondary or “partial phenomena” such as delusions, hallucinations, negativism, stupor, etc. However interesting this formulation proved to be, the psychologic abnormalities are so difficult to define precisely that this arbitrary division has been of only mnemonic value.

Other early theories were those of Adolf Meyer and Sigmund Freud. Meyer, who introduced the “psychobiologic approach” to psychiatry, sought the origins of schizophrenia, as well as other psychiatric syndromes, in the personal and medical history of patients emphasizing particularly their habitual reactions to life events. Freud viewed schizophrenia as a manifestation of a “weak ego” and an inability to use the ego defenses to control anxiety and instinctual forces—the result of a fixation of libido at an early (“narcissistic”) stage of psychosexual development. None of these theories has been corroborated, and none ever gained wide acceptance.

In 1937, Langfeldt advanced the important concept that schizophrenia consists principally of two different types of psychosis: (1) one that corresponds to the disease considered briefly earlier, i.e., Kraepelin’s *dementia praecox* and Bleuler’s schizophrenia (characterized essentially by early onset of anhedonia and asociality and by a poor prognosis), and (2) a type that occurs acutely, on a background of a stable premorbid personality, often with clouding of consciousness, prominent delusions and hallucinations, and demonstrable precipitating factors. For the second type, which could be a manifestation of several diseases, Langfeldt proposed the term *schizophreniform psychosis*. Cases of the latter type tend to have a favorable prognosis. Subsequent studies have validated this distinction, as indicated further on.

A more contemporary biologic approach to schizophrenia has involved the isolation of its many persistent mental and behavioral features into three clusters: (1) so-called *negative symptoms* of diminished psychomotor activity (poverty of speech and spontaneous movement, flatness of affect); (2) a “disorganization” syndrome, or *thought disorder* (fragmentation of ideas, loosening of associations, tangentiality, and inappropriate emotional expression); and (3) *reality distortion*, comprising hallucinations and delusions or so-called positive symptoms (Liddle; Liddle and Barnes). The separation of behavior into “positive” and “negative” symptoms was believed to be useful in distinguishing among the types of schizophrenia and perhaps to align the mental status with conventional physiologic analysis but this view is an oversimplification (see review by Andreasen). Although there is still disagreement as to whether each of these groups is primary or secondary, positive or negative, they have the value of lending themselves to objective study and correlation with other biologic measures.

Epidemiology Schizophrenia has been found in every racial and social group so far studied. On average, 35 new cases per 100,000 population appear annually (Jablensky). As indicated earlier, studies of prevalence suggest that at any given time 0.85 percent of the world population is suffering from schizophrenia, and expectancy rates are estimated to be as high as one chance in 100 that a person will manifest the condition during his or her lifetime. The incidence of schizophrenia has remained more or less the same over the past several decades. Males and females are affected with equal frequency. For unknown reasons, the incidence is higher in social classes showing high mobility and disorganization. It has been suggested that this is a secondary result of “downward drift” as a result of deteriorating function caused by the disease to the lowest socio-economic stratum, where one finds poverty, crowding, limited education, and associated handicaps; and the same data have been used to support the idea that schizophrenia can be caused by such social factors. The fertility of schizophrenics, formerly lowered by institutionalization, is now approaching that of the general population, which will probably result in an increase in the number of cases.

Schizophrenic patients occupy about half the beds in mental hospitals—more hospital beds than are allocated to any other single disease---and they constitute 20 to 30 percent of all new admissions to psychiatric hospitals (100,000 to 200,000 new cases per year in the United States). The age of admission to the hospital is between 20 and 40, with a peak between 28 to 34 years. The economic burden created by this disease is enormous—in 1990, the direct and indirect costs in the United States were estimated to be \$33 billion (Rupp and Keith).

Clinical Syndrome of Schizophrenia

The central abnormalities in schizophrenia are hallucinations and a special disorder in the perception of one's self in relation to the external world. It is unlike the condition that prevails in delirium and other confusional states, dementia, and depression. Some patients with chronic schizophrenia, before the onset of a flagrant psychosis or when in remission, show none of the schneiderian first-rank symptoms and—during brief testing of mental status—might even pass for normal. But on long-term observation they are vague and preoccupied with their own thoughts. They seem unable to think in the abstract, to understand fully figurative statements such as proverbs, or to separate relevant from irrelevant data. There is what has been called a circumstantiality and tangentiality about their remarks. They fail to communicate their ideas clearly. Their thinking no longer respects the logical limits of time and space. Parts are confused with the whole or are clustered together or condensed in an illogical way. Opposites may be considered as identical, and conceptual relationships are distorted. In an analysis of a problem or a situation, there is a tendency to be overinclusive rather than underinclusive (as happens in dementia). In conversation and in writing, the trend of an argument or thought sequence is often interrupted abruptly, with a resulting disorder of verbal communication. Such disorders of thinking are reflected in the patient's behavior. There is over time a general deterioration in functioning, social withdrawal and at times bizarre actions, idleness, self-absorption, and aimlessness.

In more severely affected schizophrenic patients, thinking is even more disintegrated. They appear to be totally preoccupied with their inner psychic life (thus the early use of the term *autism*) and may do no more than utter a series of meaningless phrases or

neologisms, or their speech may be reduced to a nonsensical “word salad.” They are unable to attend to any task or to concentrate, and their performance is interrupted by sudden “blocking” or by insertion of some extraneous idea or inexplicable act, somewhat like that observed in a severely confused or delirious patient. At times these patients are talkative and exhibit odd behavior; at other times they are quiet and idle; in the extreme, the patients are mute or assume and maintain imposed postures or remain immobile (catalepsy). With remission, they may remember much of what has happened or they may have only fragmentary memories of events that occurred.

Typical of schizophrenia is the patient's expression of remarkably unusual experiences and ideas. The patient may express the thought that his body is somehow separated from his mind, that he does feel like himself, that his body belongs to someone else, or that he is unsure of his own identity or even sex. These experiences have been called *depersonalization*. *Thought insertion*, wherein it seems to the patient that an idea has been implanted into his mind, or *thought withdrawal*, wherein an idea has been extracted from his mind by an outside agency, are other parts of this problem. Closely related, and characteristic of schizophrenia, are ideas of being under the control of some external agency or being made to speak or act in ways that are dictated by others, often through the medium of radar, telepathy, or the internet (*passivity feelings*). Frequently, there are *ideas of reference*—that the remarks or actions of others are subtly or overtly directed to the patient. Finally, the patient may feel that the world about him is changed or unnatural, or his perception of time may be altered, not in a brief episode like the *jamais vu* of a temporal lobe seizure, but continuously; this is the phenomenon of *derealization*.

Auditory hallucinations are frequent and a core feature of the classic illness. They consist of voices that comment on the patient's character and activities and are usually accusatory, threatening, or claiming control of the patient's actions. The voices may or may not be recognized; they may belong to one person or two or more persons who converse with the patient or with one another. Seldom can the voices be localized to a point outside the patient. Instead, they seem to come from within the patient, so that at times they cannot be distinguished from his own feelings and thoughts. Certain somatic hallucinations and delusions may predominate in any one individual. Visual, olfactory, and other types of hallucinations also occur but are much less frequent. The patient believes in the reality of these hallucinations and often weaves them into a delusional system.

It should be reiterated here that hallucinations are a feature of a number of neurologic processes but in most, visual hallucinations predominate whereas auditory hallucinations are the hallmark of schizophrenia. Of interest in this regard is “The Report on the Census of Hallucinations” by Sidgwick in 1894 that suggested (as cited by Frith) that almost one in ten ostensibly normal respondents had experienced hallucinations, mostly visual. The illnesses in which hallucinations and delusions are prominent, for example hallucinogenic drug ingestion and the Charles Bonnet syndrome (see pages 220 and 405), have been reviewed by Frith.

Of interest has been the belated affirmation of the importance of negative symptoms in schizophrenia. Liddle and Barnes, looking objectively at all aspects of schizophrenic thought and behavior, divided them into four groups: (1) flat affect, diminution in expressive gestures, latency of response, reduced spontaneous movements, apathy, restricted recreational activities, inability to feel intimate or close, and motor retardation. These negative symptoms,

which have resemblances to frontal lobe behavioral syndromes, correlate with reduced blood flow in the frontal lobes and a poor prognosis: (2) disorganization of thought, incoherence, inappropriate affect, illogicality, bizarre behavior, aggression, agitation, and tangentiality. These abnormalities are nonfrontal: (3) hallucinations and delusions that the patient's mind is being read and that thoughts are being extracted from his mind or being controlled or broadcasted; (4) suspicion, hostility, and delusions of reference. These authors also found an overlap of symptoms from one group of symptoms to another, i.e., the four syndromes can coexist in various combinations. However valid such subdivisions prove to be, they offer a more systematic neurologic approach to schizophrenia and direct attention to the functional anatomy and physiology of particular neuronal systems in the brain (see further on; also Friston et al).

The behavior of the schizophrenic who experiences these ideas and feelings is correspondingly altered. Early in the course of the illness, normal activities may be slowed or interrupted. No longer does the patient function properly in school or at work. Associates and relatives are likely to find the patient's complaints and ideas disturbing. The patient may be idle for long periods—preoccupied with inner ruminations—and may withdraw socially. A panic or frenzy of excitement may lead to an emergency ward visit (a high degree of anxiety occurring for the first time in a young person should always raise the suspicion of a developing schizophrenia); or the patient may become mute and immobile, i.e., *catatonic*. Attacks of catatonia are infrequent, but lack of will, drive, assertiveness, etc., are characteristic of the disease. Ultimately a deteriorated and dilapidated state occurs which, in the extreme, results in an unkempt and malnourished state with which the public unfortunately associates schizophrenia. Some individuals of this type roam the streets and live in appalling conditions on the fringes of society where they are subject to the criminal behavior of others.

Much has been made of the change in affect observed in schizophrenic patients. Usually the affect is said to be "flat," i.e., the patient's manner is bland or apathetic; he may casually express ideas that would be disturbing to a normal person, even smiling or laughing over a morbid idea. To the authors, this has not been an impressive feature of the illness. More often one observes agitation and an appropriate display of emotion in response to a threatening hallucination or delusion, although as the illness advances increasing indifference and preoccupation appear, as though the patient had become inured to the abnormal thoughts and feelings.

That schizophrenia of all types carries a significant risk of suicide is not generally appreciated. In a 40-year follow-up study of schizophrenic and manic-depressive patients, Winokur and Tsuang found that in each group the proportion of patients who had committed suicide was the same (about 10 percent). Suicide occurs most often among young schizophrenic patients living apart from their families who are frightened and overwhelmed by their symptoms and experience the difficulties of independent existence. Sometimes suicide is a response to terrifying and commanding vocal hallucinations. The schizophrenic patient may also be homicidal, usually acting upon a delusion that he or she has been wronged by the victim. Incidents of this type are unpredictable, but the presence of escalating paranoia should be a warning.

Finally, whether a genuine dementia results from chronic schizophrenia has been much debated over the years. The notion of this type of "dementia praecox" was discarded but clinicians continue to encounter cases of progressive generalized and sometimes severe intellectual impairment in both acute and long-stand-

ing cases of schizophrenia; this has been true before and after the modern era of therapeutics. The problem has been highlighted by de Vries and colleagues who analyzed what they considered to be a frontotemporal type of dementia in 8 patients after 9 to 30 years of schizophrenia; they found minor changes on computed tomography (CT) scans, and frontal or temporal hypoperfusion on single photon emission computed tomography (SPECT).

Diagnostic Criteria

Included in the early definitions of the disease, both of Kraepelin and of Bleuler, were a characteristic premorbid personality, an insidious onset of the more flagrant symptoms in adolescence or early adult life, and a chronic but fluctuating course with a tendency to progressive deterioration. Both regarded hallucinations and delusions as secondary or accessory symptoms that could be absent, as in their "simple schizophrenia." They emphasized the absence of primary disturbances of perception, orientation, memory, and other cognitive functions, which played such a large role in other cerebral diseases. Embodied in both their definitions was the concept of disease characterized by a poor prognosis and, as stated earlier, a unique constellation of symptoms different from those of delirium, confusion, depression, mania, dementia—the other manifestations of brain diseases.

Attempts to apply these diagnostic criteria initially met with difficulty, especially when hallucinations and delusions were absent. In order to overcome this, Schneider proposed that the distinction between primary and accessory manifestations be abandoned. He attached more importance and reliability to the occurrence of auditory hallucinations, perceptual delusions (misinterpretation of what the patient hears and feels), and disturbances of thinking, often reflected in the experience that one's thoughts and actions are being broadcast and are not one's own but are under the influence of some outside agency (experiences of alienation and influence). This constellation of symptoms, which was more precise and easy to recognize, came to be known as *Schneider's first-rank symptoms of active schizophrenia*. Strict adherence to Schneider's diagnostic criteria, when applied to a group of patients admitted to the hospital with a diagnosis of schizophrenia, served to distinguish two groups of patients—those with and those without first-rank symptoms (Taylor). Those without hallucinations, delusions, and thought control or projection responded more poorly to treatment and required a more prolonged period in the hospital and higher doses of neuroleptic drugs than did those with these features. The two groups correspond closely to two categories of schizophrenic disorders recognized by Robins and Guze on the basis of prognosis. The Schneider-positive, poor-prognosis schizophrenia (also referred to in older literature as *nuclear or process schizophrenia*) corresponds closely to Kraepelinian schizophrenia; many of the Schneider-negative patients with good prognosis are probably suffering from some other nonschizophrenic illness or schizopreniform illness, or manic-depressive disease (see Chap. 57).

Feighner and colleagues, who drew up a set of diagnostic criteria for research in the major psychiatric syndromes [which were subsequently incorporated in successive editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)], stated that the diagnosis of schizophrenia is tenable only in the presence of (1) a chronic illness of at least 6 months' duration and a failure (after an acute episode) to return to the premorbid level of psychosocial adjustment, (2) delusions or hallucinations without significant confusion or disorientation (i.e., without clouding of consciousness),

(3) verbal productions that are so illogical and confusing as to make communication difficult (if the patient is mute, diagnosis should be deferred), and (4) at least three of the following manifestations: (a) among adults, the lack of a partner or spouse; (b) poor premorbid social adjustment or work history; (c) family history of schizophrenia; or (d) onset of illness prior to age of 40 years. Important negatives include the absence of a family history of manic-depressive disease, absence of an earlier illness with depressive or manic symptoms, and absence of alcoholism, drug abuse, or other organic disease.

While the Feighner criteria are so strict as to exclude certain patients with a schizophrenic illness, those patients who are included will be found to constitute a fairly homogeneous group. Morrison and colleagues, who used these criteria, noted that after a 10-year period there was practically no change in diagnosis; they had reliably separated schizophrenia from schizophreniform psychosis (in which only the acute delusional-hallucinatory syndrome was present), and from manic-depressive psychosis.

Subtypes of Schizophrenia

Psychiatrists have traditionally distinguished a number of subtypes of schizophrenia, although the usefulness of these distinctions has been questioned in recent years. Indeed, the various types may overlap or change during the course of the illness. And, there are cases that do not conform entirely to the conventional subtypes or display characteristics of more than one type (referred to as *undifferentiated* or mixed types). Despite these limitations, the subtyping of schizophrenia still has descriptive value and carries the imprimatur of DSM-IV, for which reasons the traditional categories are briefly reviewed here.

Simple Schizophrenia In this least florid form, the patient exhibits thought disorder, bland affect, social withdrawal, and reduction in speech and movement, all of which impair work performance. Poverty of psychomotor activity is the dominant feature; however, hallucinations and delusions are absent. At this stage the diagnosis is often uncertain. A disorder of thinking may be difficult to elicit, but from time to time a peculiar idea emerges in conversation or is discovered in letters. Objective study of thinking, by means of formal psychologic tests (Solovay et al), has shown it in most instances to be "disorganized, confused, and ideationally fluid with many peculiar words and phrases." This is a refinement of Bleuler's characterization of "loosening of associations." Terms such as *schizoid*, *schizotypal*, *latent*, or *borderline schizophrenia* have been applied to this form of the illness. In many cases this seems to be an extension of the childhood schizoid personality traits into adolescence. Eventually, in most cases an outbreak of flagrant hallucinations and delusions occurs—an acute schizophrenic episode that brings the patient to the attention of a physician. The patient usually needs to be hospitalized and medicated because of a suicidal or, rarely, homicidal attempt or some other unexpected behavior. As a rule, a remission follows within a few weeks or months, during which the patient is again able to function, but at a level below that which is expected on the basis of his natural abilities and intelligence, and he continues to be lacking in drive, initiative, and enterprise, much as he was before the outbreak.

These patients may attract notice in middle and high school because they behave in an odd manner, tending to remain by themselves ("loners"), making no effort to adjust to a social group at

school or to find work, have dates, or later, to establish a family unit. If support and protection is not provided, such persons drift from one menial job to another, always shy, withdrawn, and relatively indifferent to their surroundings.

Catatonic Schizophrenia This, the most readily differentiated type of schizophrenia, is now quite rare. Characterized by an extreme diminution in psychomotor activity, it was originally described by Kahlbaum and considered to be a mental disturbance *sui generis* until Kraepelin recognized it as another form of schizophrenia. In about 60 percent of cases the onset is relatively acute. In the remainder, after a long prodrome of slackening interest, apathy, and dreamy preoccupation, a state of dull stupor supervenes, with mutism, inactivity, refusal of food, and a tendency to maintain one position "like a mummy" (*catalepsy*). The facial expression is vacant, the lips are pursed; the patient lies supine without motion or sits for hours with hands on knees and head bowed (a form of catalepsy). If a limb is lifted by the examiner, it will sometimes be held in that position for hours (*flexibilitas cerea*). Urine and feces are retained or there is incontinence. The patient may require tube-feeding (or will eat mechanically) and has to be dressed and undressed. Pinprick or pinch induces no reaction. Extreme "negativism," every command being resisted, characterizes some cases. Echolalia and echopraxia are observed occasionally. Yet these patients may be fully aware of what is said to them or happening around them and will reproduce much of this information during a later spontaneous remission or one induced by intravenous sodium amytal or midazolam. Even if untreated, the patient, after weeks or months in this state, begins to talk and act more normally, and there is then rapid recovery. In certain phases of catatonia there may be a period of excitement and impulsivity, during which the patient may be suicidal or homicidal.

As mentioned, for reasons that are unclear, this form of schizophrenia is now seen infrequently, and there is increasing recognition of the fact that its catatonic features are often manifestations of a depressive illness rather than of schizophrenia.

Disorganized, or Hebephrenic, Schizophrenia This was believed by Kraepelin to be a particularly malignant form of the disease. It tends to occur at an earlier age than the other varieties, hence the prefix *hebe* ("youth"). The thought disorder is pronounced—there is a striking incoherence of ideas and a grossly inappropriate affect; the frequent occurrence of hallucinations and delusions leaves little doubt that the patient is psychotic. The visual and auditory illusions and hallucinations are usually more in the nature of symbolic interpretations than abnormal perceptions. Kraepelin remarked on the changeable, fantastic, and bizarre character of the delusions. Motor symptoms, in the form of grimacing, stereotyped mannerisms, and other oddities of behavior, are prominent. In hebephrenic patients, since early life, there is likely to have been a history of tantrums and of being overly pious, shy, fearful, solitary, conscientious, and idealistic—traits that may have marked these individuals as odd. This latter state corresponds to what was referred to earlier on as a *schizoid personality* but could just as well represent the early phase of the disease itself (see Chap. 56).

Paranoid Schizophrenia This is one of the most frequent and well-circumscribed types. The mean age of onset is in the early forties, much later than that of the preceding types (Winokur). The central feature is the preoccupation with one or more delusions related to a single or to a limited ensemble of themes, accompanied

by auditory hallucinations. More often than not, the delusional hallucinatory content is persecutory, but it may also be religious, depressive, grandiose, or bizarrely hypochondriacal in nature. Delusional jealousy may be added. Many such patients settle into a chronic hallucinatory psychosis with disorders of thinking featuring mistrust and suspiciousness. They appear cold, aloof, and indifferent.

Some European psychiatrists, impressed with the lack of schizoid traits in the premorbid period and late onset have insisted that paranoid schizophrenia is a separate disease. The studies of Rosenthal and colleagues and the clinical and family studies of Winokur tend to bear them out in that simple, catatonic, and hebephrenic types have different characteristics from paranoid schizophrenia.

There are, of course, other psychiatric illnesses in which paranoid delusions appear, notably manic-depressive psychosis, dementia, and delirium. Alcoholic auditory hallucinosis also stands as a separate illness (page 1008). There is, in addition, a special form of *delusional disorder (paranoia)* in which the individual is consumed by a single persecutory, grandiose, or amorous delusional system without any other disorder of thinking. An exotic form is known as *folie à deux*, in which two closely related persons share a delusional system. These types of paranoia are discussed further on in this chapter.

Acute Schizophreniform Psychosis A special problem arises in the diagnosis of a rapidly evolving psychotic syndrome with florid hallucinations or delusions that clear in several weeks or less, with or without treatment. This most often turns out to be the initial attack of mania or of intoxication with a psychotropic-hallucinogenic drug, for which reason it is not accorded a separate subtype of schizophrenia. The resolution of the diagnostic dilemma often depends on the patient's premorbid status and the course of events that follows the acute episode. This topic is discussed further on under "Diagnosis."

Remissions and Exacerbations Some schizophrenic patients are subject to periodic exacerbations of their illness, sometimes at regular intervals, as if the process was a metabolic disorder. Remissions that allow some degree of functioning in society are more frequent and lasting when medication is given and long institutionalization is avoided. A small proportion of patients (about 10 percent), after an acute schizophrenic episode, have a long-lasting and fairly complete remission before lapsing into a chronic form of the illness. Unfortunately, these latter patients, at the time of their acute psychosis, cannot be distinguished from those few who will have a permanent remission.

Modern therapeutic programs have vastly reduced the number of patients in mental hospitals. However, readmission rates have also risen (revolving-door phenomenon), and the total number of very young and very old patients in hospitals has even increased slightly. The life expectancy of schizophrenic patients is somewhat reduced, possibly because of the malnutrition, neglect, and exposure to infections that occur in some public institutions and from living on the streets or in marginal circumstances.

Neurologic and Neuropsychologic Abnormalities in Schizophrenia

The early findings of Kraepelin and of Bleuler, that many schizophrenic patients will, on detailed examination, show some neuro-

logic abnormalities, have been substantiated by Stevens, Kennard, Hertzig and Birch, Tucker and colleagues, and Woods. They all found a much higher frequency of "soft neurologic signs" in schizophrenic patients than they did in a healthy population. The signs to which they refer include impersistence in assigned tasks, asterognosis and graphesthesia, sensory extinction, hyperreflexia and hyporeflexia, slight tendency to grasping, mild impairment of coordination and disturbances of balance, abnormal (choreiform) movements, abnormalities of motor activity, adventitious and overflow movements, anisocoria, slight esotropia, and faults in visual auditory integration. Signs of this type were noted in 50 percent of patients and correlated with the degree of cognitive disorder. Also evident in about one half of schizophrenic patients are subtle defects in ocular tracking movements (Levin et al). These take the form mainly of slowed smooth pursuit and intrusions of saccades during pursuit; some relatives of schizophrenic patients also show these eye signs when carefully tested. In contrast, "hard neurologic signs" (such as unilateral motor or sensory defects) are not seen unless they are due to an engrafted neurologic disease. Electroencephalographic (EEG) abnormalities have been detected in about one third of patients but are generally minor; their meaning is uncertain, especially if they have occurred after long-standing treatment. When these were the focus of research in the past, they were more frequent in the group of schizophrenic patients who had a positive family history and in those with enlarged ventricles (Murray et al).

Sophisticated psychometric testing has disclosed abnormalities not so much in intelligence and memory (which are only slightly reduced in 20 to 30 percent of cases) as in other psychologic functions. Alertness is not impaired, but the ability to maintain attention, as measured by continuous performance tasks, is reduced (Seidman). In tests of verbal and visual pattern learning, problem solving, and memorizing, Cutting found a surprising degree of impairment in both acute and chronic schizophrenic patients (and in patients with retarded depression) not attributable to electroconvulsive therapy, seizures, drugs, or other diseases. In the acute schizophrenic patient, verbal memory was more affected than visual pattern memory, in agreement with the findings of Flor-Henry that left-hemispheric functions are more reduced than right-sided ones. Yet, in the chronic schizophrenic, there was evidence of bihemispherical impairment.

Theories of Causation and Mechanism

Although there is no universal agreement as to the cause of the disease, an increasing weight of evidence favors an interaction between a genetic predisposition and one or more early developmental events. One widely held contemporary hypothesis is that this disease reflects an underlying developmental disorder, determined either genetically or because of an environmental insult, leading to abnormalities of synaptic connectivity, prominently affecting the hippocampus and prefrontal cortex. The evidence supporting this view is summarized briefly later. More detailed analysis of potential causes than can be given here may be found in reviews of Waddington, Carpenter and Buchanan, Harrison, Pearson, and Freedman.

Genetic Factors Several authors have estimated that genetic factors can account for upward of 80 percent of the risk of developing schizophrenia. The early studies of Kallmann showed that the frequency of disease in 5000 siblings of schizophrenic patients was

11 percent, in contrast to slightly less than 1 percent in the general population. In 90 sets of fraternal twins of whom one had schizophrenia, the incidence of disease in the other twin was also 11 percent, the same as in nontwin siblings; however, in 62 sets of monozygotic twins, the incidence in the second twin was 68 percent. The risk that a child of a schizophrenic parent will develop schizophrenia is the same as that for the sibling of a schizophrenic patient (i.e., 11 percent); if one sibling and one parent have schizophrenia, the risk is 17 percent; if both parents are schizophrenic, the chances are 46 percent that the child will have the disease. Subsequent family and twin studies have repeatedly confirmed these findings (see Goodwin and Guze for a more complete tabulation). It is noteworthy that the penetrance of this trait appears to be less than it is for manic-depressive disease.

While the importance of genetic factors in the etiology of schizophrenia is undeniable, a mendelian pattern of inheritance has not been determined. Within the last several years, polymorphisms in several genes have been implicated as risk factors for schizophrenia. Such genes include those expressing neuregulin, dysbindin, COMT (catechol-O-methyltransferase), proline dehydrogenase, and DISC1 ("disrupted in schizophrenia 1"; Harrison and Owen, O'Donovan et al).

The studies implicating these genes must be interpreted cautiously because the functional significance, if any, of the allelic variants are not defined. Nonetheless, considered together, these findings point to disorders both of neuronal development and neurotransmission. Further supporting this view is the provocative finding that allelic variants associated with specific neurotransmitter systems (in the genes that code for serotonin receptors and COMT) are overrepresented in schizophrenia; these are more compelling than the aforementioned ones because the genetic variants have well-defined functional consequences. A summary of the genetic studies to date is given by Harrison and Owen and by O'Donovan et al.

Environmental and Developmental Aspects There continues to be debate concerning the relative importance of genetic versus environmental factors in the causation of the disease. The lack of complete concordance between monozygotic twins and the fact that approximately 80 percent of schizophrenic patients have no other family members with the disease indicate that factors other than genetic ones probably play a role. Some of these appear to be early events that occur *in utero* or infancy and alter normal developmental programs.

The neuropsychiatric literature contains tentative and only circumstantial evidence that schizophrenia is associated with brain injury during the intrauterine or neonatal period. Reportedly, there is an increased incidence of obstetrical complications during the gestational period and birth of schizophrenic patients. Also consistent with an early adverse environmental factor is the observation by several groups that in the northern latitudes, more schizophrenic persons are born in the winter months and to women who were exposed to influenza during midpregnancy—inviting speculation that a viral infection may have damaged the fetal brain. Mortenson and colleagues found that being born in an urban region, particularly in February or March, carried with it a higher risk for developing the disease than having an affected parent or sibling. They suggested that these inexplicable demographic features accounted for more cases than did inheritance. Among 5362 infants who were followed prospectively since their birth in 1946 by Jones and colleagues, the 30 individuals who later developed schizo-

phrenia had been delayed in the attainment of motor milestones and speech and exhibited greater social withdrawal and schoolroom anxiety as well as lower scholastic achievement. Thus it appears that schizophrenic patients are not entirely normal in early childhood, but whether their abnormalities are already early manifestations of schizophrenia or risk factors for the disease has not been determined.

Neuropathologic, Brain Imaging, and Neurophysiologic Findings

Notably lacking in all the previously described reports of developmental changes are neuropathologic data. Dunlap, in 1928, in a critical analysis, repudiated all earlier interpretations of cellular alterations that had been reported in the brains of schizophrenic patients. He pointed out that many of them, such as dark "sclerotic" nerve cells, were artifacts and that the presence of lipofuscin was a nonspecific age change. He also asserted that the neuronal loss described by Alzheimer was based on impression and could not be corroborated by quantitative methods. Similarly, the claim of Oscar Vogt of neuronal loss in the cortex was rejected by his contemporaries, Spielmeyer and Scholz, who were unable to find any consistent cellular abnormality in schizophrenia. Spielmeyer, in a critical study of the problem in 1930, concluded that such changes as had been described up to that time could not be clearly distinguished from the normal, and that the more marked changes in some cases were likely due to coincidental causes (age, complicating disease, etc.). Corsellis, on the basis of yet another thorough review of the neuropathologic data in 1976, found no reason to deviate from Spielmeyer's view. The uncertain neuropathologic findings were responsible for the enigmatic categorization of schizophrenia as a "functional" disorder, i.e., a disorder with no structural basis.

Nonetheless, there has been a general sense that the number of neurons in the gray matter is normal, but the pyramidal cells are smaller and more densely packed, resulting in a thinning of laminae II and III. These cytoarchitectonic changes have been the most difficult to interpret and to confirm. Capricious methods such as the rapid Golgi stain indicate that density of dendritic spines is decreased in the frontal and temporal cortex of chronic schizophrenic patients.

A number of more contemporary reports using special cell-labeling studies have found cytoarchitectonic abnormalities in the brains of schizophrenic patients. For example, Akbarian and colleagues, following previous similar findings, have described an aberrant distribution of interstitial neurons in the frontal lobe white matter. These cells have their origin in the embryologic subplate that guides neuronal migration, and the inference is that the abnormally migrating cells have formed aberrant neuronal connections. Benes and colleagues observed that the number of small neurons was reduced in at least one layer (usually layer II) of the anterior cingulate cortex. These are gamma aminobutyric acid (GABA)-releasing (inhibitory) neurons. She also noted that the arrays of macrocolumns of cortical neurons were smaller in the occipital lobes (vertical axons increased in number), but without gliosis. More recent studies have also described a paucity of GABA-ergic, inhibitory interneurons (so-called chandelier cells) in the prefrontal cortex (Woo et al). These observations suggest a developmental rather than an acquired lesion, and the absence of gliosis supports but does not prove that the developmental disorder occurs prenatally.

The advent of CT and subsequently of magnetic resonance imaging (MRI) of the brain provided a new stimulus to the ana-

tomic study of schizophrenia. Johnstone and coworkers were the first to describe ventricular enlargement and sulcal widening in 18 patients and correlate these findings with dulling of intellect and affect. In a study of 58 chronic schizophrenics under the age of 50 years, Weinberger and colleagues found enlargement of the lateral ventricles in 40 percent. In 9 of 11 CT studies, the third ventricle was found to be enlarged, and in 14 of 17 studies, the sulci were widened. In 15 pairs of monozygotic twins, one of whom had schizophrenia, the anterior hippocampi were found to be smaller and the lateral and third ventricles larger in the affected twin (Suddath et al). Shenton and colleagues demonstrated a reduction in the volume of gray matter in the posterior part of the left superior temporal gyrus, which includes Heschl's gyri and the planum temporale. The degree of volumetric reduction correlated roughly with the severity of the thought disorder. A reduction in volume of the superior temporal gyrus has also been associated with the occurrence of auditory hallucinations (Barta et al). Other MRI studies have shown a volumetric change in the gray matter of the left hippocampus, parahippocampal gyrus, and amygdala (in right-handed patients). Equally compelling is the finding that young individuals having two or more relatives with the disease, and therefore being at risk for developing schizophrenia, have certain volumetric brain changes detected by imaging studies (Lawrie et al). In unaffected relatives, the left hippocampal-amygdaloid region was smaller than in healthy people but slightly larger than in affected relatives.

In an attempt to organize the neuroradiologic findings, Murray and coworkers have raised the possibility that there are two types of this disease—one with ventricular enlargement and a negative family history and the other with normal ventricles and a positive family history. In the first group of sporadic, “acquired” schizophrenia, environmental factors, such as birth injury and EEG abnormalities (see later) were thought to be more frequent. In summarizing the many cerebral changes observed in schizophrenic patients, Harrison concluded that several are quite consistent. These include mild enlargement of the lateral and third ventricles; decreased cortical volume, perhaps disproportionate in the temporal lobe; and—microscopically—diminution in size of cortical and hippocampal neurons; a diminished number of neurons in the dorsal thalamus; and a notable absence of gliosis.

Detailed neuropsychologic testing has disclosed deficits in attention and abnormalities of the P300 waves (cortical “event-related” potentials). These deficits correlate with reduced cognitive activation activity in functional MRI. It is unclear, however, if these changes represent primary defects or are secondary to an inherent lack of motivation.

Attention has also been drawn to the regional alterations of cerebral blood flow in chronic stable schizophrenic patients, as revealed by positron emission tomography (PET) and functional MRI. Weinberger and colleagues and Liddle and Barnes have reported a decrease in blood flow in the prefrontal areas during cognitive performances. Friston and associates found consistent abnormalities in the left parahippocampal region in all forms of chronic schizophrenia. Studies of regional glucose metabolism and postmortem norepinephrine measurements have yielded equivocal data, although most patients show a reduction in glucose metabolism in the thalamus and frontal cortex. Several lines of investigation point to the medial part of the left temporal lobe and related limbic and frontal systems as being the focus of a developmental abnormality (see Tsuang et al and Friston et al for pertinent references). According to Sabri et al, the inconsistent findings on func-

tional imaging may be accounted for by correlations between certain blood flow patterns and specific symptoms. For example, the formal thought disorder corresponded to increased flow in the frontal and temporal regions, while delusions and hallucinations were associated with reduced flow in the cingulate, left frontal, and temporal areas. Silbersweig et al have performed PET studies in schizophrenic patients while they were experiencing auditory hallucinations and found increased blood flow mainly in both thalamus, left hippocampus, and right striatum, but also in the parahippocampal, orbitofrontal, and cingulate areas. One of their drug-naïve patients with visual and auditory hallucinations showed activation in these regions.

Neurotransmitter Abnormalities When certain hallucinogens, such as mescaline and lysergic acid diethylamide (LSD), were first observed to induce hallucinations and abnormalities of thinking, it was hoped that they might provide experimental models of schizophrenia. This hope was never realized, but there are instances, difficult to interpret, in which these drugs have induced a prolonged relapse in a schizophrenic patient. Similarly, when methionine, a potent source of methyl groups, was observed to exacerbate the symptoms of some schizophrenic patients, it was thought that a primary metabolic fault had been discovered; increased serum concentrations of dimethoxyphenylethylamine and *N*-methylated indoleamines lent support to this idea. Again, none of these observations has been unequivocally corroborated.

The leading *biochemical hypothesis* has been based on the response of psychotic symptoms to phenothiazine medications, thereby implicating the dopaminergic system of the temporal lobe (see review by Carlsson). The evidence for this is circumstantial but is supported by observations that antipsychotic drugs reduce the electrical activity of mesolimbic dopaminergic neurons in experimental models. Furthermore, there have been several demonstrations of increased concentrations of dopamine or its metabolite, homovanillic acid, in schizophrenic brains obtained at autopsy. The finding that dopamine receptors are organized in two systems, one limbic and the other cortical, has led to an expanded but purely speculative hypothesis that an excess of dopaminergic activity in the mesolimbic system gives rise to the positive symptoms of schizophrenia—i.e., psychosis—whereas a diminished activity in the mesocortical system accounts for the negative symptoms. The involvement of the mesolimbic system, which plays a role in attention, has prompted further speculation that the thought disorder of schizophrenia is attributable to a breakdown of the normal “filtering” of stimuli reaching cognition. As mentioned earlier, it has been found that a variant in the gene for COMT that enhances metabolism of dopamine is overrepresented in schizophrenia. This finding incriminates a disorder of dopaminergic neurotransmission in the pathophysiology of this disease (Egan et al).

As pointed out in the review by Freedman, however, the dopamine hypothesis has many weaknesses, the most prominent of which is the relative ineffectiveness of dopamine blocking drugs in alleviating many aspects of the disease. The complexity of dopamine systems and their interaction with other neurotransmitter circuits makes a simplistic mechanism unlikely.

More recently, an hypothesis based on changes in the serotonergic system has been proposed. As with the dopaminergic model, attention was drawn to mechanisms relating to serotonin when a new class of antipsychotics (clozapine, risperidone), which have effects on the latter system, were found to ameliorate the psychosis. Several groups have reported alterations in serotonin

receptors in the brains of schizophrenic patients (see later). A further connection is based on the finding by Williams and colleagues of an allelic variation in the gene on chromosome 13 encoding for a serotonin receptor (5-HT_{2A}) that confers a susceptibility to schizophrenia. A similar finding has been reported in a Japanese population. The variation in this gene is not sufficient to explain the presence of the disease in any one individual, if for no other reason than that many patients who are homozygous for the suspect allele do not develop schizophrenia. Perhaps a nearby region relating to the receptor may be at fault through linkage disequilibrium (see commentary by Harrison and Geddes). A third hypothesis derives from the psychosis syndrome produced by chronic ingestion of phencyclidine (PCP), an *N*-methyl-D-aspartate (NMDA) antagonist. This implicates the glutaminergic system but it must be pointed out that the dopaminergic and glutaminergic systems converge on certain cortical neurons and that glutaminergic release is modulated in several places in the brain by dopamine.

A great variety of physiologic and endocrine differences between schizophrenic and healthy subjects have been claimed. None has proved to be significant. Since psychoses may complicate corticosteroid administration and certain endocrine disorders (Cushing syndrome, thyrotoxicosis, see later), there have been many attempts to uncover such abnormalities in the schizophrenic patient. All have failed.

Psychosocial Hypotheses The notion that psychosocial factors play an important role in the genesis of schizophrenia was a recurrent theme in older psychiatric writings but is now given little credence. Prominent in these early writings was Freud's view, already mentioned, that the schizophrenic process represents a fixation at an early autoerotic stage of sexual development. There is no way of affirming or refuting this proposition. The same can be said for the many suggestions that disturbed intrafamily relationships engender schizophrenic traits or possibly provoke psychosis in persons who are genetically vulnerable. Behind all these suggestions was the notion that disturbed interpersonal relations in the family in some way interfered with the normal maturation of personality. Adolf Meyer believed that schizophrenia was a reaction to a series of traumatic life situations—a maladaptive response to some organic, psychologic, or sociologic factor. Others have stressed the importance of disturbed interpersonal relationships. However, with all these hypotheses, proof is lacking that such environmental factors are unique to the development of schizophrenia. Furthermore, the extent to which these aberrations of family relationships are primary or secondary cannot be ascertained.

The often-cited observations of Harlow on the deleterious effects of maternal and peer deprivation in primates opened the possibility that similar deprivations in humans may be responsible for the development of schizophrenia. However, such severe degrees of familial deprivation have rarely been documented in humans and when they were, as in some orphans, the effects were only transitory.

Diagnosis

From a neurologic standpoint, the main initial distinction to be made is between an acute schizophrenia-like psychosis (schizophreniform reaction; "good-prognosis" schizophrenia) and the chronic disease, schizophrenia (nuclear, or "process," schizophrenia). The *acute schizophreniform illness* takes the form of a delu-

sional-hallucinatory syndrome in which there is little if any disturbance of consciousness. Although such a syndrome is characteristic of schizophrenia, it may occur in the manic phase of manic-depressive disease, encephalitis, temporal lobe epilepsy, chronic amphetamine intoxication, withdrawal from alcohol after a sustained period of intoxication, and most often in the emergency department, PCP, angel dust, LSD, and other drug intoxications. On rare occasions it is seen with postpartum psychosis (see further on) and with certain endocrine and metabolic disorders, in which consciousness is not impaired. Whenever this syndrome is recognized, therefore, these several causes need to be differentiated. On our services, less than one out of five of the acute schizophreniform psychoses have proved to be due to the disease schizophrenia. This distinction is made by the premorbid history and the course of the illness. Restated, a longitudinal observation is necessary before concluding that a particular acute syndrome is due to schizophrenia. If the patient had been reclusive, withdrawn, and socially maladroit and does not seem to recover fully from the acute psychosis, then the diagnosis of schizophrenia is more likely. Lacking these features, and in particular with a full remission, one assumes the occurrence of hypomania or of a toxic-metabolic psychosis, which can usually be detected by laboratory screening for drugs and endocrine diseases. Only 10 percent of patients with classic schizophrenia will have such an acute episode. Adherence to the criteria enumerated earlier, particularly to those devised by Feighner and colleagues, will avoid most errors in diagnosis.

It is the present authors' opinion that the status of acute schizophrenia and of the so-called schizothymic and schizoaffective states brings to light a crucial nosologic problem. Namely, is the traditional separation of depressive disease, manic-depressive disease, and schizophrenia biologically sound? The suggestion is that they are linked in some way by these transitional forms. Neurologists should keep an open mind about these and other theoretical problems that lack a firm genetic and neuropathologic basis.

In addition to the acute schizophreniform psychosis described earlier, the authors have encountered the greatest difficulties in the diagnosis of schizophrenia in the following clinical situations:

1. A patient with a healthy family and premorbid history *with an acute illness* having many of the typical features of schizophrenia but *associated with confusion, forgetfulness, and/or clouding of consciousness*. Mood change may be prominent. Thus the illness combines the features of an affective disorder, schizophrenia, and a confusional state. This syndrome is characteristic of chronic hallucinogenic drug use, particularly phencyclidine intoxication, corticosteroid psychosis (drug-induced or Cushing disease), thyrotoxic psychosis, puerperal psychosis, and combat fatigue of wartime. Usually recovery is complete, and schizophrenia is excluded by the fact that the patient remains well. This may be a form of "schizoaffective" disorder.
2. *Adolescents and young adults whose social relationships are disorganized* and who are unusually sensitive, resentful, rebellious, fearful, discouraged, in trouble with school authorities and the law, and using drugs. The latter may have caused seizures, hallucinations, and withdrawal symptoms or may have resulted in addiction. Such patients are usually classified as having a borderline personality or "character disorder" that appears to go back several years; if they are incorrigible, unable to profit by experience, amoral, and in trouble with social agencies, they are called *sociopaths*. This

- type of personality disorder and social maladjustment usually turns out not to be schizophrenia.
3. There is another type of diagnostic problem, arising in *an individual who has been only marginally competent because of personality problems and many vague neurotic and hypochondriacal symptoms*, often requiring prolonged psychotherapy. Many such individuals will indeed be found to have simple schizophrenia (so-called "pseudoneurotic" form). Here errors in diagnosis usually result from a failure to assess mental status carefully and to ascertain the life profile of the disorder.
 4. *A chronic delusional-hallucinatory state in a chronic alcoholic patient* (chronic alcoholic hallucinosis). Usually the history will disclose that the illness began when alcohol was withdrawn, after a period of sustained drinking, and at first took the form of an acute auditory hallucinosis, characterized by threatening, exteriorized auditory hallucinations to which the patient's emotional reaction was appropriate. Only later do a few of these patients drift into a quiet hallucinatory, mildly paranoid state, with rather bland affect. Evidence of the prepsychotic schizoid personality cannot be detected, and there is usually no family history of schizophrenia. Cases of this type with which we are familiar had their onset between 45 and 50 years of age, i.e., much later than the usual age of onset of schizophrenia. This alcoholic, schizophrenia-like illness should be differentiated from the paranoid type of schizophrenia.
 5. *A patient who is confused or stuporous and seemingly catatonic-negativistic, refusing or unable to speak, to execute commands, or to be activated in any way.* If signs of focal cerebral or brainstem disease are absent, one is tempted to make a diagnosis of catatonic schizophrenia, not appreciating that *catatonia as a phenomenon* may be indistinguishable from akinetic mutism (page 306); it may also appear with widespread disease of the associational cortices and as mentioned earlier, with severe depression, certain confusional states, and hysteria. The error can be avoided if one makes diagnoses on the basis of positive findings, not on the absence of specific data. The authors have seen cases of hypoxic and other metabolic encephalopathies, Schilder disease, certain storage diseases, and Creutzfeldt-Jakob disease mistaken for schizophrenia because of failure to adhere to this principle.
 6. *A patient with temporal lobe epilepsy* who, apart from intermittent psychomotor seizures, has long periods (weeks or months) of hallucinations, delusions, bizarre behavior, and disorganization of thinking. Such a mental disturbance often reflects the presence of a persistent state of temporal lobe seizures (temporal lobe status), which in some cases have been demonstrated by depth electrodes to originate in the amygdaloid or other medial temporal areas. The nature of the disturbances of emotionality and mentation in such patients, a somewhat controversial subject, is discussed in Chaps. 16 and 25.
 7. *Schizophrenic patients with prominent depressive symptoms who have made repeated suicide attempts* pose an exceptionally difficult problem in diagnosis. They were referred to in the past as *schizothymic*, and to this day it is not certain whether they have schizophrenia, a relatively mild chronic depressive illness (dysthymia), depressive disease, or both schizophrenia and depression ("schizoaffective"). When in remission, patients with affective disorders are usually normal, whereas those with schizophrenia are not.
 8. *One should always be hesitant to make the diagnosis of schizophrenia during childhood*, although such a diagnosis has been entertained in children who have a variety of developmental and adjustment problems and who at some time become psychotic, i.e., they become excited, depressed, or hallucinatory and express bizarre ideas. There is no evidence that such children go on to have schizophrenia later in life. And although what are thought to be "schizoid" traits may be recognized in childhood, a frank psychosis is hardly ever recorded at this age. Of particular importance in such children is to exclude the presence of metabolic errors, mental retardation, or an early-onset depressive illness. Similarly, childhood autism and particularly its milder forms (Asperger syndrome, page 889) should not be confused with schizophrenia. That the incidence of schizophrenia is not increased in the families of autistic children supports the idea that the two are separate diseases.

Treatment

The aims of treatment are to suppress psychotic symptoms, ameliorate the disorder of thinking and the apathetic state, prevent relapse, and optimize social adjustment. It is often possible, once the diagnosis of schizophrenia is established and the optimal regimen of medication decided upon, for a general physician to share the responsibility for following the patient with a psychiatric social worker or nurse. The physician soon becomes accustomed to the particular pattern of the patient's behavior and can help support the patient and his family during difficult periods. Relapse with psychotic decompensation demands drug therapy, and if there is a hazard of injury or suicide or difficulty in management at home, hospitalization becomes necessary. Many general hospitals and specialized psychiatric institutions have facilities for the management of such patients; state hospitals and other institutions are able to provide long-term treatment. The aim of hospitalization is to protect the patient, relieve the family of the need for constant vigilance and supervision, and assure the administration of drugs until the exacerbation spends itself. Later, instead of mere custodial care, the patient needs a supervised program of planned activities, vocational and milieu therapy, often in a "halfway house," which involves the patient as a contributing member during the more chronic phases of the disease. If medication is successful in preventing progressive decompensation, the patient can many times return to the family and community. It is invaluable to have a competent social worker or nurse maintain frequent contact with the patient and his family and assure continuity of medication.

The modern era of treatment of schizophrenia began in 1952, with the incidental demonstration by the French surgeon Henri Laborit of the antipsychotic properties of chlorpromazine. Subsequently, a large number of other phenothiazines have been used to treat chronic and acute psychosis. Treatment consists essentially of the administration of one of several similar antipsychotic medications. The various classes of antipsychotic drugs, their mode of action, and neurologic ("neuroleptic") side effects have been discussed in Chap. 43.

In recent years a second generation of "atypical" nonphenothiazine antipsychotic agents that have complex effects on the dopamine and serotonin systems has been added to the standard do-

pamine antagonists, the phenothiazines and the butyrophenones. (They are atypical in that their extrapyramidal side effects are far less than that for the phenothiazines.) They all serve to calm the patient, blunt the emotional responses, and reduce hallucinosis and aggressive and impulsive behavior, leaving cognitive functions relatively intact. The main side effects, pertaining mostly to the phenothiazine group, are summarized in Table 58-1 and on page 1024 (see also the review by Freedman and chapter by Baldessarini). The antipsychotic action of these drugs is more impressive in the short and intermediate term than over the long run, although some data suggest that they are also of value in preventing relapses. Negative symptoms (apathy and withdrawal) respond less well than positive ones, and it is generally acknowledged that 10 to 20 percent of patients respond little or not at all to medication.

Clozapine, olanzapine, risperidone, quetiapine, and others listed in Table 58-2 are the more recently introduced atypical drugs with incompletely defined pharmacologic properties but with narrower affinities for certain receptors. In addition to their reduced motor side effects, they produce clinical improvement in about half of patients who have proved to be unresponsive to other antipsy-

chotic medications. These drugs bind to and inhibit serotonin receptors and, to some extent, to dopamine receptors (Meltzer and Nash) but have a much lower affinity for striatal dopamine receptors, thus providing a major advantage—the absence of immediate or tardive extrapyramidal side effects. This has led most psychiatrists to use one of the newer drugs rather than the phenothiazines as a first choice. About 1 percent of patients treated with one of the most effective drugs, clozapine, develop leukopenia, which may prove fatal; there is less risk with the related agent, olanzapine, but leukopenia and agranulocytosis have been reported in rare instances with it as well. Orthostatic hypotension, tachycardia, fever, and hypersalivation may be troublesome in the first days and weeks of therapy with any agent in this class. *Risperidone* is a potent serotonin and dopamine receptor antagonist. Low doses reportedly attenuate the negative symptoms of schizophrenia (apathy, emotional withdrawal, lack of social interaction) and the incidence of extrapyramidal side effects is low provided that the dosage is kept below 6 mg daily. Typical dosages of these antipsychotic drugs are indicated in Table 58-2. In the higher dose ranges, parkinsonian features may nonetheless appear. Tardive dyskinesias, however, are

Table 58-1
Neurologic side effects of the neuroleptic-antipsychotic drugs

REACTION	CLINICAL FEATURES	PERIOD OF MAXIMUM RISK	PROPOSED MECHANISM	TREATMENT
Acute dystonias	Spasm of muscles of tongue, face, neck, back	1–5 days	Dopamine excess? Acetylcholine excess?	Antiparkinson agents are diagnostic and curative (IM or IV, then PO)
Parkinson syndrome	Bradykinesia, rigidity, masked facies, shuffling gait, variable tremor	5–30 days (may persist)	Dopamine blockade	Antiparkinson agents (PO); dopamine agonists risky?
“Rabbit” syndrome	Perioral tremor, flexed posture; usually reversible	Months or years	Unknown	Antiparkinson agents: reduce dose of neuroleptic
Akathisia	Motor restlessness with anxiety or agitation	1–60 days (commonly persists)	Adrenergic excess?	Reduce dose or change drug; low doses of propranolol ^a ; antiparkinson agents or benzodiazepines may help
Neuroleptic malignant syndrome	Catatonia, stupor, fever, unstable pulse and blood pressure, myoglobinemia, elevated CPK ^b ; can be fatal	Weeks	Unknown	Stop neuroleptic; antiparkinson agents usually fail; bromocriptine and dantrolene often help; expert supportive care crucial, ICU best
Tardive dyskinesia	Oral-facial dyskinesia, choreoathetosis, often slowly reversible, rarely progressive	6–24 months (worse on withdrawal)	Dopamine excess?	Prevention best; treatment unsatisfactory; slow, spontaneous remission

IM, intramuscularly; IV, intravenously; PO, per os (orally); ICU, intensive care unit.

^a There may be an increased risk of hypotension on interaction between high doses of propranolol and some antipsychotic agents; clonidine may also be effective at doses of 0.2 to 0.8 mg/day but carries a high risk of hypotension, and tolerance (loss of efficacy) may develop.

^b CPK, creatine-phosphokinase in serum, released from hypertonic muscle.

Table 58-2

Newer antipsychotic drugs with limited extrapyramidal side effects

MEDICATION	BRAND NAME	INITIAL DOSE	TARGET OR MAXIMAL DOSE	POTENTIAL SIDE EFFECTS ^a
Olanzapine	Zyprexa	5 mg	10 mg	Orthostatic hypotension, transaminase elevation, hyperprolactinemia
Quetiapine	Seroquel	25 mg bid	300 mg	Orthostatic hypotension, cataracts, transaminase elevation
Clozapine	Clozaril	12.5 mg bid	300 mg	Agranulocytosis, transient fever, anticholinergic activity, hyperglycemia
Risperidone	Risperidol	1 mg bid	3 mg bid	Orthostatic hypotension
Ziprasidone	Geodon	20 mg	160 mg	Less weight gain than others in this class. Prolongation of QT interval
Aripiprazole	Abilify	5 mg	30 mg	Less weight gain than others in this class. Prolongation of QT interval
Amisulpride	Solian	100 mg	1000 mg	

^a All have the potential to cause tardive dyskinesias and neuroleptic malignant syndrome (see Table 58-1), but these complications are less frequent than with phenothiazines and haloperidol. Weight gain is common with this class of drugs.

infrequent. Common to all the drugs in the class is variable weight gain. With long-term treatment this may accumulate to 20 percent of the patient's original weight. Hypercholesterolemia and diabetes then often emerge and may require additional treatment. In a few cases the newer generation antipsychotics have induced some obsessive-compulsive symptoms. Finally, it might be commented that according to Leucht and colleagues who performed a meta-analysis of extrapyramidal symptoms and various drugs, that low potency first-generation antipsychotics (excluding haloperidol) may have comparable complications to the new generation of drugs when dose-equivalent amounts are given. Not all clinicians agree with this perspective.

The optimal daily dose for treatment of an acute psychotic episode is in the range of 10 to 20 mg daily of haloperidol or the equivalent amount (400 to 800 mg) of a phenothiazine such as chlorpromazine or escalating doses of the newer agents as listed in Table 58-2. The administration of much higher doses of phenothiazines or haloperidol is popular with some psychiatrists but this practice entails serious risks and the advantages have not been demonstrated in controlled trials (see Kane and Marder). Attempts are made to individualize and eventually lower the dosage until the patient's behavior suggests that a relapse is imminent. Long-acting piperazine phenothiazines, given subcutaneously every week or two, are used in patients who are unable to take oral medication or refuse to do so. Extrapyramidal side effects are troublesome and tardive dyskinesias may be even more problematic (page 94).

Antidepressants and lithium have also been used in those schizophrenic patients with prominent affective symptoms. Electroconvulsive therapy (ECT) is now seldom used except in patients who are catatonic or severely agitated or who have prominent affective symptoms, or, in exceptional instances, where there has been no response to medication.

To some extent, the extrapyramidal side effects of haloperidol and the phenothiazines can be prevented or at least minimized by the simultaneous parenteral administration of antihistaminic drugs—e.g., diphenhydramine (Benadryl), 25 mg tid—and the anticholinergic drugs used in the treatment of Parkinson disease—e.g., benzotropine mesylate (Cogentin), 0.5 to 1 mg bid. However, the latter drugs must be given cautiously for they may interfere with the action of the antipsychotic drugs and, if given in large doses, may themselves induce a toxic confusional state. If it becomes necessary to treat the extrapyramidal side effects, it is usu-

ally possible to eliminate the anticholinergic drugs after 2 to 3 months without a return of symptoms. In chronically medicated patients, 20 to 40 percent of whom develop tardive dyskinesias, an increased dose of the antipsychotic drug may suppress the dyskinesia, but only temporarily. The most dreaded complication of pharmacotherapy is the neuroleptic malignant syndrome. The nature and management of tardive dyskinesias have been discussed on pages 94–95.

Supportive psychotherapy (repeated explanation, reassurance, encouragement) is of course necessary, as in any prolonged illness, and the family needs the same type of help. The physician should be understanding and sympathetic but also firm and professional. The general purpose of psychotherapy is to help the patient get a grasp on reality and to strengthen his self-esteem and psychologic defenses. Psychoanalytic therapy has little to offer as a primary mode of treatment.

Outcome With modern drug therapy and supportive psychiatric management, fully 60 percent of schizophrenic patients will recover sufficiently to return to their homes and become socially adjusted to a varying degree (about half of this group can engage in some occupation). About 30 percent remain helpless and severely handicapped and 10 percent remain hospitalized.

DELUSIONAL DISORDER (PARANOIA)

The term *paranoid* (*para* = beside, *nous* = mind) literally means a mind beside itself. It designates patients who show "fixed suspicions, persecutory delusions, dominant ideas or grandiose trends logically elaborated and with due regard for reality once the false interpretation or premise has been accepted. Further characteristics that differentiate pure paranoia from typical schizophrenia are formally correct conduct, adequate emotional reactions, and coherence of the train of thought" (Rosanoff). In other words, in pure paranoia (*delusional disorder* in DSM-IV), there is supposed to be no mental defect other than the delusional system—no dementia, hallucinations, or emotional disturbance. In past years, a large group of the mentally ill was classified as paranoid. But with advancing knowledge of mental illness, fewer and fewer have been left in this category.

The trouble that psychiatrists have taken to couch this definition in negatives implies that paranoia is frequently a feature of

other forms of mental illness, notably schizophrenia, manic-depressive disease, Alzheimer disease, Lewy-body disease, toxic or alcoholic psychosis, general paresis, etc. This fact about paranoia was known from the beginning, when Heinroth originally described it in 1818 and classified it as a limited disorder of the intellect. Krafft-Ebing, in his monograph on the subject, took pains to distinguish two syndromes: (1) "original paranoia," developing about the time of puberty and attributable to heredity (surely paranoid schizophrenia by present-day criteria), and (2) acquired paranoia, developing in later life, particularly in the involutional period (the condition under discussion). Kraepelin, in agreement with the ideas of Kahlbaum, distinguished between paranoia and dementia praecox but remarked that approximately 40 percent of patients who developed paranoia early in life went on to become schizophrenic. The others represented true paranoia or a closely related condition that he called *paraphrenia*, a term no longer used. In DSM-IV, this disorder is classified as "delusional (paranoid) disorder" and defined as a *persistent* delusion that is not part of any other mental disorder. Furthermore, the delusions are nonbizarre, i.e., they involve situations that could occur in real life, such as being followed, poisoned, infected, loved at a distance, deceived by a spouse, or having a disease.

Figures on the frequency of true paranoia are probably not reliable because they are of necessity based on hospital records. Doubtless there are many individuals with mild forms of the disorder who have never crossed the threshold of a mental hospital. They are relatively harmless and in their communities are judged to be mildly "cracked," or monomaniacs. Males and females are about equally affected. Among psychiatric hospital patients, true isolated paranoia is rare (0.1 percent of admissions, according to Winokur).

Clinical Manifestations

It would be difficult in a neurology text to give an account of all the many ways in which patients with paranoia behave. A simple paradigm will suffice—that of a middle-aged man of uneasy, brooding, asocial, eccentric nature who gradually develops a dominating idea or belief of his own importance, of having in his possession special powers that make him the envy of others, who become bent on persecuting him. As the delusion grows, he becomes more preoccupied, less efficient, and increasingly suspicious of others, with a tendency to interpret every one of their words, gestures, or actions as having some reference to himself. Only when his behavior becomes noticeably bizarre or when he does something to annoy others does his condition come to medical attention. On examining such a person, one is impressed with his capacity for careful reasoning, even betraying good intelligence. Whatever the delusional theme—erotomanic (a delusion that another person, usually of higher status, is in love with the patient), grandiose, jealous, persecutory, or somatic, the last being the most common—the patient's arguments are logical and buttressed cogently by evidence. The patients express their false beliefs with certainty and conviction and are totally unaccepting of all arguments that impugn their rationality. Also, the views of such patients about matters other than their delusions can be quite sensible.

As mentioned, the illness usually does not lead to hospitalization, and if admitted to hospital, the patient does not stay long. The querulous patients with paranoia are the most annoying. They usually remain in the community, flooding the mails with copies of documents accusing people falsely, incessantly writing to news-

papers, and expressing their worthless opinions about anything and everything. As the years pass, the patient changes little, though a few such patients may later break down and begin to hallucinate and finally end in a deteriorated state much like that of schizophrenia. This trend supports Bleuler's opinion that the illness is often a variant of schizophrenia.

Regarding causation, there have been several interesting but unverifiable ideas. The Freudian school attributed paranoia to repressed homosexuality and fixation at the narcissistic level. Meyer invoked a long-standing personality disorder, the *paranoid constitution*. He used the term to refer to persons with a lifelong tendency to hold biased views, to be overly concerned about what others think of them, and to attribute deliberate intentions to indifferent actions. This behavior seems but an exaggeration of a mild suspiciousness that is part of the personality makeup of many individuals. Manschreck presented a detailed discussion of the proposed psychologic mechanisms of paranoia.

The authors' experience with pure paranoia in a general hospital has been rather limited. One sees deluded patients, to be sure, but usually their abnormal ideas have centered on self-persecution, health and bodily functions, infidelity of a spouse, theft of possessions, and the like. The claim that poisoning by carbon monoxide has left the person with ill-defined defects in concentration and other mental functions or the belief that there exists an unobservable parasitic skin infestation have been the most common delusions in our experience. One of our patients, functioning normally in every other way, carried the unshakable idea that people were sneaking into her house at night and when she was away and rearranging the furniture. Also, several physicians under our care have woven extensive or more limited delusional ideas around tenuous scientific theories; these ideas have applied to personal life events as well as physical and psychologic symptoms, and in some cases have resulted in bizarre regimens of self-medication. Rarely, a patient comes to the hospital for some other medical reason and it is found that he or she has been living quietly in the community, preoccupied with a bizarre delusional system yet appearing neither depressed nor schizophrenic. Certainly one often sees delusions in depressed patients who decompensate as their depression deepens.

Sharply separated from the more or less pure delusional disorders are the ones that occur as part of a confusional state or delirium. Delusions occurring in the latter setting are characteristically bizarre, changeable, poorly systematized, and, with rare exceptions, transitory; they are associated with many other aberrations of mental function. The same can be said for delusions that occur in the early stages of a dementing disease. Such events are common, of course, in elderly persons with an incipient or well-compensated dementia ("beclouded dementia," page 363). Rarely, one of the degenerative dementing diseases of middle and late life (Alzheimer, Huntington, and especially Lewy body) presents with a delusional disorder. Otherwise healthy persons without known mental illness may experience a brief delusional episode, notably after surgical procedure or the administration of sedative drugs. In most, there are no subsequent mental problems but a proportion of these older patients will be found to later develop dementia. Certain drugs have a tendency to produce paranoia in otherwise nonpsychotic individuals; phencyclidine, amphetamine, and cocaine are the main offenders seen in patients arriving in emergency departments, and anticholinergic drugs are often responsible in hospitalized patients. These "organic delusions" have been discussed by Cummings.

Management

The methods and objectives of psychotherapy for paranoia are discussed fully by Manschreck. We have no way of deciding whether psychotherapy has influenced this state. In a general hospital, where most of our paranoid patients have been depressed or manic, we have several times been gratified by the effects of antidepressant or antipsychotic medication. In the treatment of patients with pathologic jealousy, Mooney has found phenothiazine drugs to be useful.

From what has been said, the clinical analysis of patients with delusions requires a careful study of mood and intelligence to rule out manic-depressive psychosis and dementia. If either of these two states exists, the treatment proceeds along the lines discussed in Chaps. 57 and 21. A matter of practical importance is for the physician to evaluate carefully the nature of the delusional ideas and try to judge whether the patient is homicidal or suicidal. Occasionally, physicians and others have been killed or maimed by patients with paranoia who thought they were being mistreated.

PUERPERAL (POSTPARTUM) PSYCHOSES

Parturition, associated as it is with many biologic disturbances such as the effects of pain, drugs, eclampsia, hemorrhage, infection, and an abrupt hormonal adjustment, is frequently associated with a disturbance of mood. Obstetricians have repeatedly observed that the woman may feel extraordinarily well immediately postpartum, only to lapse in the following days into a weepy, depressed state in which she may be distressed by lack of feeling for her newborn infant. Usually this lasts for only a few days ("postpartum blues"), being quelled by the return home, responsibility for the infant, nursing, etc. In some patients the depressive symptoms persist for months (see later).

The period after childbirth is also one in which there is a strong disposition to psychosis. Opinion varies as to whether there is a special *puerperal psychosis*. Most psychiatrists believe that the psychotic break that may occur at this time is either a confusional-delirious state or a schizophreniform or depressive psychosis, and that these illnesses do not differ from those occurring at other times in life. As mentioned in the previous chapter, some authors have questioned the existence of a special depressive illness that is linked to the postpartum period, an opinion that is not supported by our clinical experience (see Brockington).

Additionally, there occurs a postpartum psychosis that cannot be categorized in this way. Usually it has its onset between 48 and 72 h after a delivery that may have been complicated by excessive bleeding or infection. The patient alternates between periods of noisy hyperactivity and of mutism and inactivity. She is disoriented and incapable of thinking clearly. The baby is sometimes rejected as not belonging to her (instances of infanticide are not unknown). Although the illness has some features of delirium, it may merge with a schizophrenic or depressive type of psychosis that persists for months. Boyd found in a series of such cases that about 40 percent were predominantly affective, 20 percent schizophreniform, and the remainder self-limited confusional psychoses of the type previously described.

In some patients, a typical depressive illness has followed each of several pregnancies, disabling the patient for weeks to months at a time. Some women with manic-depressive disease have had their early depressive attacks only after delivery. Also, as consultants to hospitals for women and babies, we had observed a number

of patients with an acute postpartum schizophrenic episode. These patients were without family history or prepyschotic schizoid personality and seemed to have a better prognosis than one usually expects in schizophrenia. These are only impressions, however. The treatment of such patients follows the methods described in Chap. 57 and below.

In the diagnosis of postpartum psychosis, one must also keep in mind the possibility of eclampsia, the consequences of pituitary infarction, cerebral vein thrombosis or transitory stroke of arterial type, ergot-induced psychosis, and hypotensive-hypoxic cerebral injury.

THE ENDOCRINE PSYCHOSES

One of the most provocative observations in contemporary psychiatry is that apparently healthy individuals may become psychotic when they develop hyper- or hypothyroidism or Cushing syndrome (or less often, adrenal insufficiency), or when they receive therapeutic doses of corticosteroids. If these conditions were no more than examples of drug-induced psychosis, they would be interesting enough. The fact is, however, that they differ considerably from the usual toxic deliria or confusional states. The syndrome, somewhat reminiscent of puerperal psychosis and some cases of "combat fatigue" seen in wartime, comprises features that are suggestive of manic-depressive psychosis or schizophrenia on the one hand and of confusional psychosis on the other. These endocrine psychoses have far-reaching medical significance, for they provide artificial models of psychoses created by the manipulation of metabolic and by exogenous factors. It is appropriate that they are in the last chapter in a book about neurology, for they provide a remarkable neurologic perspective on mental disorders.

Corticosteroid and Adrenocorticotrophic Hormone Psychosis

First described in arthritic patients being treated with cortisone, these syndromes are now occurring far less frequently than when corticosteroids were introduced into medical practice. The psychosis usually develops over a period of a few days after the patient has received the hormone for a week or more. The features are extremely variable. Depression and insomnia are the most frequent early symptoms, but some patients become elated, agitated, excited, and talkative, as though under pressure to speak, while others are mute; or the prevailing emotional response may be one of anxiety and panic. Thinking may be slightly illogical, tangential, or incoherent. Hallucinations and sensory misinterpretations may appear. However, clouding of the sensorium and disorientation, the hallmarks of deliria and the confusional psychoses, have not been prominent. Nevertheless, the state of awareness is not altogether normal, and at times the patient is frankly bewildered. In the motor sphere there may be incessant activity or immobility, resistiveness, and even negativism verging on catatonia. If administration of the hormone is discontinued as soon as symptoms appear, the psychosis subsides gradually over several days to weeks, with complete recovery.

In patients with Cushing disease, mental changes are frequent. There is in some patients a combination of affective disorder and impairment of cognitive function, usually apparent during mental status testing. Among athletes taking anabolic steroids, some develop affective and psychotic symptoms—reduced sleep, irritability, paranoid delusions, auditory hallucinations, and euphoria or depression. Mental changes in *Addison disease* are frequent but varied. Irritability, confusion, disorientation, and convulsions, with

or without symptoms of hypoglycemia, are the main features. The mechanisms are not well understood.

The mechanism of acute steroid psychosis is obscure. From the few available studies it has been learned that the occurrence of the psychosis is not related to the premorbid personality. Although the dosage of ACTH (corticotropin) or corticosteroid has usually been high, there has been no definite correlation between the dosage and the occurrence, severity, and duration of the psychosis. Nor does the mental disturbance appear to be related to the rapidity and intensity of the therapeutic response to ACTH and cortisone. In a study of patients with systemic lupus erythematosus by Chau and Chi, 5 percent of patients became psychotic with steroid treatment and for an obscure reason, only hypoalbuminemia was found on a statistical analysis to be an associated factor. A history of anxiety or of a family history of psychiatric disease had only a marginal predictive value steroid-induced psychosis. The notion that dexamethasone is less frequently associated with psychosis than other corticosteroids is unproven. Lithium is often effective in controlling the symptoms, allowing continuation of the corticosteroid therapy. The dose is the same as for manic states (see Falk et al.).

Thyroid Psychosis A great deal has been said about the pervasive effects of abnormal thyroid function on all organs, including the neuromuscular apparatus and central nervous system. These effects are discussed in Chap. 40, under acquired metabolic diseases of the nervous system.

The hyperthyroid patient often shows minor changes in emotions and mentation. Restlessness, irritability, apprehension, emotional lability, and at times even agitation and a generalized chorea may occur. Either of two trends may be observed in the relatively rare thyrotoxic patient who develops a psychosis. There may be a manic state, with its characteristic increase in psychomotor activity,

overtalkativeness, and flight of ideas, or there may be depression, with its somber mood, weeping, and anxiety. Visual and auditory hallucinations may be present in both groups. The clinical picture is seldom clear. Usually there is something more than simple mania or agitated depression, i.e., some clouding of the sensorium with perplexity and confusion, suggestive of delirium. The condition is said to be related to the premorbid personality, some personality types being more vulnerable, but this point is disputed; it is not directly related to the severity of the thyrotoxicosis. Careful studies of cerebral blood flow and metabolism during and after the psychosis have not been done. Treatment of the hyperthyroidism does not result in prompt arrest of the psychic disorder; recovery usually takes place over a period of months. One must distinguish this illness from other types of recurrent psychosis that happen to be coincidental with or precipitated by hyperthyroidism.

With *myxedema* there is a characteristic slowness and thickness of speech, drowsiness, hypothermia, mental dullness, listlessness and apathy, irritability, and sometimes suspiciousness. The patient may sleep most of the time, having to be awakened for meals. A disturbance of memory and the lack of genuine symptoms of depression, such as feelings of hopelessness and loss of self-esteem, help to distinguish the mental disorder of myxedema from that of a depressive illness. Nevertheless, unless one thinks of myxedema in cases of psychomotor retardation, the diagnosis will be missed. Reduced cerebral blood flow and metabolism have been found in myxedema; with specific therapy, these functions are restored to normal within 2 to 3 weeks.

An entirely different type of mental disturbance, characterized by intermittent delirium and stupor, associated with myoclonus and probably autoimmune in nature, may occur in patients with Hashimoto thyroiditis (page 978). The diagnosis is confirmed by the finding of certain specific circulating antibodies.

- Adie pupil, 243, 465
- Adiposogenital dystrophy, 486
- Adolescents, 496
 - depression in, 1312
- EEG in, 25–26
- inherited metabolic diseases in, in late childhood, 825–830
- seizures in, 289–290
- Adrenal glands, neuroendocrine syndromes related to, 488–489
- Adrenergic receptors, 458
- Adrenocortical insufficiency, 489, 1237–1238
- Adrenocorticotropic hormone (ACTH)
 - for multiple sclerosis, 787
 - for myoclonic encephalopathy of infants, 828
 - for seizures, 292*t*
- Adrenocorticotropic hormone (ACTH) psychosis, 1330–1331
- Adrenoleukodystrophy (ALD), 515, 836–838, 837*f*
- Adrenomyeloneuropathy, 1154*t*
- Adson test, 186, 187
- Advanced-sleep-phase syndrome, 341
- Aerocele, 762
 - pneumocephalus and rhinorrhea with (cerebrospinal fluid rhinorrhea), with head injury, 749–750, 750*f*
- Affect, disturbances of, in acute confusional states, 358
- Afferent pupillary defect, 206, 242, 284
- Age. *See also* specific age groups
 - sensory function and, 134–135
 - sleep and, 333
- Age-associated memory impairment, 520
- Agenesis of corpus callosum, 852
- Ageusia, 197, 200
- Aggressiveness, 439, 446–448
- Aging, 519*t*, 519–524. *See also* Elderly people
 - cognitive functions and, 520–521
 - gerontologic neurology and, 523

Aging (*continued*)
 morphologic and physiologic changes
 in nervous system and, 522–523
 of muscle, 1244
 muscles and nerves and, 523–524
 neurologic effects of, 519
 neurologic signs of, 519–520, 520*t*
 personality changes associated with,
 521
 spinal changes associated with,
 168–169
 stance, gait, and motor impairments
 and, 521–522

Agnosia
 in acute confusional states, 359
 anosognosia, 401
 auditory, with temporal lobe lesions,
 398, 397
 color, 407
 in degenerative diseases, 371
 environmental, 407
 olfactory, 199
 tactile, 138
 visual, 219, 406–408

Agranular cortex, 386

Agraphia, 423–424

Agyria. *See* Lissencephaly

Aicardi syndrome, 852, 857

AIDS. *See* HIV/AIDS

AIDS dementia complex, 644–646, 645*f*

AIDS-related complex (ARC), 644

Air embolism, cerebral, 702

Akathisia, 97, 359
 with phenothiazines, 1025

Akinesthesia, 61–62

Akinetic mutism, 305–306, 394

Alarm reactions, 458–459

Albendazole, for cysticercosis, 627

Alcohol, 1004–1014
 abstinence (withdrawal) syndrome and,
 290, 1007–1011, 1008*f*
 delirium tremens and, 1007,
 1009–1010
 hallucinosis in, 1008
 seizures in, 1008–1009
 treatment of, 1010–1011
 tremulousness in, 1007–1008
 addiction to, treatment of, 1013–1014
 blackouts due to, 1006
 cerebellar degeneration associated
 with, 997–998, 998*f*
 coma and stupor due to, 1006–1007
 depression and, 1312
 disorders associated with, 1011–1012
 nutritional, 984–988, 990–992,
 1011
 for essential tremor, 82
 fetal alcohol syndrome and, 1012–1013

intoxication due to, 1006–1007
 pathologic, 1006, 1007
 treatment of, 1007

myopathy induced by, 1239, 1242

pharmacologic effects of, 1004–1005

physiologic effects of, 1005–1006

tolerance and, 1005–1006

Alcohol withdrawal tremor, 80–81

Alcoholic cerebellar degeneration, 935

Alcoholic dementia, 1011–1012

Alcoholic-nutritional polyneuropathy,
 1150

Aldosteronism, primary, 1237–1238
 hypokalemic weakness in, 1272

Alertness
 anatomy and neurophysiology of,
 307–308
 reduced, acute confusional states
 associated with, 360–361, 361*t*

Alexander disease, 811, 852

Alexia
 visual, 219
 without agraphia, 407, 409, 418*t*, 422

Alien hand, 49

Allergic meningitis, 635

Allesthesia
 definition of, 135
 visual, 220

Allocortex, 386

Allodynia, 118, 118*t*, 134

Alloesthesia
 definition of, 135
 visual, 220

Alpers disease, 811, 814*t*

Alpha adrenergic receptors, 458

Alpha coma, 29, 307

Alpha motor neurons, 40

Alpha synuclein, 916*t*, 920

Alpha waves, in EEG, 24

Alport syndrome, deafness in, 255*t*

Alprazolam (Xanax), 1023
 for panic attacks, 1294

Alternate beat tremor, 81*t*

Alternate cover test, 232–233

Alternating strabismus, 230

Aluminum intoxication, 1038

Alzheimer's disease, 522–523, 898–906
 cerebrovascular disease versus, 738
 clinical features of, 898–901
 diagnosis of, 904, 905*f*
 differential diagnosis of, 904–905

Down syndrome and, 863, 906

EEG in, 29

epidemiology of, 898

myoclonus in, 276

pathogenesis of, 902*f*, 902–904, 904*t*

pathologic states associated with, 906

pathology of, 901*f*, 901–902

treatment of, 905–906

Amantadine, for ataxia, degenerative, 938
 for Parkinson disease, 921*t*, 923

Amaurosis, 203

Amaurosis fugax, 203, 209
 with internal carotid artery occlusion,
 669
 with transient ischemic attacks, 692

Amblyopia, 203, 230
 deficiency (nutritional optic
 neuropathy; tobacco-alcohol
 amblyopia), 991–992

Amblyopia ex anopsia, 230

Amebic meningoencephalitis, 624–625

Amenorrhea-galactorrhea syndrome,
 575–576

Amentia, 356

Amikacin, for meningitis, 599*t*

Aminergic fibers, 75

Aminoacidopathies (aminoacidurias)
 branched-chain, in neonates, 803–804
 in children, 816–818
 vitamin-responsive, in neonates, 801

Amiodarone, peripheral neuropathy due
 to, 1133

Amisulpride (Solian), for schizophrenia,
 1328*t*

Amitriptyline
 for depression, 1314
 for insomnia, 340
 for migraine prophylaxis, 155
 for pain, 125
 peripheral neuropathy due to, 1134
 for postherpetic neuralgia, 163

Ammonia, in cerebrospinal fluid, 16
 in hepatic encephalopathy, 968

Amnesia
 anterograde, 357, 376
 with concussion, 751
 in Wernicke-Korsakoff syndrome,
 985
 epileptic, transient, 278
 global, transient, 379–380
 hysterical, 1299
 retrograde, 357, 376
 with concussion, 751
 in Wernicke-Korsakoff syndrome,
 985

Amnesic dysnomia, 399

Amnesic psychosis, seizures with, 278

Amnesic state. *See* Korsakoff amnesia
 state (Korsakoff syndrome or
 psychosis)

Amorphosynthesis, 401–402

Amphetamine (Adderall; Benzedrine),
 1028

Amphetamine, for narcolepsy, 348

- Amphiphilic cationic drug myopathy, 1240*t*
- Amphotericin B, for cryptococcosis, 621–622
- Ampicillin
for bacterial encephalitis, 602
for meningitis, 599*t*
- Amusia
congenital, 511
with temporal lobe lesions, 397
- Amyl alcohol ingestion, 1007
- Amyloid angiopathy, 708
intracranial bleeding caused by, 726–727
- Amyloid neuropathy
inherited, 1160–1161
polyneuropathy, familial, 1153*t*
primary (nonfamilial), 1146–1147
- Amyloid-protein precursor (APP), 902, 902*f*
- Amyoplasia, 1245
- Amyotrophic lateral sclerosis (ALS), 939–940
differential diagnosis of, 942–943
- Amyotrophy, 585
diabetic, 1135–1136, 1170
hypoglycemic, 966
neuralgic, 1165–1166
hereditary, 1157, 1166
nuclear, restricted, 1245–1246
syphilitic, 1078
with spastic-ataxic paraparesis, 618
- Analgesia, definition of, 118*t*, 135
- Analgesics. *See also specific drugs and drug types*
nonopioid, 124*t*
opioid. *See Opioids/opiates*
- Anankastic personality, 1302*t*
- Anaplastic astrocytomas, 553, 554, 555
- Anarthria, 426–427
- Anatomic diagnosis, 3
- Andermann syndrome, 852
- Andersen disease, 1231*t*–1232*t*, 1233, 1266*t*, 1273
- Anderson-Fabry disease (*see also Fabry disease*), 1159
- Androgen receptor, 947
- Anemia
aplastic, stroke complicating, 737
with hypocupric myelopathy, 1078
pernicious, 992
sickle cell, stroke due to, in children, 708–709
- Anencephaly, 854–855
- Anesthesia
complications of, 1057, 1224
definition of, 118*t*, 135
in myasthenia gravis, 1259
- spinal, myelopathy following, 1057
- Aneurysms
mycotic, 727
saccular
ruptured. *See Subarachnoid hemorrhage, spontaneous (ruptured saccular aneurysm)*
unruptured, 722
of spinal arteries, 1071
- Angelman syndrome, 864–865

- Subacute spongiform encephalopathy (SSE). *See* Creutzfeldt-Jakob disease (CJD)
- Subaortic stenosis, 328
- Subarachnoid block, spinal, 13
- Subarachnoid hemorrhage, 755*t*
spontaneous (ruptured saccular aneurysm), 716*f*, 716–722
clinical syndromes of, 717–719
course and prognosis of, 720–721
giant aneurysms and, 722
laboratory findings in, 719*f*, 719–720, 720*f*
systemic changes associated with, 720
treatment of, 721–722
unruptured aneurysms and, 722
- Subarachnoid puncture, cervical, lateral, 11
- Subclavian artery, compression of, 186
- Subcortical dementia, 372–373
- Subcortical infarction, familial, 707–708
- Subdural effusion, in meningitis, bacterial, 595*t*
- Subdural empyema, 603–604
- Subdural hematoma, 755*t*
acute, 758, 758*f*
chronic, 758–760, 759*f*, 760*f*
EEG in, 28
head enlargement and, 852
treatment of, 760
- Subdural hemorrhage, 727
spinal, 1072
- Subdural hygroma, 755*t*, 760
- Subfascial brain herniation, 551–552
- Sudanophilic leukodystrophies, in infants, 810
- Sudeck atrophy, 188, 189
- Sudeck-Leriche syndrome, 188
- Sudomotor function, tests of, 461
- Suggestibility, sensory loss due to, 142
- Suicide, 1316
- Sulfadiazine, for toxoplasmosis, 624
- Sulfite oxidase deficiency, 839
in neonates, 804
- Sumatriptan
for headache, 159
for migraine, 154
- Summation theory of pain, 111
- Sundowning, 303
- Sunset sign, 240
- Superior sagittal sinus thrombophlebitis, septic, 605–606
- Superior thoracic aperture syndrome, 183, 186–188
- Superoxide dismutase, 943
- Supplementary motor area, 44
- Supranuclear palsy, 222
- Suprascapular nerve, mononeuropathy of, 1167, 1167*t*
- Suprasellar germinomas, 569
- Surgery. *See also specific procedures*
ablative, for pain, 126
confusion following, 363–364, 710–711
epilepsy, 298
- Susac syndrome, 733
- Swallowing, 475–477
anatomy and physiology of, 476
- Sweating, disorders of, 466–467
- Swing phase of gait cycle, 100, 101*f*
- Sydenham chorea, 64*t*, 65
- Sylvian epilepsy, 279
- Sympathectomy, thoracolumbar, 466
- Sympathetic apraxia, 49
- Sympathetic nervous system
anatomy of, 453, 453*f*, 455*f*, 455–456, 456*f*
primary failure of, syncope and, 326–327
- Sympathetic skin-resistance test, 461
- Sympathetic storm, 465–466
- Sympathetic system, hypothalamic regulation of, 457
- Synaptic vesicles, paucity of, 1260*t*
- Syncope, 322–331
cardiac, 323, 327–328
carotid sinus, 323
with cerebrovascular disease, 328
clinical features of, 322–323
convulsive, 322
differential diagnosis of, 328–329
examination in, 329–330
neurogenic, 324–326
carotid sinus, 325
deglutitional, 326
exercise-induced, 325
with glossopharyngeal neuralgia, 325–326
micturition, 326
neurocardiogenic, 324–325
tussive, 326
- Valsalva, 326
- vasodepressor (vasovagal), 322, 323, 324
- primary failure of sympathetic nervous system and, 326–327
seizures versus, 287
treatment of, 330–331
of unknown cause, 328
- Syndactylic-craniocerebral abnormalities, 856
- Syndrome(s), 3, 4
- Syndrome of inappropriate antidiuretic hormone (SIADH), 485, 971–972
- Syndromic diagnosis, 3
- Synuclein, 920
- Syphilis. *See* Neurosyphilis
- Syphilitic meningomyelitis, 1078
- Syringobulbia, 1085
- Syringomyelia, 861, 1082, 1084–1087
clinical features of, 1085–1086
diagnosis of, 1086–1087, 1087*f*
historical background of, 1084–1085
pathogenesis of, 1086
- Syringomyelic syndrome, 140*f*, 140–141, 1082
- Syringostomy, for syringomyelia, 1087
- Systemic inflammatory response syndrome (SIRS), 1128
- Systemic lupus erythematosus, neurologic manifestations of, 733

T

- Tabes dorsalis, 617–618
- Tabetic syndrome, 139–140, 140*f*
- Tachycardia, orthostatic, postural, 463
- Tacrolimus (FK-506) intoxication, 1041
- Tactile agnosia, 138
- Tactile sensation, testing of, 135
- Takayasu disease, 732
- Tandem walking test, 102
- Tangier disease, 1154*t*, 1158–1159
- Tapetoretinal degeneration, 950
congenital, 857
- Tapia syndrome, 1180*t*
- Tardive dyskinesia, 94–95, 1025, 1328
- Tarlov cysts, 179
- Tarsal tunnel, 1171
- Tarui disease, 1231*t*–1232*t*, 1233
- Taste sense, 199–201
anatomy and physiology of, 199–200
disturbances of, 200–201, 398
loss of, with head injury, 748
- Tay-Sachs disease, 806*t*, 807*f*, 807*t*, 807–808, 814*t*, 852
- Tearing, testing, 461
- Tectospinal tract, 45
- Teichopsia, 150
- Telangiectasia, Osler-Rendu-Weber, 607, 872–873

Telegrapher's palsy, 94
 Temazepam, for restless legs syndrome and periodic leg movements of sleep, 339
 Temporal arteritis, 149*t*, 159, 215, 235, 730, 731
 Temporal artery biopsy, 34
 Temporal crescent, 219
 Temporal lobe(s)
 anatomy and physiology of, 395–396
 lesions of, clinical effects of, 396–399
 Temporal lobe seizures, 277–279, 279*f*
 rage in, 447
 Temporal sclerosis, medial, 278, 279*f*
 Temporomandibular joint pain, 164–165
 Tendon reflexes
 age-related changes in, 519
 patellar, 40, 40*f*
 in peripheral nerve disease, 1114
 Tennis elbow, 188
 Tensilon test, in myasthenia gravis, 1254–1255
 Tension headache, 149*t*, 156–157
 Tension hydrocephalus. *See*
 Hydrocephalus, obstructive (tension)
 Teratogens, 865

 Thalamus
 lesions of, hemisensory loss due to, 141–142
 pain fibers terminating in, 115–116
 Thalidomide intoxication, 1041–1042, 1134
 Thallium intoxication, 1038
 peripheral neuropathy due to, 1132
 Thallium salts, polyneuropathy due to, 1130
 Thermal sense, testing of, 136
 Thermoregulation, disorders of, 487

Theta waves, in EEG, 27
 Thiabendazole, for trichinosis, 626, 1202
 Thiamine
 deficiency of, in infants, 988
 inherited neurologic diseases
 responsive to, 1000*r*
 for Wernicke-Korsakoff syndrome, 987–988
 Thigh, lateral cutaneous nerve of, neuropathy affecting, 1170
 Third occipital nerve headache, 164
 Third ventricle, tumors of, 571, 571*f*
 Thomsen disease, 1265, 1266*t*, 1267
 Thoracic nerve (of Bell), long,
 mononeuropathy of, 1166–1167
 Thoracic outlet syndrome, 183, 186–188, 187*f*
 Thoracolumbar sympathectomy, 466
 Thought disturbances
 in acute confusional states, 357–358
 bizarre ideation developing over weeks or months and, 450
 in schizophrenia, 1319
 Thromboangiopathy, occlusive (aortic branch disease; Takayasu disease), 732
 Thrombocytemia, stroke complicating, 737
 Thrombocytopenic purpura, aplastic, 737
 Thrombocytosis, stroke complicating, 737
 Thrombolytic agents
 for atherothrombotic infarction and transient ischemic attacks, 694–695
 intracranial bleeding caused by, 726
 Thrombophlebitis, septic, intracranial, 605–606
 Thrombosis
 of carotid arteries, 667–671
 of cerebral arteries, 671–682
 of cerebral veins and venous sinuses, 734–737, 735*f*
 of meningeal veins, in meningitis, bacterial, 595*t*
 in muscle, 1282
 Thrombotic thrombocytopenic purpura (TTP), stroke complicating, 736
 Thunderclap headache, 150, 160
 Thymectomy, for myasthenia gravis, 1258
 Thymic tumors, in myasthenia gravis, 1252
 Thymus, in myasthenia gravis, pathologic features of, 1252–1253
 Thyroid disease, ophthalmoparesis in, 216, 235–236
 Thyroid encephalopathy, 978–980
 Thyroid myopathy, 1235–1237
 Thyroid ophthalmopathy, 216, 235–236
 Thyroid psychosis, 1331
 Thyrotoxic myopathy, chronic, 1235
 Thyrotoxic period paralysis, 1236
 Thyrotoxicosis
 in myasthenia gravis, 1252
 with myasthenia gravis, 1255–1256
 with periodic paralysis, 1272
 Thyrotropin-releasing hormone (TRH), 481
 TIA. *See* Transient ischemic attack
 Tiagabine (Gabitril), for seizures, 292*t*, 295–296
 Tibial muscular dystrophy, 1224*t*
 Tibial neuropathy, 1171
 Tic(s), 95–97
 in Tourette syndrome, 95–97
 Tic douloureux, 161, 162*t*, 163, 785–786, 1178–1179
 Tick paralysis, 1034
 Ticlopidine, for atheroembolic infarction and transient ischemic attacks, 697
 Tilt table testing, in syncope, 330
 Time perception, disorders of, with temporal lobe lesions, 398
 Timolol, for migraine prophylaxis, 155
 Tin intoxication, 1038
 Tinel sign, 138
 in carpal tunnel syndrome, 1168
 in sensory perineuritis, 1142
 Tinnitus, 251–252
 tonal, 252
 Tip-of-the-tongue phenomenon, 520
 Tissue-type plasminogen activator (t-PA),
 for atherothrombotic infarction and transient ischemic attacks, 694–695
 Titin, 1224*t*
 Titubation, 77
 Tobacco-alcohol amblyopia, 991–992
 Tobey-Ayer test, 13
 Tobramycin
 for bacterial encephalitis, 602
 for meningitis, 599*t*
 Tocainide
 for hyperkalemia periodic paralysis, 1269
 for myotonia congenita, 1267
 Todd's paralysis, 276, 278, 737
 Tolerance
 alcohol and, 1005–1006
 opioids and, 1019
 Tolosa-Hunt syndrome, 156, 162*t*, 234–235, 1189
 Toluene, 1039
 Tonal tinnitus, 252

Table 46-1
Actions of the principal muscles and their nerve root supply^a

ACTION TESTED	ROOTS	NERVES	MUSCLES
<i>CRANIAL</i>			
Closure of eyes, pursing of lips, exposure of teeth	Cranial 7	Facial	Orbicularis oculi Orbicularis oris
Elevation of eyelids, movement of eyes	Cranial 3, 4, 6	Oculomotor, trochlear, abducens	Levator palpebrae, extraocular
Closing and opening of jaw	Cranial 5	Motor trigeminal	Masseters
Protrusion of tongue			Pterygoids
Phonation and swallowing			Lingual
Elevation of shoulders, anteroflexion and turning of head			Palatal, laryngeal, and pharyngeal
<i>BRACHIAL</i>			
Adduction of extended arm	C5, C6	Brachial plexus	Pectoralis major
Fixation of scapula	C5, C6, C7	Brachial plexus	Serratus anterior
Initiation of abduction of arm	C5, C6	Brachial plexus	Supraspinatus
External rotation of flexed arm	C5, C6	Brachial plexus	Infraspinatus
Abduction and elevation of arm up to 90°	C5, C6	Axillary nerve	Deltoid
Flexion of supinated forearm	C5, C6	Musculocutaneous	Biceps, brachialis
Extension of forearm	C6, C7, C8	Radial	Triceps
Extension (radial) of wrist	C6	Extensor carpi radialis longus	Extensor carpi radialis longus
Flexion of semipronated arm	C5, C6	Radial	Brachioradialis
Adduction of flexed arm	C6, C7, C8	Brachial plexus	Latisimus dorsi
Supination of forearm	C6, C7	Posterior interosseous	Supinator
Extension of proximal phalanges	C7, C8	Posterior interosseous	Extensor digitorum
Extension of wrist (ulnar side)	C7, C8	Posterior interosseous	Extensor carpi ulnaris
Extension of proximal phalanx of index finger	C7, C8	Posterior interosseous	Extensor indicis
Abduction of thumb	C7, C8	Posterior interosseous	Abductor pollicis longus and brevis
Extension of thumb	C7, C8	Posterior interosseous	Extensor pollicis longus and brevis
Pronation of forearm	C6, C7	Median nerve	Pronator teres
Radial flexion of wrist	C6, C7	Median nerve	Flexor carpi radialis
Flexion of middle phalanges	C7, C8, T1	Median nerve	Flexor digitorum superficialis
Flexion of proximal phalanx of thumb	C8, T1	Median nerve	Flexor pollicis brevis
Opposition of thumb against fifth finger	C8, T1	Median nerve	Opponens pollicis

CRURAL

Extension of middle phalanges of index and middle fingers	C8, <i>T1</i>
Flexion of terminal phalanx of thumb	C8, T1
Flexion of terminal phalanx of second and third fingers	C8, T1
Flexion of distal phalanges of ring and little fingers	C7, C8
Adduction and opposition of fifth finger	C8, <i>T1</i>
Extension of middle phalanges of ring and little fingers	C8, <i>T1</i>
Adduction of thumb against second finger	C8, <i>T1</i>
Flexion of proximal phalanx of thumb	C8, T1
Abduction and adduction of fingers	C8, <i>T1</i>
Hip flexion from semiflexed position	<i>L1, L2, L3</i>
Hip flexion from externally rotated position	L2, L3
Extension of knee	<i>L2, L3, L4</i>
Adduction of thigh	<i>L2, L3, L4</i>
Abduction and int. rotation of thigh	<i>L4, L5, S1</i>
Extension of thigh	<i>L5, S1, S2</i>
Flexion of knee	<i>L5, S1, S2</i>
Dorsiflexion of foot (medial)	<i>L4, L5</i>
Dorsiflexion of toes (proximal and distal phalanges)	<i>L5, S1</i>
Dorsiflexion of great toe	<i>L5, S1</i>
Eversion of foot	<i>L5, S1</i>
Plantar flexion of foot	<i>S1, S2</i>
Inversion of foot	<i>L4, L5</i>
Flexion of toes (distal phalanges)	<i>L5, S1, S2</i>
Flexion of toes (middle phalanges)	<i>S1, S2</i>
Flexion of great toe (proximal phalanx)	<i>S1, S2</i>
Flexion of great toe (distal phalanx)	<i>L5, S1, S2</i>
Contraction of anal sphincter	<i>S2, S3, S4</i>

First, second lumbricals	
Flexor pollicis longus	
Flexor digitorum profundus	
Flexor digitorum profundus	
Hypothenar	
Third, fourth lumbricals	
Adductor pollicis	
Flexor pollicis brevis	
Interossei	

Median nerve	
Anterior interosseous nerve	
Anterior interosseous nerve	
Ulnar	
Iliopsoas	
Sartorius	
Quadriceps femoris	
Adductor longus, magnus, brevis	
Gluteus medius	
Gluteus maximus	
Biceps femoris	
Semitendinosus	
Semimembranosus	
Anterior tibial	
Extensor digitorum longus and brevis	
Extensor hallucis longus	
Peroneus longus and brevis	
Gastrocnemius, soleus	
Tibialis posterior	
Flexor digitorum longus	
Flexor digitorum brevis	
Flexor hallucis brevis	
Flexor hallucis longus	
Perineal muscles	

^a Predominant root(s) supplying a particular muscle are indicated in bold italic type.
