NEUROLOGY

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

PREFACE

The esteemed authors who conceived and wrote *Principles of Neurology* through its early editions, Dr. Raymond Adams and Dr. Maurice Victor, have ceded the authorship to two of their students. On this occasion, we take an opportunity to restate the premise of the book and the characteristics that distinguish it from others in the field. Based on the comments of colleagues, residents, and students over the years, the general recognition accorded the book has been due to its emphasis on the disciplined presentation of clinical data and on lucid descriptions of the underlying disease process and also to its readability. Time and knowledge have moved on in neurology but these basic virtues are still to be emulated.

In undertaking the writing of any textbook of neurology, one must concede that most patients present problems that are not easily abbreviated to stereotyped clinical descriptions. Many of the large problems in neurology, such as the nature of the degenerative and demyelinating diseases, not to mention behavioral aberrations, remain, for the most part, abstruse. It has been our goal in choosing the background material in each chapter to provide a wide intellectual scope that promotes understanding of pathophysiologic processes and challenges the clinician's innate synthetic capacity. For these reasons, as in previous editions of the book, an attempt is made to guide the reader to the fullest possible understanding of all aspects of neurologic disease, including both clinical and new scientific data. This necessitates that rote and algorithmic or abstracted versions of the clinical method be avoided in favor of detailed descriptions. A larger medical context is provided for each category of disease, so that an entire story can be told about a subject rather than presenting terse and disembodied information. Such a perspective includes the historical development of ideas about major categories of neurologic disorders, classical clinical-pathologic correlations, and, increasingly, molecular and physiologic processes. We believe this provides a conceptual framework that brings coherence to the large subjects of clinical neurology such as demyelinating disease, stroke, head injury, neuropathy, dementia, and degenerative disorders. This plan is the soundest basis for mastering the complexities of clinical neurology.

We adhere to the belief that there are advantages to limited authorship. The comprehensive involvement of two neurologists in rewriting this edition has promoted an evenness of style and a uniform approach across subject matter that should be pleasing to the reader. In keeping with the perspective expressed above, and as an aid to the practicing neurologist, we have included descriptions of the uncommon variants of disease and the results of treatment based on our personal experiences in office practice and in the wards of large tertiary hospitals in Boston as well as on the experiences of colleagues whose observations we have found trustworthy. One of our aims, conforming to Oslerian tradition, is to rely on clinical phenomena that we ourselves have observed.

The modern neurologist is, of course, encouraged to expand his notion of a disease by knowledge of its current scientific foundations. Weaving the meaningful aspects of scientific discovery into a larger clinical context has proved challenging. In the process of choosing which material to include in each chapter, our strategy

was to provide the largest framework that should be meaningful to the educated clinician. We do not view the inclusion of this neurobiologic material as a "modernization" of the text but, in the best interest of scholarship, as a deliberate accretion of dependable and meaningful knowledge as the foundation for clinical work. No attempt is made to recapitulate all, or even most, of the exciting discoveries and hypotheses of modern neuroscience, but instead we refer only to those that bear on and explain neurologic phenomena and disease.

The compass of our book differs in several other ways from most contemporary textbooks on neurology. Included are discussions of a number of subjects that form the core of pediatric neurology, which is heavily weighted with developmental and metabolic disease in children. These are presented in the context of normal development and maturation of the nervous system. The effects of aging and age-linked diseases (which constitute geriatric neurology) are also accorded a separate chapter. Finally, a considerable portion of the book has been allotted to psychiatric syndromes and the major psychiatric diseases. This has been done in the belief that these diseases are neurologic in the strict sense and that it is not possible to understand the brain or to practice clinical neurology effectively without a knowledge of them. The neuropsychiatric effects of alcohol and drug addiction are no less neurologic than psychiatric and therefore are assigned important sections of the book. For reasons of limitation of space, the material on inherent disorders of personality, and other entities of which neurologists need have at least passing knowledge, has been reduced from the prior edition.

We have chosen to avoid certain popular groupings of diseases based on medical specialties such as "neurology of obstetric disorders," "emergency neurology," "neurology of hematologic disorders," etc. While expounded usefully in several neurology textbooks, this classification does not conform to the general principles of arranging diseases with respect to particular parts of the nervous system (cerebrum, spinal cord, peripheral nerve, muscle, etc.) or in accordance with their mechanism (vascular, traumatic, degenerative, neoplastic, metabolic) and age periods.

We view our plan of chapter arrangement as being useful to neurosurgery, psychiatry, and general medicine. The book therefore provides information that is essential to these specialties. To aid the reader from these and other specialties in finding relevant material, we suggest they turn to the following chapters: internists: 8, 10, 11, 16, 18, 32, 33, 34, 35; emergency and intensive care physicians: 16, 17, 18, 34, 35; orthopedists: 8, 11, 44, 45; psychiatrists: 20, 21, 22, 24, 25, 56, 57, 58.

It is not possible to enumerate and adequately thank our colleagues who in one way or another have been instrumental in the development and growth of this textbook. Foremost is our indebtedness to Drs. Adams and Victor and also to C. Miller Fisher, Edward P. Richardson, and Betty Banker. We express our gratitude to the many colleagues who provided extensive advice in previous editions—Robert Young, Jay Mohr, Hugo Moser, Edwin Kolodny, Harvey Levy, and Shirley Wray. Individual chapters for

the current edition were very graciously reviewed by Drs. Richard Blair (Chap. 2), Irving Weissman and George Santos (Chap. 13), Yale Berry and Stephen Parker (Chap. 15), Andrew Cole (Chap. 16), David Paydarfar (Chap. 26), Lester Adelman (Chap. 30), Michael Worthington (Chaps. 32 and 33), Steven Kalkanis (Chap. 35), Al Sandrock, Peter Riskind, and Stephen Hauser (Chap. 36), and Christopher Walsh (Chap. 38). We are particularly grateful to John Henson and Richard Blair for assistance in obtaining neuroradiologic images.

The successful completion of the book is a tribute to the diligent efforts of Dolores Araujo, our administrative assistant, and to the staff at McGraw-Hill, including Lester Sheinis, Charissa Baker, Karen Edmonson, and Janet Foltin.

We thank our wives, Sandy Ropper and Elaine Beilin, for their generous support of our work and commitment of time in this endeavor.

The eighth edition of *Principles* introduces Dr. Robert H. Brown, a noted clinician and neuroscientist. Dr. Brown's experience in the molecular and genetic aspects of neurologic disease is

evident throughout the book. He has added, through his years of experience and clinical sensibilities, many aspects of neuroscience that are relevant to a full understanding of each subject and are an appropriate part of the education and knowledge of a modern neurologist. His expertise in clinical neuroscience, especially as related to neuromuscular and degenerative disease, has allowed for a deeper revision of each chapter. Readers of previous editions will also notice a change in format of the book that we hope is pleasing and marks a transition from the original authors to the new ones.

Raymond Adams has graciously continued to review much of the material in the current edition and has offered scholarly criticism and help in settling many difficult problems of presentation. Our friend Maurice Victor died in 2002 and is greatly missed for his warmth, for his incisive views on neurologic and almost all other subjects, and for his outstanding ability to phrase clinical writing. The authors are grateful to him and endeavor to find a modern voice for his classical command of the language and his astute approach to clinical neurology. We dedicate this edition to him.

Dr. Maurice Victor

PART 1

THE CLINICAL METHOD OF NEUROLOGY

This page intentionally left blank.

CHAPTER 1

APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASE

Neurology is regarded by many as one of the most difficult and exacting medical specialties. Students and residents coming to the neurology ward or clinic for the first time are easily discouraged by what they see. Having had brief contact with neuroanatomy, neurophysiology, and neuropathology, they are already somewhat intimidated by the complexity of the nervous system. The ritual they then witness of putting the patient through a series of maneuvers designed to evoke certain mysterious signs, the names of which are difficult to pronounce, is hardly reassuring; in fact, the procedure often appears to conceal the very intellectual processes by which neurologic diagnosis is attained. Moreover, the students have had little or no experience with the many special tests used in neurologic diagnosis—such as lumbar puncture, electroencephalography, CT, MRI, and other imaging procedures—nor do they know how to interpret the results of such tests. Neurology textbooks only confirm their fears as they read the detailed accounts of the many rare diseases of the nervous system.

The authors believe that many of the difficulties in comprehending neurology can be overcome by adhering to the basic principles of clinical medicine. First and foremost, it is necessary to learn and acquire facility in the use of the *clinical method*. Without a full appreciation of this method, the student is virtually as helpless with a new clinical problem as a botanist or chemist who would undertake a research problem without understanding the steps in the scientific method. And even the experienced neurologist faced with a complex clinical problem resorts to this basic approach.

The importance of the clinical method stands out more clearly in the study of neurologic disease than in certain other fields of medicine. In most cases, the clinical method consists of an orderly series of steps, as follows:

1. The symptoms and signs are secured by history and physical examination.
2. The symptoms and physical signs considered relevant to the problem at hand are interpreted in terms of physiology and anatomy—that is, one identifies the disorder(s) of function and the anatomic structure(s) that are implicated.
3. These analyses permit the physician to localize the disease process, i.e., to name the part or parts of the nervous system involved. This step is called *anatomic*, or *topographic, diagnosis*. Often one recognizes a characteristic clustering of symptoms and signs, constituting a *syndrome* of anatomic, physiologic, or temporal type. The formulation of symptoms and signs in syndromic terms is particularly helpful in ascertaining the locus and nature of the disease. This step is called *syndromic diagnosis* and is often conducted in parallel with anatomic diagnosis.
4. From the anatomic diagnosis and other medical data—particularly the mode and speed of onset, evolution, and course of the illness, the involvement of nonneurologic organ systems, the relevant past and family histories, and the laboratory findings—one deduces the *pathologic diagnosis* and,

when the mechanism and causation of the disease can be determined, the *etiological diagnosis*. This may include the rapidly increasing number of molecular and genetic etiologies if they have been worked out for a particular process.

5. Finally, the physician should assess the degree of disability and determine whether it is temporary or permanent (*functional diagnosis*); this is important in managing the patient's illness and judging the potential for restoration of function.

It goes without saying that all of these steps are undertaken in the service of effective treatment, an ever-increasing prospect in neurology. As will be emphasized repeatedly in later sections, there is therefore always a premium in the diagnostic process on the discovery of treatable diseases.

The foregoing approach to the diagnosis of neurologic disease is summarized in Fig. 1-1, a procedural diagram by which the clinical problem is solved in a series of sequential finite steps. This systematic approach, allowing the confident localization and often precise diagnosis of disease, is one of the intellectual attractions of neurology.

Of course, the solution to a clinical problem need not always be schematized in this way. The clinical method offers a much wider choice in the order and manner by which information is collected and interpreted. In fact, in some cases, adherence to a formal scheme is not necessary at all. In relation to the aforementioned syndromic diagnosis, the clinical picture of Parkinson disease, for example, is usually so characteristic that the nature of the illness is at once apparent. In other cases it is not necessary to carry the clinical analysis beyond the stage of the anatomic diagnosis, which in itself may virtually indicate the cause of a disease. For example, when cerebellar ataxia, a unilateral Horner syndrome, paralysis of a vocal cord, and analgesia of the face of acute onset are combined with loss of pain and temperature sensation in the opposite arm, trunk, and leg, the most likely cause is an occlusion of the vertebral artery, because all the involved structures can be localized to the lateral medulla, within the territory of this artery. Thus, the anatomic diagnosis determines and limits the etiologic possibilities. If the signs point to disease of the peripheral nerves, it is usually not necessary to consider the causes of disease of the spinal cord. Some signs themselves are almost specific—e.g., opsoclonus for paraneoplastic cerebellar degeneration and Argyll Robertson pupils for neurosyphilic or diabetic oculomotor neuropathy.

Irrespective of the intellectual process that one utilizes in solving a particular clinical problem, the fundamental steps in diagnosis always involve the accurate elicitation of symptoms and signs and their correct interpretation in terms of disordered function of the nervous system. Most often when there is uncertainty or disagreement as to diagnosis, it will be found later that the symptoms of disordered function were incorrectly interpreted in the first place. Thus, if a complaint of dizziness is identified as vertigo instead of light-headedness or if partial continuous epilepsy is mistaken for

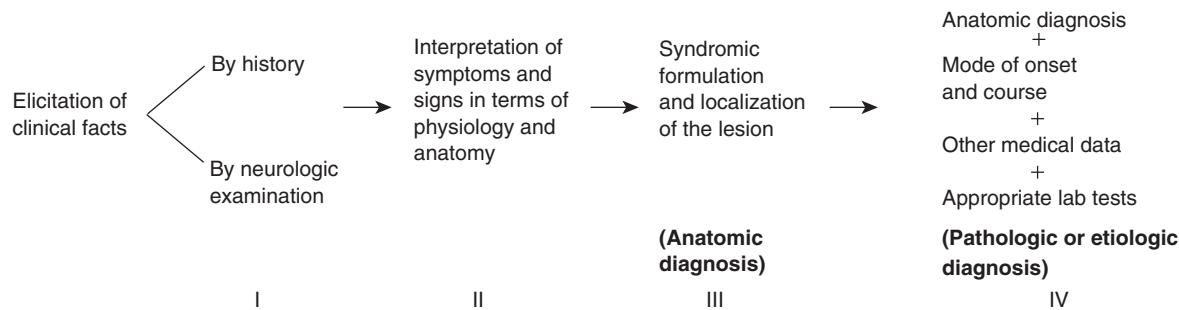

Figure 1-1. Steps in the diagnosis of neurologic disease.

an extrapyramidal movement disorder such as choreoathetosis, then the clinical method is derailed from the beginning. Repeated examinations may be necessary to establish the fundamental clinical findings beyond doubt and to ascertain the course of the illness. Hence the aphorism that a second examination is the most helpful diagnostic test in a difficult neurologic case.

Different disease processes may cause identical symptoms, which is understandable in view of the fact that the same parts of the nervous system may be affected by any one of several processes. For example, a spastic paraparesis may result from spinal cord tumor, a genetic defect, or multiple sclerosis. Conversely, the same disease may present with different groups of symptoms and signs. However, despite the many possible combinations of symptoms and signs in a particular disease, a few combinations occur with greater frequency than others and can be recognized as highly characteristic of that disease. The experienced clinician acquires the habit of attempting to categorize every case in terms of a characteristic symptom complex, or *syndrome*. One must always keep in mind that syndromes are not disease entities but rather abstractions set up by clinicians in order to facilitate the diagnosis of disease. For example, the symptom complex of right-left confusion and inability to write, calculate, and identify individual fingers constitutes the so-called Gerstmann syndrome, recognition of which determines the anatomic locus of the disease (region of the left angular gyrus) and at the same time narrows the range of possible etiologic factors.

In the initial analysis of a neurologic disorder, anatomic diagnosis takes precedence over etiologic diagnosis. To seek the cause of a disease of the nervous system without first ascertaining the parts or structures that are affected would be analogous in internal medicine to attempting an etiologic diagnosis without knowing whether the disease involved the lungs, stomach, or kidneys. Discerning the cause of a clinical syndrome (etiologic diagnosis) requires knowledge of an entirely different order. Here one must be conversant with the clinical details, including the mode of onset, course, and natural history of a multiplicity of disease entities. Many of these facts are well known and not difficult to master; they form the substance of later chapters. When confronted with a constellation of clinical features that do not lend themselves to a simple or sequential analysis, one resorts to considering the broad classical division of diseases in medicine, as summarized in Table 1-1.

To offer the physician the broadest perspective on the relative frequency of neurologic diseases, our estimate taken from several sources of their approximate prevalence in the United States is given in Table 1-2. Donaghay and colleagues have given a similar but more extensive listing of the incidence of various neurologic diseases that are likely to be seen by a general physician practicing in the United Kingdom. They note stroke as by far and away the

Neoplastic
Inflammatory-immune

most commonly encountered condition; those that follow are listed in Table 1-3, adapted from Donaghay and colleagues' *Brain's Diseases of the Nervous System*. Data such as these assist in guiding societal resources to the cure of various conditions, but they are somewhat less helpful in leading the physician to the correct diagnosis except insofar as they emphasize the oft stated dictum that "common conditions occur commonly" and therefore should not be overlooked (see discussion of Bayes theorem, further on, under "Shortcomings of the Clinical Method").

TAKING THE HISTORY

In neurology more than any other specialty, the physician is dependent upon the cooperation of the patient for a reliable history, especially for a description of symptoms that are unaccompanied by observable signs of disease. And if the symptoms are in the sensory sphere, only the patient can tell what he* sees, hears, or feels. The first step in the clinical encounter is to enlist the patient's trust and cooperation and make him realize the importance of the examination procedure.

The practice of making notes at the bedside or in the office is particularly recommended. Immediate recording of the history assures maximal reliability. Of course, no matter how reliable the history appears to be, verification of the patient's account by a knowledgeable and objective informant is always desirable.

The following points about taking the neurologic history deserve further comment:

1. Special care must be taken to avoid suggesting to the patient the symptoms that one seeks. In the clinical interview, the

*Throughout this text we follow the traditional English practice of using the pronoun *he*, *his*, or *him* in the generic sense whenever it is not intended to designate the gender of a specific individual.

conduct of the examiner has a great influence on the patient. Repetition of this truism may seem tedious, but it is evident that conflicting histories can often be traced to leading questions that either suggested symptoms to the patient or led to a distortion of the patient's story. Errors and inconsistencies in the recorded history are as often the fault of the physician as of the patient. As a corollary, the patient should be discouraged from framing his symptom(s) in terms of a diagnosis that he may have heard; rather, he should be urged to give as accurate a description of the symptom as possible—being asked, for example, to choose a single word that best describes his pain and to describe precisely what he means by a particular term, such as *dizziness*, *imbalance*, or *vertigo*. The patient who is given to highly circumstantial and rambling accounts can be kept on the subject of his illness by discreet questions that draw out essential points.

- The setting in which the illness occurred, its mode of onset and evolution, and its course are of paramount importance. One must attempt to learn precisely how each symptom began and progressed. Often the nature of the disease process can be decided from these data alone. If such information cannot be supplied by the patient or his family, it may be necessary to judge the course of the illness by what the patient was able to do at different times (e.g., how far he could walk, when he could no longer negotiate stairs or carry on his usual work) or by changes in the clinical findings between successive examinations, provided that the physician

had recorded the findings accurately and has quantitated them in some way.

- Since neurologic diseases often impair mental function, it is necessary, in every patient who might have cerebral disease, for the physician to decide, by an initial assessment of the mental status and the circumstances under which symptoms occurred, whether or not the patient is competent to give a history of the illness. If the patient's powers of attention, memory, and coherence of thinking are inadequate, the history must be obtained from a spouse, relative, friend, or employer. Also, illnesses that are characterized by seizures or other forms of episodic confusion abolish or impair the patient's memory of events occurring during these episodes. In general, students (and some physicians as well) tend to be careless in estimating the mental capacities of their patients. Attempts are sometimes made to take histories from patients who are feeble-minded or so confused that they have no idea why they are in a doctor's office or a hospital, or from patients who for other reasons could not possibly have been aware of the details of their illnesses.

THE NEUROLOGIC EXAMINATION

The neurologic examination begins with observations of the patient while the history is being obtained. The manner in which the patient tells the story of his illness may betray confusion or incoherence in thinking, impairment of memory or judgment, or difficulty in comprehending or expressing ideas. Observation of such matters is an integral part of the examination and provides information as to the adequacy of cerebral function. The physician should learn to obtain this type of information without embarrassment to the patient. A common error is to pass lightly over inconsistencies in history and inaccuracies about dates and symptoms, only to discover later that these flaws in memory were the essential features of the illness. Asking the patient to give his own interpretation of the possible meaning of symptoms may sometimes expose unnatural concern, anxiety, suspiciousness, or even delusional thinking.

One then generally proceeds from an examination of the cra-

Table 1-3

Approximate order of incidence and prevalence of neurologic conditions in a general practice in the United Kingdom

INCIDENCE IN GENERAL PRACTICE	PREVALENCE IN THE COMMUNITY
Stroke (all types)	Migraine
Carpal tunnel syndrome	Chronic tension headache
Epilepsy	Stroke
Bell's palsy	Alzheimer disease
Essential tremor	Epilepsy
Parkinson disease	Essential tremor
Brain tumor	Multiple sclerosis
Multiple sclerosis (especially in Scotland)	Chronic fatigue syndrome
Giant cell arteritis	Parkinson disease
Migraine	Unexplained motor symptoms
Unexplained motor symptoms	Neurofibromatosis
Trigeminal neuralgia	Myasthenia gravis

SOURCE: Adapted from Donaghay and colleagues: *Brain's Diseases of the Nervous System*.

nial nerves, neck, and trunk to the testing of motor, reflex, and sensory functions of the upper and lower limbs. This is followed by an assessment of the function of sphincters and the autonomic nervous system and suppleness of the neck and spine (meningeal irritation). Gait and station (standing position) should be observed before or after the rest of the examination. In addition, it is often instructive to observe the patient in the course of his natural activities, such as walking or dressing; this may disclose subtle abnormalities of gait and movement that might not be evident in formal testing.

When an abnormal finding is detected, whether cognitive, motor, or sensory, it becomes necessary to analyze the problem in a more elaborate fashion. Details of these more extensive examinations are to be found in appropriate chapters of the book (motor, Chaps. 3, 4 and 5; sensory, Chaps. 8 and 9; and cognitive and language disorders, Chaps. 22 and 23).

The neurologic examination is ideally performed and recorded in a sequential and uniform manner in order to avoid omissions and facilitate the subsequent analysis of case records. Some variation in the precise order of examination from physician to physician is permissible, but each examiner establishes an accustomed pattern.

The thoroughness of the neurologic examination must of necessity be governed by the type of clinical problem presented by the patient. To spend a half hour or more testing cerebral, cerebellar, cranial nerve, and sensorimotor function in a patient seeking treatment for a simple compression palsy of an ulnar nerve is pointless and uneconomical. The examination must also be modified according to the condition of the patient. Obviously many parts of the examination cannot be carried out in a comatose patient; also, infants and small children as well as patients with psychiatric disease must be examined in special ways.

Not to be neglected are certain portions of the general physical examination that may be particularly informative in the patient with neurologic disease. For example, examination of the pulse and blood pressure as well as carotid and cardiac auscultation are essential in a patient with stroke; likewise, the skin can reveal a number of conditions that pertain to congenital, metabolic, and infectious causes of neurologic disease; and so on.

PATIENTS WHO PRESENT WITH SYMPTOMS OF NERVOUS SYSTEM DISEASE

Numerous guides to the examination of the nervous system are available (see the references at the end of this chapter). For a full account of the methods, the reader is referred to the monographs of DeMyer, Ross, Mancall, Bickerstaff and Spillane, Glick, Haerer, and of the staff members of the Mayo Clinic, each of which approaches the subject from a somewhat different point of view. An inordinately large number of tests of neurologic function have been devised, and it is not proposed to review all of them here. Some are described in subsequent chapters dealing with disorders of mentation, cranial nerves, and motor, sensory, and autonomic functions. Many tests are of doubtful value or are repetitions of simpler tests and should therefore not be taught to students of neurology. Merely to perform all of them on one patient would require several hours and probably, in most instances, would not make the examiner any the wiser. The danger with all clinical tests is to regard them as indisputable indicators of disease rather than as ways of uncovering disordered functioning of the nervous system. The fol-

lowing tests are relatively simple and provide the most useful information.

Testing of Higher Cortical Functions

These functions are tested in detail if the patient's history or behavior during the general examination has provided a reason to suspect some defect. Questions should then be directed toward determining the patient's orientation in time and place and insight into his current medical problem. Attention, speed of response, ability to give relevant answers to simple questions, and the capacity for sustained and coherent mental effort all lend themselves to straightforward observation. Useful bedside tests of attention, concentration, memory, and clarity of thinking include the repetition of a series of digits in forward and reverse order, serial subtraction of 3s or 7s from 100, recall of three items of information or a short story after an interval of 3 min, and naming the last six presidents or prime ministers. The patient's account of his recent illness, medical consultations, dates of hospitalization, and his day-to-day recollection of medical procedures, meals, and other incidents are excellent tests of memory; the narration of the illness and the patient's choice of words (vocabulary) provide information about his intelligence and coherence of thinking. Many other tests can be devised for the same purpose. Often the examiner can obtain a better idea of the clarity of the patient's sensorium and soundness of intellect by using these few tests and noting the manner in which he deals with them than by relying on the score of a formal intelligence test.

If there is any suggestion of a speech or language disorder, the nature of the patient's spontaneous speech should be noted. In addition, his ability to read, write, and spell, execute spoken commands, repeat words and phrases spoken by the examiner, name objects and parts of objects, and solve simple arithmetical problems should be assessed.

The ability to carry out commanded tasks (praxis) has great salience in the evaluation of several aspects of cortical function. Bisecting a line, drawing a clock or the floor plan of one's home or a map of one's country, and copying figures are useful tests of visuospatial perception and are indicated in cases of suspected cerebral disease. The testing of language, cognition, and other aspects of higher cerebral function are considered in Chaps. 21, 22, and 23.

Testing of Cranial Nerves

The function of the cranial nerves must be investigated more fully in patients who have neurologic symptoms than in those who do not. If one suspects a lesion in the anterior fossa, the sense of smell should be tested in each nostril; then it should be determined whether odors can be discriminated. Visual fields should be outlined by confrontation testing, in some cases by testing each eye separately; if any abnormality is suspected, it should be checked on a perimeter and scotomas sought on the tangent screen or, more accurately, by computed perimetry. Pupil size and reactivity to light and accommodation during convergence, the position of the eyelids, and the range of ocular movements should next be observed. Details of these test procedures and their interpretation are given in Chaps. 12, 13, and 14.

Sensation over the face is tested with a pin and wisp of cotton; also, the presence or absence of the corneal reflexes may be determined. Facial movements should be observed as the patient speaks

and smiles, for a slight weakness may be more evident in these circumstances than on movements to command.

The auditory meati and tympanic membranes should be inspected with an otoscope. A 256 double-vibration tuning fork held next to the ear and on the mastoid discloses hearing loss and distinguishes middle-ear (conductive) from neural deafness. Audiograms and other special tests of auditory and vestibular function are needed if there is any suspicion of disease of the eighth nerve or the cochlear and labyrinthine end organs (see Chap. 15). The vocal cords must be inspected with special instruments in cases of suspected medullary or vagus nerve disease, especially when there is hoarseness. Voluntary pharyngeal elevation and elicited reflexes are meaningful if there is a difference on the two sides; bilateral absence of the gag reflex is seldom significant. Inspection of the tongue, both protruded and at rest, is helpful; atrophy and fasciculations may be seen and weakness detected. Slight deviation of the protruded tongue as a solitary finding can usually be disregarded. The pronunciation of words should be noted. The jaw jerk and the snout, buccal, and sucking reflexes should be sought, particularly if there is a question of dysphagia, dysarthria, or dysphonia.

Tests of Motor Function

In the assessment of motor function, it should be kept in mind that observations of the speed and strength of movements and of muscle bulk, tone, and coordination are usually more informative than the state of tendon reflexes. It is essential to have the limbs fully exposed and to inspect them for atrophy and fasciculations. The next step is to watch the patient maintain the arms outstretched in the prone and supine positions; perform simple tasks, such as alternately touching his nose and the examiner's finger; make rapid alternating movements that necessitate sudden acceleration and deceleration and changes in direction, such as tapping one hand on the other while alternating pronation and supination of the forearm; rapidly touch the thumb to each fingertip; and accomplish simple tasks such as buttoning clothes, opening a safety pin, or handling common tools. Estimates of the strength of leg muscles with the patient in bed are often unreliable; there may seem to be little or no weakness even though the patient cannot arise from a chair or from a kneeling position without help. Running the heel down the front of the shin, alternately touching the examiner's finger with the toe and the opposite knee with the heel, and rhythmically tapping the heel on the shin are the only tests of coordination that need be carried out in bed. The maintenance of both arms against gravity is a useful test; the weak one, tiring first, soon begins to sag, or, in the case of a corticospinal lesion, to resume the more natural pronated position ("pronator drift"). The strength of the legs can be similarly tested, either with the patient supine and the legs flexed at hips and knees or with the patient prone and the knees bent. Also, abnormalities of movement and posture and tremors may be exposed (see Chaps. 4, 5, and 6).

Tests of Reflex Function

Testing of the biceps, triceps, supinator (radial-periosteal), patellar, Achilles, and cutaneous abdominal and plantar reflexes permits an adequate sampling of reflex activity of the spinal cord. Elicitation of tendon reflexes requires that the involved muscles be relaxed; underactive or barely elicitable reflexes can be facilitated by voluntary contraction of other muscles (Jendrassik maneuver). The

plantar response poses special difficulty because several different reflex responses can be evoked by stimulating the sole of the foot along its outer border from heel to toes. These are (1) the quick, high-level avoidance response; (2) the slower, spinal flexor nociceptive (protective) reflex (flexion of knee and hip and dorsiflexion of toes and foot, "triple flexion")—dorsiflexion of the large toe as part of this reflex is the well-known Babinski sign (see Chap. 3); (3) plantar grasp reflex; and (4) support reactions. Avoidance and withdrawal responses interfere with the interpretation of the Babinski sign and can sometimes be overcome by utilizing the several alternative stimuli that are known to elicit the Babinski response (squeezing the calf or Achilles tendon, flicking the fourth toe, downward scraping of the shin, lifting the straight leg, and others). An absence of the superficial cutaneous reflexes of the abdominal, cremasteric, and other muscles are useful ancillary tests for detecting corticospinal lesions.

Testing of Sensory Function

This is undoubtedly the most difficult part of the neurologic examination. Usually sensory testing is reserved for the end of the examination and, if the findings are to be reliable, should not be prolonged for more than a few minutes. Each test should be explained briefly; too much discussion of these tests with a meticulous, introspective patient may encourage the reporting of useless minor variations of stimulus intensity.

It is not necessary to examine all areas of the skin surface. A quick survey of the face, neck, arms, trunk, and legs with a pin takes only a few seconds. Usually one is seeking differences between the two sides of the body (it is better to ask whether stimuli on opposite sides of the body feel the same than to ask if they feel different), a level below which sensation is lost, or a zone of relative or absolute analgesia (loss of pain sensibility) or anesthesia (loss of touch sensibility). Regions of sensory deficit can then be tested more carefully and mapped out. Moving the stimulus from an area of diminished sensation into a normal area enhances the perception of a difference. The vibration sense may be tested by comparing the thresholds at which the patient and examiner lose perception at comparable bony prominences. We usually record the number of seconds for which the examiner appreciates vibration at the malleolus or toe after the patient reports that the fork has stopped buzzing. The finding of a zone of heightened sensation ("hyperesthesia") calls attention to a disturbance of superficial sensation.

Variations in sensory findings from one examination to another reflect differences in technique of examination as well as inconsistencies in the responses of the patient. Sensory testing is considered in greater detail in Chaps. 8 and 9.

Testing of Gait and Stance

The examination is completed by observing the patient stand and walk. An abnormality of stance and gait may be the most prominent or only neurologic abnormality, as in certain cases of cerebellar or frontal lobe disorder; and an impairment of posture and highly automatic adaptive movements in walking may provide the most definite diagnostic clues in the early stages of Parkinson disease and progressive supranuclear palsy. Having the patient walk tandem or on the sides of the soles may bring out a lack of balance and dystonic postures in the hands and trunk. Hopping or standing on one foot may also betray a lack of balance or weakness, and standing with feet together and eyes closed will bring out a dis-

equilibrium that is due to deep sensory loss (Romberg test). Disorders of gait are discussed in Chap. 7.

THE MEDICAL OR SURGICAL PATIENT WITHOUT NEUROLOGIC SYMPTOMS

In this situation, brevity is desirable, but any test that is undertaken should be done carefully and recorded accurately and legibly. As indicated in Table 1-4, the patient's orientation, insight, and judgment and the integrity of language function are readily assessed in the course of taking the history. With respect to the cranial nerves, the size of the pupils and their reaction to light, ocular movements, visual and auditory acuity, and movements of the face, palate, and tongue should be tested. Observing the bare outstretched arms for atrophy, weakness (pronating drift), tremor, or abnormal movements; checking the strength of hand grip and dorsiflexion at the wrist; inquiring about sensory disturbances; and eliciting the supinator, biceps, and triceps reflexes are usually sufficient for the upper limbs. Inspection of the legs while the feet, toes, knees, and hips are actively flexed and extended; elicitation of the patellar, Achilles, and plantar reflexes; testing of vibration and position sense in the fingers and toes; and assessment of coordination by having the patient alternately touch his nose and the examiner's finger and run his heel up and down the front of the opposite leg, and observation of walking complete the essential parts of the neurologic examination.

This entire procedure does not add more than 5 min to the physical examination. The routine performance of these few simple tests may provide clues to the presence of disease of which the patient is not aware. For example, the finding of absent Achilles reflexes and diminished vibratory sense in the feet and legs alerts the physician to the possibility of diabetic or alcoholic-nutritional neuropathy even when the patient has no symptoms referable to these disorders. Carotid auscultation has been adopted as a component of the screening examination by many neurologists and, as mentioned, recording of the pulse, blood pressure, and carotid arteries and heart is included as routine part of the examination in stroke patients.

Accurate recording of negative data may be useful in relation to some future illness that requires examination.

THE COMATOSE PATIENT

Although subject to obvious limitations, careful examination of the stuporous or comatose patient yields considerable information concerning the function of the nervous system. It is remarkable that, with the exception of cognitive function, almost all parts of the nervous system, including the cranial nerves, can be evaluated in the comatose patient. The demonstration of signs of focal cerebral or brainstem disease or of meningeal irritation is particularly useful in the differential diagnosis of diseases that cause stupor and coma. The adaptation of the neurologic examination to the comatose patient is described in Chap. 17.

THE PSYCHIATRIC PATIENT

One is compelled in the examination of psychiatric patients to rely less on the cooperation of the patient and to be unusually critical of his statements and opinions. The depressed patient, for example, may claim to have impaired memory or weakness when actually

Table 1-4

Brief neurologic examination in the general medical or surgical patient (performed in 5 minutes or less)

1. Orientation, insight into illness, language assessed during taking of the history
2. Size of pupils, reaction to light, visual and auditory acuity
3. Movement of eyes, face, tongue
4. Examination of the outstretched hands for atrophy, pronating or downward drift, tremor, power of grip, and wrist dorsiflexion
5. Biceps, supinator, and triceps tendon reflexes
6. Inspection of the legs during active flexion and extension of the hips, knees, and feet
7. Patellar, Achilles, and plantar (Babinski) reflexes
8. Vibration sensibility in the fingers and toes
9. Finger-to-nose and heel-to-shin testing of coordination
10. Gait

there is neither amnesia nor diminution in muscular power, or the sociopath or hysteric may feign paralysis. The opposite is sometimes true—a psychotic patient may make accurate observations of his symptoms, only to have them ignored because of his mental state.

If the patient will speak and cooperate even to a slight degree, much may be learned about the functional integrity of different parts of the nervous system. By the manner in which the patient expresses ideas and responds to spoken or written requests, it is possible to determine whether there are hallucinations or delusions, defective memory, or other recognizable symptoms of brain disease merely by watching and listening to the patient. Ocular movements and visual fields can be tested with fair accuracy by observing the patient's response to a moving stimulus or threat in all four quadrants of the fields. Cranial nerve, motor, and reflex functions are tested in the usual manner, but it must be remembered that the neurologic examination is never complete unless the patient will speak and cooperate in testing. On occasion, mute and resistive patients judged to be schizophrenic prove to have some widespread cerebral disease such as hypoxic or hypoglycemic encephalopathy, a brain tumor, a vascular lesion, or extensive demyelinative lesions.

INFANTS AND SMALL CHILDREN

The reader is referred to the methods of examination described by Gesell and Amatruda, André-Thomas, Paine and Oppe, and the staff members of the Mayo Clinic, which are listed in the references and described in Chap. 28.

THE GENERAL MEDICAL EXAMINATION

Not to be overlooked in the assessment of a neurologic problem are the findings on general medical examination. Often they disclose evidence of an underlying systemic disease that has secondarily affected the nervous system. In fact, many of the most serious neurologic problems are of this type. Two common examples will suffice: the finding of adenopathy or a lung infiltrate implicates neoplasia or sarcoidosis as the cause of multiple cranial nerve palsies, and the presence of low-grade fever, anemia, a heart murmur, and splenomegaly in a patient with unexplained stroke points to a

diagnosis of bacterial endocarditis with embolic occlusion of brain arteries. Certainly no examination of a patient with stroke is complete without a search for hypertension, carotid bruits, heart murmurs, or irregular pulse.

IMPORTANCE OF A WORKING KNOWLEDGE OF NEUROANATOMY, NEUROPHYSIOLOGY, AND NEUROPATHOLOGY

Once the technique of obtaining reliable clinical data is mastered, students and residents may find themselves handicapped in the interpretation of the findings by a lack of knowledge of neuroanatomy and neurophysiology. For this reason, each of the later chapters dealing with the motor system, sensation, special senses, consciousness, language, and so on, is introduced by a review of the anatomic and physiologic facts that are necessary for an understanding of the associated clinical disorders.

At a minimum, physicians should know the anatomy of the corticospinal tract; motor unit (anterior horn cell, nerve, and muscle); basal ganglionic and cerebellar motor connections; sensory pathways; cranial nerves; hypothalamus and pituitary; reticular formation of brainstem and thalamus; limbic system; areas of cerebral cortex and their major connections; visual, auditory, and autonomic systems; and cerebrospinal fluid pathways. A working knowledge of neurophysiology should include an understanding of the nerve impulse, neuromuscular transmission, and contractile process of muscle; spinal reflex activity; central neurotransmission; processes of neuronal excitation, inhibition, and release; and cortical activation and seizure production.

From a practical diagnostic and therapeutic point of view, the neurologist is helped most by a knowledge of pathologic anatomy—i.e., the neuropathologic changes that are produced by disease processes such as infarction, hemorrhage, demyelination, physical trauma, compression, inflammation, neoplasm, and infection, to name the more common ones. Experience with the gross and microscopic appearances of these disease processes greatly enhances one's ability to explain their clinical behavior. The ability to visualize the effects of disease on nerve and muscle, brain and spinal cord, muscle, meninges, and blood vessels gives one a strong sense of which clinical features to expect of a particular disease and which features are untenable or inconsistent with a particular diagnosis. An additional advantage of being exposed to neuropathology is, of course, that the clinician is better able to evaluate pathologic changes and reports of material obtained by biopsy.

LABORATORY DIAGNOSIS

From the foregoing description of the clinical method and its application, it is evident that the use of laboratory aids in the diagnosis of diseases of the nervous system is always preceded by rigorous clinical examination. Laboratory study can be planned intelligently only on the basis of clinical information. To reverse this process is wasteful of medical resources. However, a central goal of neurology is the prevention of disease, because the brain changes induced by many neurologic diseases are irreversible. In the prevention of neurologic disease, the clinical method in itself is inadequate; of necessity, one therefore resorts to two other approaches, namely, the use of genetic information and laboratory screening tests. Ge-

netic information enables the neurologist to identify patients and relatives at risk of developing certain diseases and prompts the search for biologic markers before the advent of symptoms or signs. Biochemical screening tests are applicable to an entire population and permit the identification of neurologic diseases in individuals, mainly infants and children, who have yet to show their first symptom; in some such diseases, treatment can be instituted before the nervous system has suffered damage. In preventive neurology, therefore, laboratory methodology may take precedence over clinical methodology.

The laboratory methods that are available for neurologic diagnosis are discussed in the next chapter and in Chap. 45, on clinical electrophysiology. The relevant principles of genetic and laboratory screening methods that are presently available for the prediction of disease are presented in the discussion of the disease(s) to which they are applicable.

SHORTCOMINGS OF THE CLINICAL METHOD

If one adheres faithfully to the clinical method outlined here, neurologic diagnosis is greatly simplified. In most cases one can reach an anatomic diagnosis. The cause of the disease may prove more elusive and usually entails the intelligent and selective employment of a number of the laboratory procedures described in the next chapter.

However, even after the most assiduous application of the clinical method and laboratory procedures, there are numerous patients whose diseases elude diagnosis. In such circumstances we have often been aided by the following rules of thumb:

1. Focus the clinical analysis on the principal symptom and signs and avoid being distracted by minor signs and uncertain clinical data. As mentioned earlier, when the main sign has been misinterpreted—say a tremor has been taken for ataxia or fatigue for weakness—the clinical method is derailed from the start.
2. Avoid early closure of diagnosis. Often this is the result of premature fixation on some item in the history or examination, closing the mind to alternative diagnostic considerations. The first diagnostic formulation should be regarded as only a testable hypothesis, subject to modification when new items of information are secured. Should the disease be in a stage of transition, time will allow the full picture to emerge and the diagnosis to be clarified.
3. When several of the main features of a disease in its classic form are lacking, an alternative diagnosis should always be entertained. In general, however, one is more likely to encounter rare manifestations of common diseases than the typical manifestations of rare diseases (a paraphrasing of Bayes theorem).
4. It is preferable to base diagnosis on one's experience with the dominant symptoms and signs and not on statistical analyses of the frequency of clinical phenomena. For the most part the methods of probability-based decision analysis have proved to be disappointing in relation to neurologic disease because of the impossibility of weighing the importance of each clinical datum.
5. Whenever reasonable and safe, obtain tissue for examination, for this adds the certainty of histopathology to the clinical study.

As pointed out by Chimowitz, students tend to err in failing to recognize a disease they have not seen, and experienced clinicians may fail to recognize a rare variant of a common disease. There is no doubt that some clinicians are more adept than others at solving difficult clinical problems. Their talent is not intuitive, as sometimes is presumed, but is attributable to having paid close attention to the details of their experience with many diseases and having catalogued them for future reference. The unusual case is recorded in memory and can be resurrected when another one like it is encountered. Long experience also teaches one to not immediately accept the obvious explanation.

THERAPEUTICS IN NEUROLOGY

Among medical specialties, neurology has traditionally occupied a somewhat anomalous position, being thought of by many as little more than an intellectual exercise concerned with making diagnoses of untreatable diseases. This disdainful view of our profession is not at all valid. There are a growing number of diseases, some medical and others surgical, for which specific therapy is now available; through advances in neuroscience, their number is steadily increasing. Matters pertaining to these therapies and to the dosages, timing, and manner of administration of particular drugs are considered in later chapters in relation to the description of individual diseases.

There are, in addition, many diseases in which neurologic function can be restored to a varying degree by appropriate rehabilitation measures or by the judicious use of therapeutic agents that have not been fully validated. Claims for the effectiveness of a particular therapy, based on statistical analysis of large-scale clinical studies, must be treated circumspectly. Was the study well conceived, was there rigid adherence to the criteria for randomization and admission of cases into the study, were the statistical methods standardized, were the controls truly comparable? It has been our experience, based on participation in a number of such

multicenter trials, that the original claims must always be accepted with caution. While not as skeptical as some of our colleagues of the recent emphasis on evidence-based medicine, we are in agreement with Caplan's point that much of this "evidence" is not applicable to difficult individual therapeutic decisions. This is in part true because small albeit statistically significant effects may be of little consequence when applied to an individual patient. It goes without saying that data derived from trials must be utilized in the context of a patient's overall physical and mental condition and age. Since newly proposed therapeutic agents are sometimes risky and expensive, it is often prudent to wait until further studies confirm the benefits that have been claimed for them or expose flaws in the design or fundamental assumptions of the original trial.

Even when no effective treatment is possible, neurologic diagnosis is more than an intellectual pastime. The first step in the scientific study of a disease process is its identification in the living patient. Until this is achieved, it is impossible to apply adequately the "master method of controlled experiment." The clinical method of neurology thus serves both the physician, in the practical matters of diagnosis, prognosis, and treatment, and the clinical scientist, in the search for the mechanism and cause of disease.

In closing this introductory chapter, a comment regarding the extraordinary burden of diseases of the nervous system throughout the world and in the United States should be made. It is not just that conditions such as brain and spinal cord trauma, stroke, epilepsy, mental retardation, mental diseases, and dementia are ubiquitous and account for the majority of illness, second only in some parts of the world to infectious disease, but that these are highly disabling and often chronic in nature, altering in a fundamental way the lives of the affected individuals. Furthermore, more so than in other fields, the promise of cure or amelioration by new techniques such as molecular biology and genetic therapy has excited vast interest, for which reason aspects of the current scientific insights are included in appropriate sections.

CHAPTER 2

SPECIAL TECHNIQUES FOR NEUROLOGIC DIAGNOSIS

The analysis and interpretation of data elicited by a careful history and examination may prove to be adequate for diagnosis. Special laboratory examinations then do no more than corroborate the clinical impression. However, it happens more often that the nature of the disease is not discerned by "case study" alone; the diagnostic possibilities may be reduced to two or three, but the correct one is uncertain. Under these circumstances, one resorts to the ancillary examinations described below. The aim of the neurologist is to arrive at a final diagnosis by artful analysis of the clinical data aided by the least number of laboratory procedures. Moreover, the strategy of laboratory study of disease should be based largely on therapeutic and prognostic considerations, not on the physician's curiosity or presumed medicolegal exigencies.

A few decades ago the only laboratory procedures available to the neurologist were lumbar puncture and examination of a sample of cerebrospinal fluid, radiology of the skull and spinal column, contrast myelography, pneumoencephalography, and electroencephalography. Now, through formidable advances in scientific technology, the physician's armamentarium has been expanded to include a multitude of neuroimaging, biochemical, and genetic methods. Some of these new methods are so impressive that there is a temptation to substitute them for a careful, detailed history and physical examination. Use of the laboratory in this way should be avoided; it certainly does not guarantee a diagnosis. In fact, in a carefully examined series of 86 consecutively hospitalized neurologic patients, laboratory findings [including magnetic resonance imaging (MRI)] clarified the clinical diagnosis in 40 patients but failed to do so in the remaining 46 (Chimowitz et al). Quite often in modern practice, ancillary testing reveals abnormalities that are of no significance to the problem at hand. The physician should therefore always keep in mind the primacy of the clinical method and judge the relevance and significance of each laboratory datum only in the context of clinical findings. Hence the neurologist must be familiar with all laboratory procedures relevant to neurologic disease, their reliability, and their hazards.

Below is a description of laboratory procedures that have application to a diversity of neurologic diseases. Procedures that are pertinent to a particular symptom complex or category of disease—e.g., audiography to study deafness; electronystagmography (ENG) in cases of vertigo; electromyography (EMG) and nerve conduction studies as well as nerve and muscle biopsy where there is neuromuscular disease—are presented in the chapters devoted to these disorders.

LUMBAR PUNCTURE AND EXAMINATION OF CEREBROSPINAL FLUID

The information yielded by examination of the cerebrospinal fluid (CSF) is crucial in the diagnosis of certain neurologic diseases, particularly infectious and inflammatory conditions, subarachnoid hemorrhage, and diseases that alter intracranial pressure. Certain

combinations of findings, or formulas, in the CSF generally denote particular classes of disease; these are summarized in Table 2-1.

Indications for Lumbar Puncture

1. To obtain pressure measurements and procure a sample of the CSF for cellular, cytologic, chemical, and bacteriologic examination.
2. To aid in therapy by the administration of spinal anesthetics and occasionally antibiotics or antitumor agents, or by reduction of CSF pressure.
3. To inject a radiopaque substance, as in myelography, or a radioactive agent, as in radionuclide cisternography.

Lumbar puncture (LP) carries a certain risk if the CSF pressure is very high (evidenced by headache and papilledema), for it increases the possibility of a fatal cerebellar or transtentorial herniation. The risk is considerable when papilledema is due to an intracranial mass, but it is much lower in patients with subarachnoid hemorrhage or pseudotumor cerebri, conditions in which repeated LPs have actually been employed as a therapeutic measure. In patients with purulent meningitis, there is also a small risk of herniation, but this is far outweighed by the need for a definitive diagnosis and the institution of appropriate treatment at the earliest moment. With this last exception, therefore, LP should be preceded by computed tomography (CT) or MRI whenever an elevation of intracranial pressure is suspected. If radiologic procedures do disclose a mass lesion that is causing displacement of brain tissue toward the tentorial opening or into the foramen magnum (the presence of a mass alone is of less concern) and if it is considered absolutely essential to have the information yielded by CSF examination, the LP maybe performed—with certain precautions. A fine-bore (no. 22 or 24) needle should be used, and if the pressure proves to be very high—over 400 mmH₂O—one should obtain the necessary sample of fluid and then, according to the suspected disease and patient's condition, administer mannitol (or urea) and observe a fall in pressure on the manometer. Dexamethasone or an equivalent corticosteroid may also be given, in an initial intravenous dose of 10 mg, followed by doses of 4 to 6 mg every 6 h in order to produce a sustained reduction in intracranial pressure.

Cisternal puncture and lateral cervical subarachnoid puncture, although safe in the hands of an expert, are too hazardous to entrust to those without experience. LP is preferred except in obvious instances of spinal block requiring a sample of cisternal fluid or myelography above the lesion.

Technique of Lumbar Puncture Experience teaches the importance of meticulous technique. LP should be done under sterile conditions. Local anesthetic is injected in and beneath the skin, which should render the procedure almost painless. Warming of the analgesic by rolling the vial between the palms seems to diminish the burning sensation that accompanies cutaneous infiltr-

Table 2-1
Characteristic CSF formulas

CONDITION	CELLS	PROTEIN	GLUCOSE	OTHER FEATURES
Bacterial infection	WBC >50/mm ³ , often greatly increased	100–250 mg%	20–50 mg%; usually lower than half of blood glucose level	Gram's stain shows organisms; pressure increased
Viral, fungal, spirochetal infection	WBC 10–100/mm ³	50–200 mg%	Normal or slightly reduced	Special culture techniques required; pressure normal or slightly increased
Tuberculous infection	WBC >25/mm ³	100–1000 mg%	<50, often markedly reduced	Special culture techniques and PCR may be needed to detect organisms
Subarachnoid hemorrhage	RBC >500/mm ³ ; slight increase in WBC	60–150 mg%	Normal	Must be distinguished from traumatic lumbar puncture by presence of xanthochromia of spun sample; greatly increased pressure
Cerebral hemorrhage, trauma	RBC 50–200/mm ³ ; higher if ventricular rupture of blood	50–150 mg%	Normal	Pressure may be elevated
Ischemic stroke	Normal or few WBC	Normal	Normal	Normal pressure unless brain swelling
Multiple sclerosis	Normal or few WBC	Normal or slightly increased	Normal	Increased IgG fraction and oligoclonal bands

tion. The patient is positioned on his side, preferably on the left side for right-handed physicians, with hips and knees flexed, the axis of the hips vertical, and the head as close to the knees as comfort permits (the tighter the fetal position, the easier the entry into the subarachnoid space). The patient's hips should be vertical, the back aligned near the edge of the bed, and a pillow placed under the ear. The puncture is easiest to perform at the L3-L4 interspace, which corresponds to the axial plane of the iliac crests, or at the space above or below. In infants and young children, in whom the spinal cord may extend to the level of the L3-L4 interspace, lower spaces should be used. Experienced anesthesiologists, from their work with spinal anesthesia, have suggested that the smallest possible needle be used and that the bevel be oriented in the longitudinal plane of the dural fibers (see below regarding atraumatic needles). It is usually possible to appreciate a palpable "give" as the needle transgresses the dura, followed by a subtle "pop" on puncturing the arachnoid membrane. At this point, the trocar should be removed slowly from the needle in order to avoid sucking a nerve rootlet into the lumen and causing radicular pain; sciatic pain during the procedure indicates that the needle is placed too far laterally. If the flow of CSF slows, the patient's head can be elevated slowly. The capillary action of the contact of CSF with the edge of a collecting tube can be utilized to speed the flow. Occasionally, one resorts to gentle aspiration with a small-bore syringe to overcome the resistance of proteinaceous and viscous CSF. Failure to enter the lumbar subarachnoid space after two or three trials can usually be overcome by performing the puncture with the patient in the sitting position and then helping him to lie on one side for pressure measurements and fluid removal. The "dry tap" is more often due to an improperly placed needle than to obliteration of the subarachnoid space by a compressive lesion of the cauda equina or chronic adhesive arachnoiditis.

There are few serious complications of LP (beyond the slight risk of inducing brain herniation in the circumstances described above). The most common is headache, which has been estimated to occur in one-third of patients, but in severe form in far fewer.

The pain is presumably the result of a reduction of CSF pressure and tugging on cerebral and dural vessels as the patient assumes the erect posture. Despite its common implementation, recumbency or oral fluid administration after LP has not been shown to prevent headache. In the study by Strupp and colleagues, the use of an atraumatic needle alone almost halved the incidence of headache. (Curiously, headaches are twice as frequent after diagnostic LP as they are after spinal anesthesia.) Patients with generally frequent headaches before LP reportedly have higher rates of headache afterwards. When it is severe, the headache may be associated with vomiting and some neck stiffness. Quite rarely there are unilateral or bilateral sixth nerve or other cranial nerve palsies, even at times without headache. The syndrome of low CSF pressure, its treatment by "blood patch," and other complications of lumbar puncture are considered further in Chap. 30.

Bleeding into the spinal meningeal spaces can occur in patients who are taking anticoagulants [prothrombin time >14, or an International Normalized Ratio (INR) >1.4], have low platelet counts (<30,000 to 50,000/mm³), or have impaired platelet function (alcoholism, uremia). Treatment is by reversal of the coagulopathy and, in some cases, surgical evacuation of the clot. Purulent meningitis and disc space infections have been known rarely to complicate LP as the result of imperfect sterile technique, and the introduction of particulate matter (e.g., talc) can produce a sterile meningitis.

Examination Procedures

Once the subarachnoid space has been entered, the pressure and—in special cases—"dynamics" of the CSF are determined (see below) and samples of fluid obtained. The gross appearance of the fluid is noted, after which the CSF, in separate tubes, can be examined for (1) number and type of cells and presence of microorganisms; (2) protein and glucose content; (3) tumor cells, using a Millipore filter or similar technique; (4) content of gamma globulin and other protein fractions and presence of oligoclonal bands;

(5) pigments, lactate, NH₃, pH, CO₂, enzymes, and substances elaborated by tumors; and (6) bacteria and fungi (by culture), cryptococcal antigen, mycobacteria, herpesvirus and cytomegalovirus DNA (by polymerase chain reaction), and viral isolation.

Pressure and Dynamics With the patient in the lateral decubitus position, the CSF pressure is measured by a manometer attached to the needle in the subarachnoid space. In the normal adult, the opening pressure varies from 100 to 180 mmH₂O, or 8 to 14 mmHg. In children, the pressure is in the range of 30 to 60 mmH₂O. A pressure above 200 mmH₂O with the patient relaxed and legs straightened reflects the presence of increased intracranial pressure. In an adult, a pressure of 50 mmH₂O or below indicates intracranial hypotension, generally due to leakage of spinal fluid or to systemic dehydration. When measured with the needle in the lumbar sac and the patient in a sitting position, the fluid in the manometer rises to the level of the cisterna magna (pressure is approximately double that obtained in the recumbent position). It fails to reach the level of the ventricles because the latter are in a closed system under slight negative pressure, whereas the fluid in the manometer is influenced by atmospheric pressure. Normally, with the needle properly placed in the subarachnoid space, the fluid in the manometer oscillates through a few millimeters in response to the pulse and respiration and rises promptly with coughing, straining, or abdominal compression.

The presence of a spinal subarachnoid block can be confirmed by jugular venous compression (Queckenstedt test). First one side of the neck is compressed, then the other, and then both sides simultaneously, with enough pressure to compress the veins but not the carotid arteries. In the absence of subarachnoid block, there is a rapid rise in pressure of 100 to 200 mmH₂O and a return to its original level within a few seconds after release. Failure of the pressure to rise with this maneuver usually means that the needle is improperly placed. A rise in pressure in response to abdominal compression (or coughing or straining) but not to jugular compression indicates a spinal subarachnoid block. Failure of the pressure to rise with compression of one jugular vein but not the other (Tobey-Ayer test) may indicate lateral sinus thrombosis. These tests are now rarely used, having been replaced by more precise and less hazardous imaging techniques, but they remain useful in appropriate circumstances. Jugular compression should not be performed when an intracranial tumor or other mass lesion is present or suspected.

Gross Appearance and Pigments Normally the CSF is clear and colorless, like water. Minor degrees of color change are best detected by comparing tubes of CSF and water against a white background (by daylight rather than fluorescent illumination) or by looking down into the tubes from above. The presence of red blood cells imparts a hazy or ground-glass appearance; at least 200 red blood cells (RBCs) per cubic millimeter (mm³) must be present to detect this change. The presence of 1000 to 6000 RBC per cubic millimeter imparts a hazy pink to red color, depending on the amount of blood; centrifugation of the fluid or allowing it to stand causes sedimentation of the RBC. Several hundred or more white blood cells in the fluid (pleocytosis) may cause a slight opaque haziness.

A traumatic tap (in which blood from the epidural venous plexus has been introduced into the spinal fluid) may seriously confuse the diagnosis if it is incorrectly interpreted to indicate a

pre-existent subarachnoid hemorrhage. To distinguish between these two types of "bloody tap," two or three serial samples of fluid should be taken at the time of the LP. With a traumatic tap, there is usually a decreasing number of RBC in the second and third tubes. Also with a traumatic tap, the CSF pressure is usually normal, and if a large amount of blood is mixed with the fluid, it will clot or form fibrinous webs. These are not seen with pre-existent hemorrhage because the blood has been greatly diluted with CSF and defibrinated. With subarachnoid hemorrhage, the RBC begin to hemolyze within a few hours, imparting a pink-red discoloration (erythrochromia) to the supernatant fluid; allowed to stand for a day or more, the fluid becomes yellow-brown (xanthochromia). Prompt centrifugation of bloody fluid from a traumatic tap will yield a colorless supernatant; only with large amounts of blood (RBC over 100,000/mm³) will the supernatant fluid be faintly xanthochromic due to contamination with serum bilirubin and lipochromes.

The fluid from a traumatic tap should contain one or two white blood cells (WBCs) per 1000 RBC assuming that the hematocrit is normal, but in reality this ratio varies widely. With subarachnoid hemorrhage, the proportion of WBC rises as RBC hemolyze, sometimes reaching a level of several hundred per cubic millimeter; but the vagaries of this reaction are such that it, too, cannot be relied upon to distinguish traumatic from pre-existent bleeding. The same can be said for crenation of RBC, which occurs in both types of bleeding.

The reason that red corpuscles undergo rapid hemolysis in the CSF is not clear. It is surely not due to osmotic differences, insofar as the osmolarity of plasma and CSF is essentially the same. Fishman suggests that the low protein content of CSF disequilibrates the red cell membrane in some way. The explanation for the rapid phagocytosis of RBC in the CSF, which begins within 48 h, is also obscure.

The pigments that discolor the CSF following subarachnoid hemorrhage are oxyhemoglobin, bilirubin, and methemoglobin; in pure form, these pigments are colored red (orange to orange-yellow with dilution), canary yellow, and brown, respectively. Mixtures of these pigments produce combinations of these colors. Oxyhemoglobin appears first, within several hours of the hemorrhage, becomes maximal in about 36 h, and diminishes over a 7- to 9-day period. Bilirubin begins to appear in 2 to 3 days and increases in amount as the oxyhemoglobin decreases. Following a single brisk bleed, bilirubin persists in the CSF for 2 to 3 weeks, the duration varying with the number of RBC that were present originally. Methemoglobin appears when blood is loculated or encysted and isolated from the flow of CSF. Spectrophotometric techniques can be used to distinguish the various hemoglobin breakdown products and thus determine the approximate time of bleeding.

Not all xanthochromia of the CSF is due to hemolysis of RBC. With severe jaundice, bilirubin of both the direct- and indirect-reacting types will diffuse into the CSF. The quantity of bilirubin is from one-tenth to one-hundredth that in the serum. Elevation of CSF protein from whatever cause results in a faint opacity and xanthochromia, more or less in proportion to the albumin-bound fraction of bilirubin. Only at levels of more than 150 mg/100 mL does the coloration due to protein become visible to the naked eye. Hypercarotenemia and hemoglobinemia (through hemoglobin breakdown products, particularly oxyhemoglobin) also impart a yellow tint to the CSF, as do blood clots in the subdural or epidural space of the cranium or spinal column. Myoglobin does not enter

the CSF, probably because a low renal threshold for this pigment permits rapid clearing of the blood.

Cellularity During the first month of life, the CSF may contain a small number of mononuclear cells. Beyond this period, the CSF normally contains no cells or at most up to five lymphocytes or other mononuclear cells per cubic millimeter. An elevation of WBC in the CSF always signifies a reactive process to bacteria or other infectious agents, blood, chemical substances, an immunologic inflammation, a neoplasm, or vasculitis. The WBC can be counted in an ordinary counting chamber, but their identification requires centrifugation of the fluid and a Wright stain of the sediment or the use of a Millipore filter, cell fixation, and staining. One can then recognize and count differentially neutrophilic and eosinophilic leukocytes (the latter being prominent in Hodgkin disease, parasitic infection, cholesterol emboli), lymphocytes, plasma cells, mononuclear cells, arachnoid lining cells, macrophages, and tumor cells. Bacteria, fungi, and fragments of echinococci and cysticerci can also be seen in cell-stained or Gram-stained preparations. An India ink preparation is useful in distinguishing between lymphocytes and cryptococci or *Candida*. On occasion, acid-fast bacilli will be found in appropriately stained samples. The monographs of Dufresne and of den Hartog-Jager and the article of Bigner are excellent references on CSF cytology. Special immunostaining techniques applied to cells of the CSF permit the recognition of lymphoma cell markers, glial fibrillary protein, and carcinoembryonic and other antigens. Electron microscopy permits more certain identification of tumor cells and may demonstrate such substances as phagocytosed fragments of myelin (e.g., in multiple sclerosis). These and other special methods for the examination of cells in the CSF are mentioned in the appropriate chapters.

Proteins In contrast to the high protein content of blood (5500 to 8000 mg/dL), that of the lumbar spinal fluid is 45 mg/dL or less in the adult. The protein content of CSF from the basal cisterns is 10 to 25 mg/dL and that from the ventricles is 5 to 15 mg/dL, reflecting a ventricular–lumbar gradient in the permeability of capillary endothelial cells to protein (blood-CSF barrier) and a lesser degree of fluid circulation in the lumbosacral region. In children, the protein concentration is somewhat lower at each level (less than 20 mg/dL in the lumbar subarachnoid space). Levels higher than normal indicate a pathologic process in or near the ependyma or meninges—in either the brain, spinal cord, or nerve roots—though the cause of modest elevations of the CSF protein frequently remains obscure.

As one would expect, bleeding into the ventricles or subarachnoid space results in spillage not only of RBC but of serum proteins. If the serum protein concentrations are normal, the CSF protein should increase by about 1 mg per 1000 RBC provided that the same tube of CSF is used in determining the cell count and protein content. (The same holds for a traumatic puncture that allows seepage of venous blood into the CSF at the puncture site). However, in the case of subarachnoid hemorrhage, due to the irritating effect of hemolyzed RBC upon the leptomeninges, the CSF protein may be increased by many times this ratio.

The protein content of the CSF in bacterial meningitis, in which choroidal and meningeal perfusion are increased, often reaches 500 mg/dL or more. Viral infections induce a less intense and mainly lymphocytic reaction and a lesser elevation of protein—usually 50 to 100 mg but sometimes up to 200 mg/dL; in some instances the protein content is normal. Paraventricular tu-

mors, by reducing the blood-CSF barrier, often raise the total protein to over 100 mg/dL. Protein values as high as 500 mg/dL or even higher are found in exceptional cases of the Guillain-Barré syndrome and chronic inflammatory demyelinating polyneuropathy. Values of 1000 mg/dL or more usually indicate loculation of the lumbar CSF (CSF block); the fluid is then deeply yellow and clots readily because of the presence of fibrinogen; a combination called *Froin syndrome*. Partial CSF blocks by ruptured discs or tumor may elevate the protein to 100 to 200 mg/dL. Low CSF protein values are sometimes found in meningismus (a febrile illness with signs of meningeal irritation but normal CSF), in the condition known as meningeal hydrops (Chap. 30), in hyperthyroidism, or after a recent LP.

The quantitative partition of CSF proteins by electrophoretic and immunochemical methods demonstrates the presence of most of the serum proteins with a molecular weight of less than 150,000 to 200,000. The protein fractions that have been identified electrophoretically are prealbumin and albumin as well as alpha₁, alpha₂, beta₁, beta₂, and gamma globulin fraction, the last of these being accounted for mainly by immunoglobulins (the major immunoglobulin in normal CSF is IgG). Quantitative values of the different fractions are given in Table 2-2. Immunoelectrophoretic methods have also demonstrated the presence of glycoproteins, haptoglobins, ceruloplasmin, transferrin, and hemopexin. Large mole-

Table 2-2
Average values of constituents of normal CSF and serum

	CEREBROSPINAL FLUID	SERUM
Osmolarity	295 mosmol/L	295 mosmol/L
Sodium	138.0 meq/L	138.0 meq/L
Potassium	2.8 meq/L	4.1 meq/L
Calcium	2.1 meq/L	4.8 meq/L
Magnesium	2.3 meq/L	1.9 meq/L
Chloride	119 meq/L	101.0 meq/L
Bicarbonate	23.0 meq/L	23.0 meq/L
Carbon dioxide tension	48 mmHg	38 mmHg (arterial)
pH	7.33	7.41 (arterial)
Nonprotein nitrogen	19.0 mg/dL	27.0 mg/dL
Ammonia	30.0 g/dL	70.0 g/dL
Uric acid	0.24 mg/dL	5.5 mg/dL
Urea	4.7 mmol/L	5.4 mmol/L
Creatinine	1.1 mg/dL	1.8 mg/dL
Phosphorus	1.6 mg/dL	4.0 mg/dL
Total lipid	1.5 mg/dL	750.0 mg/dL
Total cholesterol	0.4 mg/dL	180.0 mg/dL
Cholesterol esters	0.3 mg/dL	126.0 mg/dL
Glucose	60 mg/dL	90.0 mg/dL
Lactate	1.6 meq/L	1.0 meq/L
Total protein	15–50 mg/dL	6.5–8.4 g/100 dL
Prealbumin	1–7%	Trace
Albumin	49–73%	56%
Alpha ₁ globulin	3–7%	4%
Alpha ₂ globulin	6–13%	10%
Beta globulin (beta ₁ plus tau)	9–19%	12%
Gamma globulin	3–12%	14%

cules—such as fibrinogen, IgM, and lipoproteins—are mostly excluded from the CSF.

There are other notable differences between the protein fractions of CSF and plasma. The CSF always contains a prealbumin fraction and the plasma does not. Although derived from plasma, this fraction, for an unknown reason, concentrates in the CSF, and the level is greater in ventricular than in lumbar CSF (perhaps because of its concentration by choroidal cells). Also, the CSF beta₂, or tau fraction (transferrin) is proportionally larger than that in the plasma and again higher in the ventricular than in the spinal fluid. The gamma globulin fraction in CSF is about 70 percent of that in serum.

At present only a few of these proteins are known to be associated with specific diseases of the nervous system. The most important is IgG, which may exceed 12 percent of the total CSF protein in diseases such as multiple sclerosis, neurosyphilis, subacute sclerosing panencephalitis, and other chronic viral meningoencephalitides. The serum IgG is not correspondingly increased, which means that this immune globulin originates in (or is preferentially transported into) the nervous system. However, an elevation of serum gamma globulin—as occurs in cirrhosis, sarcoidosis, myxedema, and multiple myeloma—will be accompanied by a rise in the CSF globulin. Therefore, in patients with an elevated CSF gamma globulin, it is necessary to determine the electrophoretic pattern of the serum proteins as well. Certain qualitative changes in the CSF immunoglobulin pattern, particularly the demonstration of several discrete (oligoclonal) bands and the ratio of IgG to total protein, are of special diagnostic importance in multiple sclerosis, as discussed in Chap. 36.

The albumin fraction of the CSF increases in a wide variety of central nervous system (CNS) and craniospinal nerve root diseases that increase the permeability of the blood-CSF barrier, but no specific clinical correlations can be drawn. Certain enzymes that originate in the brain, especially the brain-derived fraction of creatine kinase (CK-BB) but also enolase and neopterin, are found in the CSF after stroke or trauma and have been used as markers of brain damage in experimental work.

Glucose Normally the CSF glucose concentration is in the range of 45 to 80 mg/dL, i.e., about two-thirds of that in the blood (0.6 to 0.7 of serum concentrations). Higher levels parallel the blood glucose; but with marked hyperglycemia, the ratio of CSF to blood glucose is reduced (0.5 to 0.6). With extremely low serum glucose, the ratio becomes higher, approximating 0.85. In general, CSF values below 35 mg/dL are abnormal. After the intravenous injection of glucose, 2 to 4 h is required to reach equilibrium with the CSF; a similar delay follows the lowering of blood glucose. For these reasons, samples of CSF and blood for glucose determinations should ideally be drawn simultaneously in the fasting state or the serum should be obtained a few hours before the puncture (this is often impractical). Low values of CSF glucose (hypoglycorrachia) in the presence of pleocytosis usually indicate pyogenic, tuberculous, or fungal meningitis, although similar reductions are observed in some patients with widespread neoplastic infiltration of the meninges and occasionally with sarcoidosis and subarachnoid hemorrhage (usually in the first week).

The almost invariable rise of CSF lactate in purulent meningitis probably means that some of the glucose is undergoing anaerobic glycolysis by polymorphonuclear leukocytes and by cells of the meninges and adjacent brain tissue. For a long time it was

assumed that in meningitis the bacteria lowered the CSF glucose by their active metabolism, but the fact that the glucose remains at a subnormal level for 1 to 2 weeks after effective treatment of the meningitis suggests that another mechanism may be operative. Theoretically at least, an inhibition of the entry of glucose into the CSF, due to an impairment of the membrane transfer system, can be implicated. As a rule, viral infections of the meninges and brain do not lower the CSF glucose, although low glucose values have been reported in a small number of patients with mumps meningoencephalitis and rarely with herpes simplex and zoster infections.

Serologic and Virologic Tests It has become routine practice to test the CSF for cryptococcal surface antigen as a rapid method of detecting this fungal infection. On occasion, a false-positive reaction is obtained in the presence of high titers of rheumatoid factor or antitreponemal antibodies, but otherwise the test is diagnostically more dependable than the conventional India ink preparation (page 621). The nontreponemal antibody tests of the blood—Venereal Disease Research Laboratories (VDRL) slide flocculation test and rapid plasma reagin (RPR) agglutination test—can also be performed on the CSF. When positive, these tests are diagnostic of neurosyphilis, but false-positive reactions may occur with collagen diseases, malaria, and yaws or with contamination of the CSF by seropositive blood. Tests that depend on the use of treponemal antigens, including the *Treponema pallidum* immobilization test and the fluorescent treponemal antibody test, are more specific and assist in the interpretation of false-positive reactions. The value of CSF examinations in the diagnosis and treatment of neurosyphilis is discussed in Chap. 32, but routine testing of CSF for treponemal antibodies is no longer practiced. Serologic tests for the Lyme spirochete are useful in circumstances of suspected infection of the central nervous system with this agent.

The utility of serum serologic tests for viruses is limited by the time required to obtain results, but they are useful in determining retrospectively the source of meningitis or encephalitis. More rapid tests that utilize the polymerase chain reaction (PCR) in CSF, which amplifies viral DNA fragments, are now widely available for diagnosis, particularly for herpesviruses and cytomegalovirus. These tests are most useful in the first week of infection, when the virus is being reproduced and its genomic material is most prevalent; after this time, serologic techniques for viral infection are more sensitive. Amplification of DNA by PCR is particularly useful in the more rapid detection of tubercle bacilli in the CSF, the conventional culture of which takes several weeks at best. New tests for the detection of prion proteins in the spinal fluid are available and may aid in the diagnosis of the spongiform encephalopathies, but the results have been erratic in our experience (Chap. 33).

Changes in Solutes and Other Components The average osmolality of the CSF (295 mosmol/L) is identical to that of plasma. As the osmolality of the plasma is increased by the intravenous injection of hypertonic solutions such as mannitol or urea, there is a delay of up to several hours in the rise of osmolality of the CSF. It is during this period that the hyperosmolality of the blood dehydrates the brain and decreases the volume of CSF.

The CSF and serum levels of sodium, potassium, calcium, and magnesium are listed in Table 2-2. Neurologic disease does not alter the CSF concentrations of these constituents in any characteristic way. The low CSF concentration of chloride that occurs in

bacterial meningitis is not specific but a reflection of hypochloremia and, to a slight degree, of a greatly elevated CSF protein.

Acid-base balance in the CSF is of considerable interest in relation to metabolic acidosis and alkalosis. Normally the pH of the CSF is about 7.31—i.e., somewhat lower than that of arterial blood, which is 7.41. The PCO_2 in the CSF is in the range of 45 to 49 mmHg—i.e., higher than in arterial blood (about 40 mmHg). The bicarbonate levels of the two fluids are about the same, 23 meq/L. The pH of the CSF is precisely regulated, and it tends to remain relatively unchanged even in the face of severe systemic acidosis and alkalosis. Measurements of acid-base balance in the CSF, while of interest, have only limited clinical value. Acid-base changes in the lumbar CSF do not necessarily reflect the presence of similar changes in the brain, nor are the CSF data as accurate an index of the systemic changes as direct measurements of arterial blood gases.

The *ammonia content* of the CSF is one-third to one-half that of the arterial blood; it is increased in hepatic encephalopathy, the inherited hyperammonemias, and the Reye syndrome; the concentration corresponds roughly with the severity of the encephalopathy. The uric acid content of CSF is about 5 percent of that in serum and varies with changes in the serum level (high in gout, uremia, and meningitis and low in Wilson disease). The urea concentration in the CSF is slightly lower than that in the serum; in uremia, it rises in parallel with that in the blood. An intravenous injection of urea raises the blood level immediately and the CSF level more slowly, exerting an osmotic dehydrating effect on the central nervous tissues and CSF. All 24 amino acids have been isolated from the CSF. The concentration of amino acids in the CSF is about one-third that in plasma. Elevations of glutamine are found in hepatic coma and the Reye syndrome and of phenylalanine, histidine, valine, leucine, isoleucine, tyrosine, and homocystine in the corresponding aminoacidurias.

Many of the *enzymes* found in serum are known to rise in CSF under conditions of disease, usually in relation to a rise in the CSF protein. None of the enzyme changes has proved to be a specific indicator of neurologic disease with the possible exception of *lactic dehydrogenase*, especially isoenzymes 4 and 5, which are derived from granulocytes and are elevated in bacterial meningitis but not in aseptic or viral meningitis. Lactic dehydrogenase is also elevated in cases of carcinomatous meningitis, as is carcinoembryonic antigen; the latter, however, is not elevated in bacterial, viral, or fungal meningitis. As to *lipids*, the quantities in CSF are small and their measurement is difficult.

The catabolites of the *catecholamines* can now be measured in the CSF. Homovanillic acid (HVA), the major catabolite of dopamine, and 5-hydroxyindoleacetic acid (5-HIAA), the major catabolite of serotonin, are normally present in the spinal fluid; both are five or six times higher in the ventricular than the lumbar CSF. The levels of both catabolites are reduced in patients with idiopathic and drug-induced parkinsonism.

Finally, it may be said that with continued development of microchemical techniques for the analysis of the CSF, we can look forward to a better understanding of the metabolic mechanisms of the brain, particularly in the hereditary metabolic diseases. Ultra refined methods such as gas-liquid chromatography will probably reveal many new catabolic products, the measurement of which will be of value in diagnosis and therapy. Thompson has reviewed the biochemical analysis of CSF and its use for diagnostic purposes.

RADIOGRAPHIC EXAMINATION OF SKULL AND SPINE

For a long time, plain films of the cranium constituted a “routine” part of the study of the neurologic patient, but it is evident that the yield of useful information from this procedure is relatively small. Even in patients with head injury, where radiography of the skull would seem to be an optimal method of examination, a fracture is found in only 1 of 16 cases, at a cost of thousands of dollars per fracture and a small risk from radiation exposure. Nevertheless plain skull films are useful in demonstrating fractures, changes in contour of the skull, bony erosions and hyperostoses, infection in paranasal sinuses and mastoids, and changes in the basal foramina. Plain films of the spine are able to demonstrate destructive lesions of vertebrae, both neoplastic and infectious, fracture-dislocations, and Paget disease.

Sequential refinements of radiologic technique have greatly increased the yield of valuable information in special cases, but without question the most important recent advances in neuroradiology, and indeed in neurology, have come about with the development of CT and MRI. They represent a quantum leap in our ability to visualize pathology in the living person.

Computed Tomography

In this procedure, conventional x-radiation is attenuated as it passes successively through the skull, CSF, cerebral gray and white matter, and blood vessels. The intensity of the exiting radiation relative to the incident radiation is measured, the data are integrated, and images are reconstructed by computer. This major achievement in mathematical methodology, attributed to Hounsfield and others, permitted the astonishing technologic advance from plain radiographs of the skull to reconstructed images of the cranium and its contents in any plane. More than thirty thousand 2- to 4-mm x-ray beams are directed successively at several horizontal levels of the cranium. The differing densities of bone, CSF, blood, and gray and white matter are distinguishable in the resulting picture. One can see hemorrhage, softened and edematous brain, abscess, and tumor tissue and also the precise size and position of the ventricles and midline structures. The radiation exposure is not significantly greater than that from plain skull films.

The latest generation of CT scanners affords pictures of brain, spine, and orbit of great clarity. As illustrated in Fig. 2-1, in transverse section of the brain, one actually sees displayed the caudate and lenticular nuclei and the internal capsules and thalamus. The position and width of all the main sulci can be measured, and the optic nerves and medial and lateral rectus muscles stand out clearly in the posterior parts of the orbit. The brainstem, cerebellum, and spinal cord are easily visible in the scan at appropriate levels. The scans are also useful in imaging parts of the body that surround peripheral nerves and plexuses, thereby demonstrating tumors, inflammatory lesions, and hematomas that involve these nerves. In imaging of the head, CT has a number of advantages over MRI, the most important being safety when metal is present in the body and the clarity of imaging of blood from the moment of bleeding. Other advantages are its lower cost, easy availability, shorter examination time, and superior visualization of calcium, fat, and bone, particularly of the skull base and vertebrae. Also, if constant monitoring and use of life-support equipment is required during the imaging procedure, it is accomplished more readily in the CT than the MRI machine. Recent advances in CT technology (spiral,

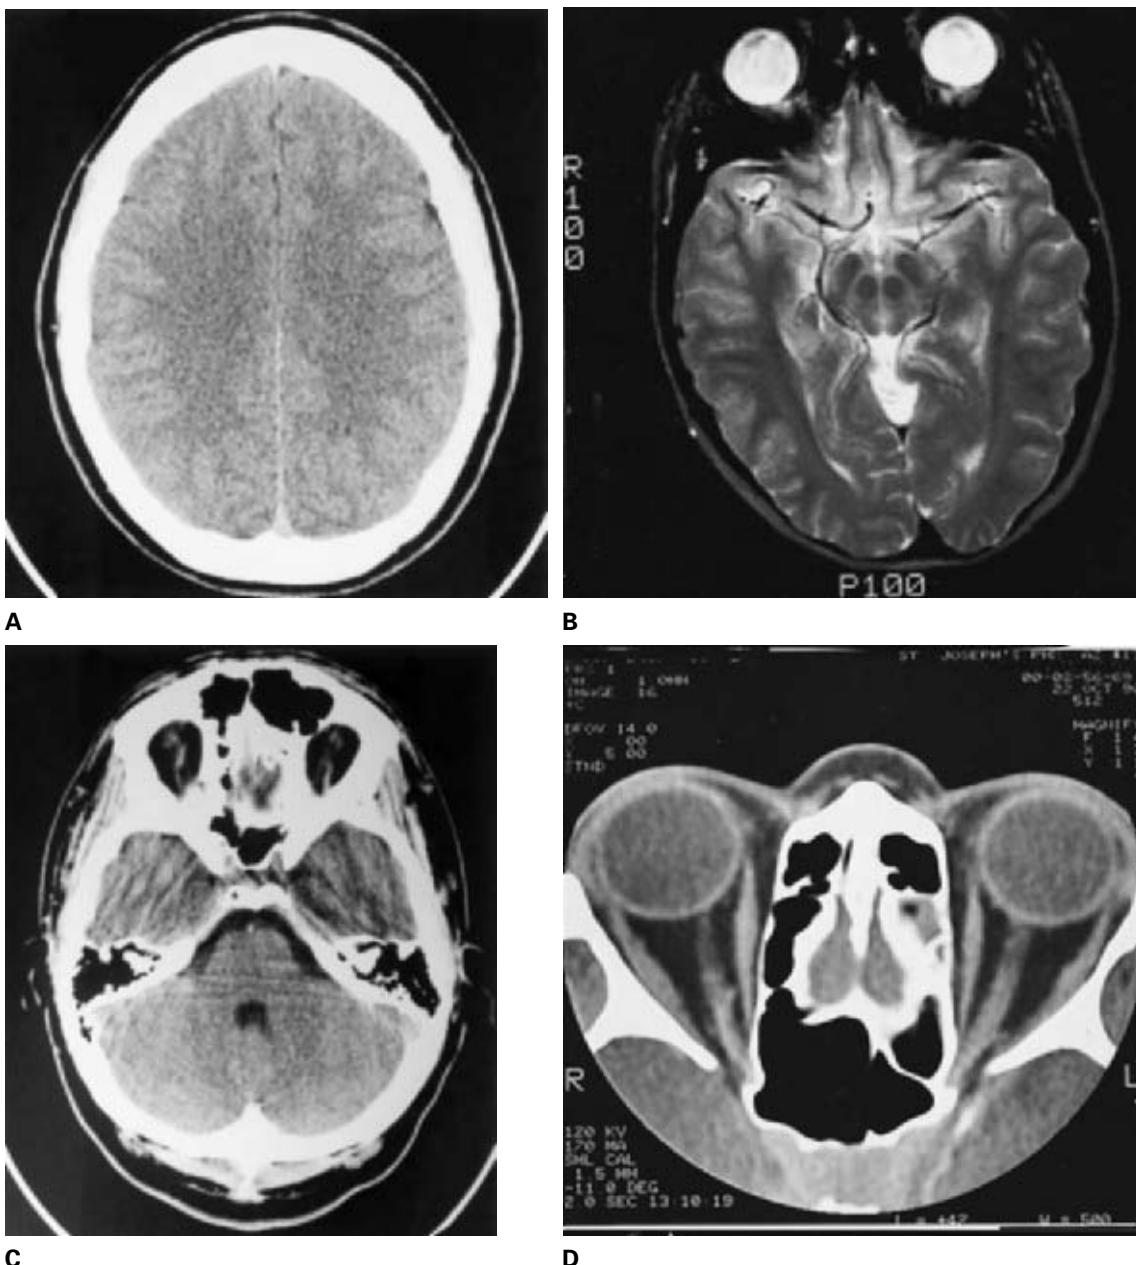

Figure 2-1. Normal axial CT scans of the brain, orbits, and lumbar spine from a young healthy man. **A.** Image through the cerebral hemispheres at the level of the corona radiata. The dense bone of the calvarium is white. Gray matter appears denser than white matter. The triangular shape of the sagittal sinus in axial section is seen posteriorly. **B.** Image at the level of the lenticular nuclei. The caudate and lenticular nuclei are more dense than the internal capsule. CSF within the frontal and occipital horns of the lateral ventricle as well as surrounding the pineal body appears dark. **C.** Image at the level of the posterior fossa. Again, the CSF within the fourth ventricle and prepontine cisterns appears dark. The basilar artery is seen as a small, round, dense focus anterior to the pons. Typical artifact generated by temporal bones creates streaking across the inferior temporal lobes. The mastoid and sphenoid sinuses are black due to their aeration. **D.** Thin-section axial image through the midorbita. The sclera appears as a dense band surrounding the globe. Medial and lateral rectus muscles have a fusiform shape. Orbital fat appears dark due to its low attenuation value. Air contained within the sphenoid sinus and ethmoid air cells appears black.

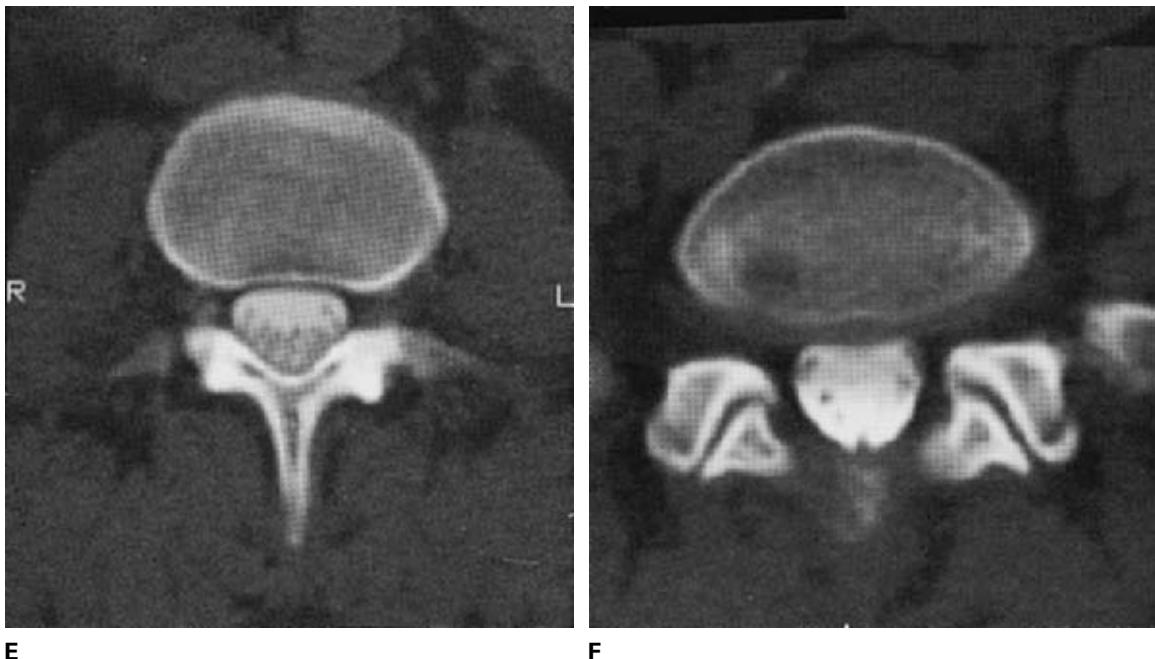

Figure 2-1 (Continued). *E.* and *F.* Axial images of the lumbar spine following myelography. Contrast contained within the thecal sac appears white. The filling defects are caused by nerve roots at the L3-4 and L5-S1 levels. Bony structures appear dense, and the facet joints are well seen. There is no evidence of disc herniation or canal stenosis. (Illustrations courtesy of Dr. Burton Drayer and Dr. Andrew Mancall.)

or helical CT) have greatly increased the speed of the scanning procedure and have made possible the visualization, with great clarity, of the cerebral vasculature (CT angiography; see further on).

Contrast Myelography

By injecting 5 to 25 mL of a water-soluble radiopaque dye through a LP needle and then tipping the patient on a tilt table, the entire spinal subarachnoid space can be visualized. The procedure is almost as harmless as the LP except for cases of complete spinal block, in which high concentrations of dye near the block can cause pain and regional myoclonus. Ruptured lumbar and cervical discs, cervical spondylotic bars and bony spurs encroaching on the spinal cord or roots, and spinal cord tumors can be diagnosed accurately. Iophendylate (Pantopaque), a formerly used fat-soluble dye, is still approved by the FDA but is now employed only in special circumstances (e.g., visualizing the upper level of a spinal canal lesion that completely obstructs the flow of dye from below). If iophendylate is left in the subarachnoid space, particularly in the presence of blood or inflammatory exudate, it may incite a severe arachnoiditis of the spinal cord and brain.

The CT body scan also provides excellent images of the spinal canal and intervertebral foramina in three planes, making the combination of water-soluble dye and CT scanning a useful means of visualizing spinal and posterior fossa lesions (Fig. 2-1*E* and *F*). Contrast myelography is particularly useful in visualizing small areas within the spinal canal, such as the lateral recesses and spinal nerve root sleeves. MRI provides even sharper visualization of the spinal canal and its contents as well as the vertebrae and intervertebral discs; it has therefore largely replaced contrast myelography because it does not require LP.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI), formerly referred to as nuclear magnetic resonance, also provides “slice” images of the brain in any plane, but it has the great advantages over CT of using non-ionizing energy and providing better resolution of different structures within the brain and other organs. For the visualization of most neurologic diseases, MRI is the procedure of choice.

An MRI examination is accomplished by placing the patient within a powerful magnetic field, causing certain endogenous isotopes (atoms) of the tissues and CSF to align themselves in the longitudinal orientation of the magnetic field. Application of a brief (few milliseconds) radiofrequency (RF) pulse into the field changes the axis of alignment of the atoms from the longitudinal to the transverse plane. When the RF pulse is turned off, the atoms return to their original alignment. The RF energy that was absorbed and then emitted results in a magnetic signal that is detected by electromagnetic receiver coils. To create contrasting tissue images from these signals, the RF pulse must be repeated many times (a pulse sequence), the signals being measured after the application of each pulse. The scanner stores the signals as a matrix of data, which is subjected to computer analysis and from which an image is constructed.

Nuclear magnetic resonance can be detected from several endogenous isotopes, but current technology uses signals derived from hydrogen atoms (^1H), because hydrogen is the most abundant element in tissue and yields the strongest magnetic signal. The image is essentially a map of the hydrogen content of tissue, therefore reflecting largely the water concentration, but influenced also by the physical and chemical environment of the hydrogen atoms. Different tissues have different rates of proton relaxation, yielding different signal intensities and hence tissue contrast. The terms *T1*

and T_2 refer to the time constants for proton relaxation; these may be altered to highlight certain features of tissue structure. In the T_1 -weighted image, the CSF appears dark and the cortical border and cortical–white matter junction are well defined, as in CT images, whereas T_2 -weighted images show the CSF as white. T_2 -weighted images highlight alterations in white matter such as infarction, demyelination, and edema (Table 2-3).

So-called FLAIR (fluid-attenuated inversion recovery) imaging is a technique that gives a high signal for parenchymal lesions and a low signal for CSF. It is sensitive to calcium and iron within brain tissue, shows early stages of infarction, and accentuates inflammatory demyelinating lesions. The images generated by the latest MRI machines are truly remarkable (Fig. 2-2A to C). Because of the high degree of contrast between white and gray matter, one can identify all discrete nuclear structures and lesions within them. Deep lesions in the temporal lobe and structures in the posterior fossa and at the cervicomedullary junction are seen much better than with CT; the structures can be displayed in three planes and are unmarred by signals from adjacent skeletal structures (bony artifact). Demyelinative lesions stand out with greater clarity and infarcts can be seen at an earlier stage than with CT. Each of the products of disintegrated RBC—methemoglobin, hemosiderin, and ferritin—can be recognized, enabling one to date the age of hemorrhages and to follow their resolution. Similarly, CSF, fat, calcium, and iron have their own signal characteristics in different imaging sequences.

MRI imaging of the spine provides clear images of the vertebral bodies, intervertebral discs, spinal cord, and cauda equina (Fig. 2-2D to F) and of syringomyelia and other lesions (herniated discs, tumors, epidural or subdural hemorrhages, areas of demyelination, and abscesses). It has practically replaced contrast myelography except in certain circumstances where very high resolution images of nerve roots and spinal cord are required.

The administration of gadolinium, a so-called paramagnetic agent that enhances the process of proton relaxation during the T_1 sequence of MRI, permits even sharper definition and highlights regions surrounding many types of lesions where the blood-brain barrier has been disrupted in the brain, spinal cord, or nerve roots.

The degree of cooperation that is required to perform MRI

Table 2-3
CT and MRI imaging characteristics of various tissues

TISSUE	CT GRAY SCALE	MRI T_1 SIGNAL	MRI T_2 SIGNAL
Brain	Gray	Gray	Gray
Air	Black		
CSF	Black	Black	White
Fat	Black	White	Black
Calcium	White	Black	Black
Bone	Very white	Black	Black
Extravasated blood	White	White	Black
Inflammation	Contrast enhancing	Gray, gadolinium enhancing	White
Edema	Dark gray	Gray	White
Tumor	Gray or white and contrast enhancing	Gray or white and gadolinium enhancing	White

limits its use in young children and in the mentally confused or retarded. Some form of sedation is required and most hospitals have services which are able to accomplish this with safety. Studying a patient who requires a ventilator is difficult but manageable by using either hand ventilation or nonferromagnetic ventilators (Barnett et al).

The main dangers in the use of MRI are torque or dislodgement of metal clips on blood vessels, of dental devices and other ferromagnetic objects, and of small metal fragments in the orbit, often acquired unnoticed by operators of machine tools. For this reason it is wise, in appropriate patients, to obtain plain radiographs of the skull so as to detect metal in these regions. Corneal metal fragments can be removed by an ophthalmic surgeon if an MRI is considered to be obligatory. The presence of a cardiac pacemaker, defibrillator, or implanted stimulator in the brain or spinal cord is an absolute contraindication to the use of MRI, since the magnetic field induces unwanted currents in the device and the wires exiting from it. However, most of the newer, weakly ferromagnetic prosthetic heart valves, intravascular access ports, and aneurysm clips do not represent an untoward risk for magnetic imaging. The same is true for joint prostheses. An extensive list of devices that have been tested for their ferromagnetic susceptibility and their safety in the MRI machine can be found in the monograph by Shellock, which is updated regularly. There have been instances over the years in which physicians have rushed into the MRI room to assist an acutely ill patient, only to have metal instruments drawn from their pockets and forcibly strike the patient or magnet.

Because of the development of cataracts in the fetuses of animals exposed to MRI, there has been hesitation in performing MRI in pregnant patients, especially in the first trimester. However, current data indicate that it may be performed in such patients provided that the study is medically indicated. In a study of 1000 pregnant MRI technicians who entered the magnetic field frequently (the magnet remains on between procedures), no adverse effects on the fetus could be discerned (Kanal et al). MRI entails some risk in these situations unless there is direct knowledge of the type of material that had been used.

Many types of MRI artifacts are known, most having to do with malfunction of the electronics of the magnetic field or of the mechanics involved in the imaging procedure (for details, see the monograph of Huk et al). Among the most common and problematic are CSF flow artifacts in the thoracic spinal cord, giving the impression of an intradural mass; distortions of the appearance of structures at the base of the brain from ferromagnetic dental appliances; and lines across the entire image induced by blood flow and patient movement.

The MRI device is costly and requires special housing and cooling to contain its powerful magnetic field. Nevertheless, as with CT earlier, MRI machines have proliferated and the technique has become indispensable for neurologic diagnosis. In most clinical circumstances, as noted above, it is advantageous to proceed directly to MRI after the clinical analysis.

The technology of MRI is constantly evolving. The visualization of blood vessels in the brain (MR angiography; see further on) as well as tumors, compressive lesions, traumatic discontinuities of peripheral nerves (Filler et al), and developmental defects of the CNS are among the more refined and promising applications of MRI. Particular attention should be drawn to diffusion-weighted imaging (DWI), a newer imaging procedure that takes only a minute to accomplish and has been invaluable in detecting the earliest

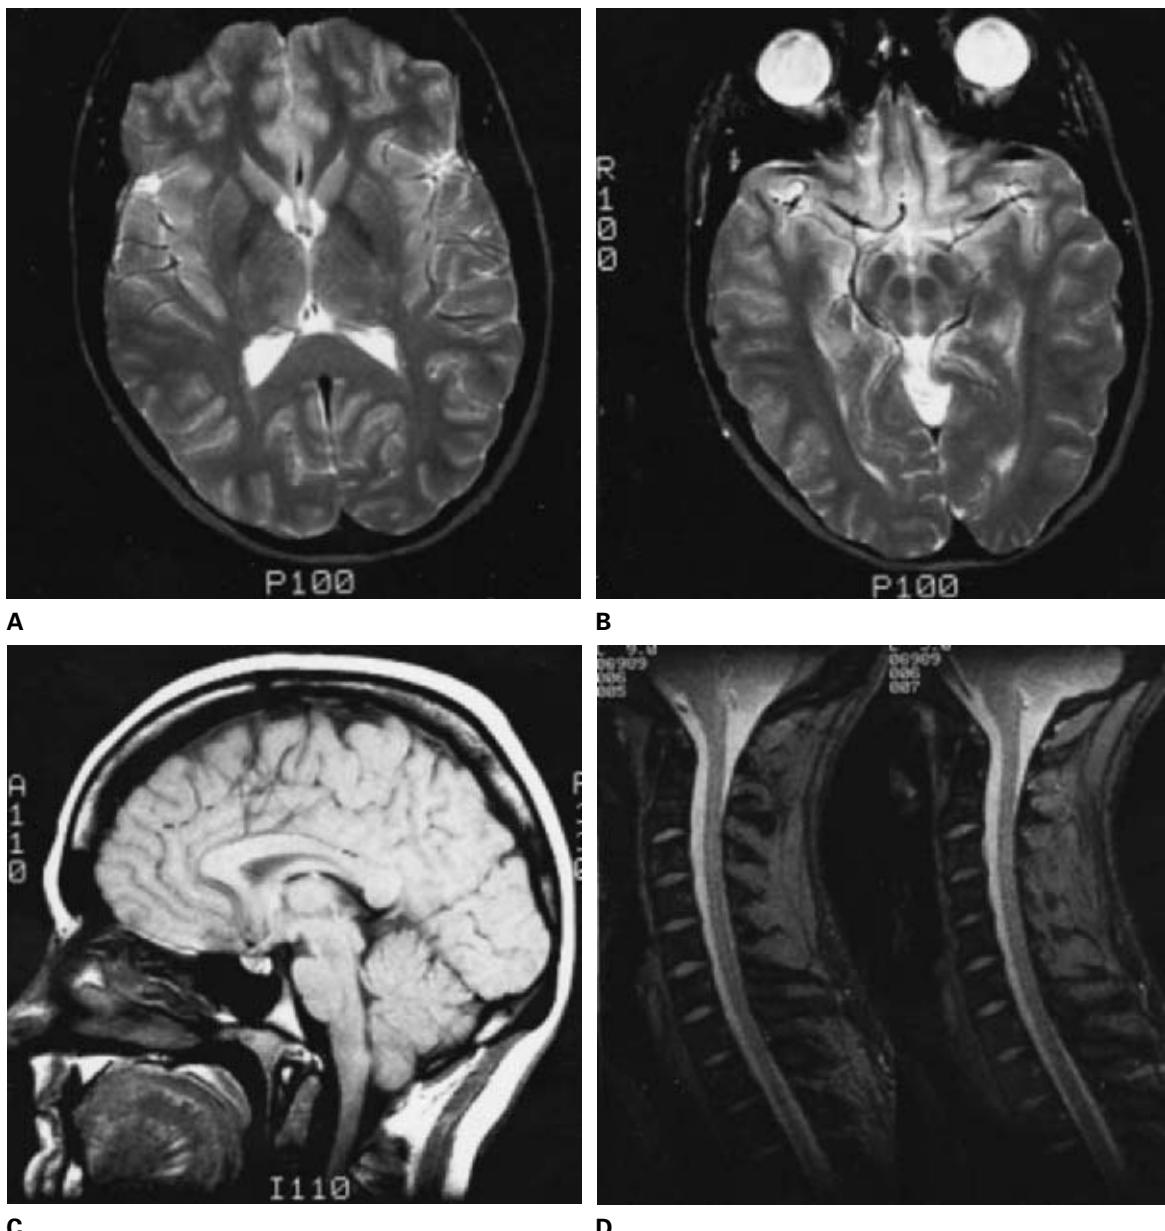

Figure 2-2. Normal MRI of the brain and the cervical and lumbar spine. *A.* T2-weighted (SE 2500/90) axial image at the level of the lenticular nuclei. Note that gray matter appears brighter than white matter. The CSF within the lateral ventricles is very bright. The caudate nuclei, putamen, and thalamus appear brighter than the internal capsule, while the globus pallidus is darker. *B.* T2-weighted (SE 2500/90) axial image at the level of the midbrain. The red nucleus and substantia nigra are dark due to normal iron accumulation. The CSF within the lateral ventricles and subarachnoid spaces appears bright, as does the vitreous. Signal is absent (“flow void”) from the rapidly flowing anterior, middle, and posterior cerebral arteries. *C.* T1-weighted (SE 700/17) midline sagittal image of the brain. Note that white matter appears brighter than gray matter and the corpus callosum is well defined. Subcutaneous fat and calvarial marrow appear very bright. The pons, medulla, and cervicomedullary junction are well delineated, and the region of the pituitary gland is normally demonstrated. *D.* Gradient echo sagittal image of the cervical spine. Note the bright signal intensity of the CSF, which provides a “myelographic” effect. Intervertebral discs also demonstrate high signal intensity. The spinal cord and brain demonstrate intermediate signal intensity, and the craniocervical junction is clearly defined.

stages of ischemic stroke (generally within 2 h or less of the onset); it is also particularly useful in distinguishing between cerebral metastases and abscesses. Here, the restricted diffusion of water in the region of cerebral infarction appears as a bright white signal. Complementary perfusion-weighted imaging (PWI) may be utilized to

detect areas that are lacking in blood flow; in parallel with DWI, it can delineate regions of ischemia that are not yet irreversibly infarcted and therefore subject to the restoration of blood flow by various techniques (Chap. 34).

The technique of MR spectroscopy, actually a derivative of

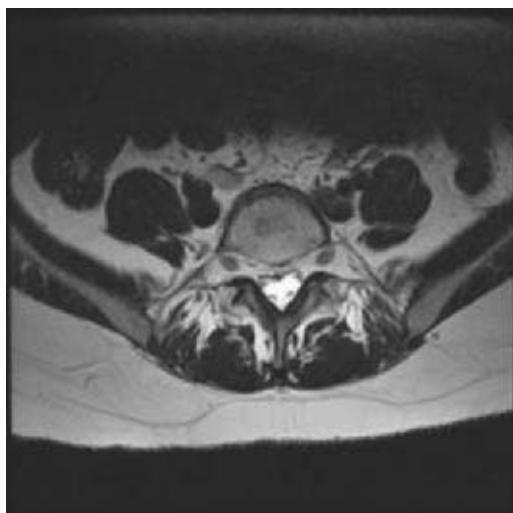

**E**

Figure 2-2 (Continued). *E.* T1-weighted (SE 600/20) axial image of the lumbar spine at the L3-4 level. Note that bone marrow appears brighter than disc material. The neural foramina are filled with fat, which demonstrates high signal intensity, and a small amount of fat is present within the spinal canal posterior to the thecal sac. The CSF within the thecal sac is dark, and nerve roots of intermediate signal intensity are demonstrated posteriorly. The facet joints are well seen. *F.* Gradient-echo sagittal image of the lumbar spine. Again, note the bright signal intensity of the CSF, creating a “myelographic” effect. The conus medullaris is well demonstrated, and individual nerve roots can be seen streaming inferiorly.

**F**

nuclear magnetic resonance (NMR), is beginning to find routine use in the analysis of certain cerebral lesions. As currently utilized, a region of brain is chosen for analysis and MR frequency sequences are applied that detect signals from the relaxation of the electrochemical bonds of various constituents of brain tissue. The main ones are choline and *N*-acetyl aspartate (NAA); the choline is contained mainly in cell membranes of myelin and NAA is a marker for neurons. Also detectable are breakdown products of myelin, which appear to the right of NAA on the spectrogram. In this way a lesion due to infarction, tumor, and demyelination can be distinguished.

Every few months some refinement in the interpretation of signal characteristics and morphologic changes appears, as do new ways of using this technology in the study of brain metabolism and blood flow (“functional” MRI or fMRI). These functional images taken in normal patients during the performance of cognitive and motor tasks and in those with neurologic and psychiatric disease are exposing novel patterns of cerebral activation and altering some of the traditional concepts of cortical function and localization. The capacity of MRI to quantitate the volume of anatomic structures offers the prospect of demonstrating neuronal atrophies. Physiologists and experimental psychologists are adapting MRI techniques to study changes in blood flow during nervous and mental activity.

The use of CT scanning and MRI in the diagnosis of particular neurologic disorders is considered in the appropriate chapters. Gilman has compiled a summary of the various imaging techniques and their utility.

Angiography

This technique has evolved over the last 50 years to the point where it is relatively safe and an extremely valuable method for the diagnosis of aneurysms, vascular malformations, narrowed or occluded arteries and veins, arterial dissections, and angiitis. Since the advent of CT and MRI, the use of angiography has practically been limited to the diagnosis of these vascular disorders, and refinements in the former two techniques [MR angiography (MRA) and spiral and helical CT scanning, described further on] promise to eliminate even these applications of conventional x-ray angiography. However, new endovascular procedures for the ablation of aneurysms, arteriovenous malformations, and vascular tumors still require the incorporation of conventional angiography.

Following local anesthesia, a needle is placed in the femoral or brachial artery; a cannula is then threaded through the needle and along the aorta and the arterial branches to be visualized. In this way, a contrast medium can be injected to visualize the arch of the aorta, the origins of the carotid and vertebral systems, and the extensions of these systems through the neck and into the cranial cavity. Highly experienced arteriographers can visualize the cerebral and spinal cord arteries down to about 0.1 mm in lumen diameter (under optimal conditions) and small veins of comparable size.

Angiography is not altogether without risk. High concentrations of the injected medium may induce vascular spasm and occlusion, and clots may form on the catheter tip and embolize the artery. Overall morbidity from the procedure is about 2.5 percent,

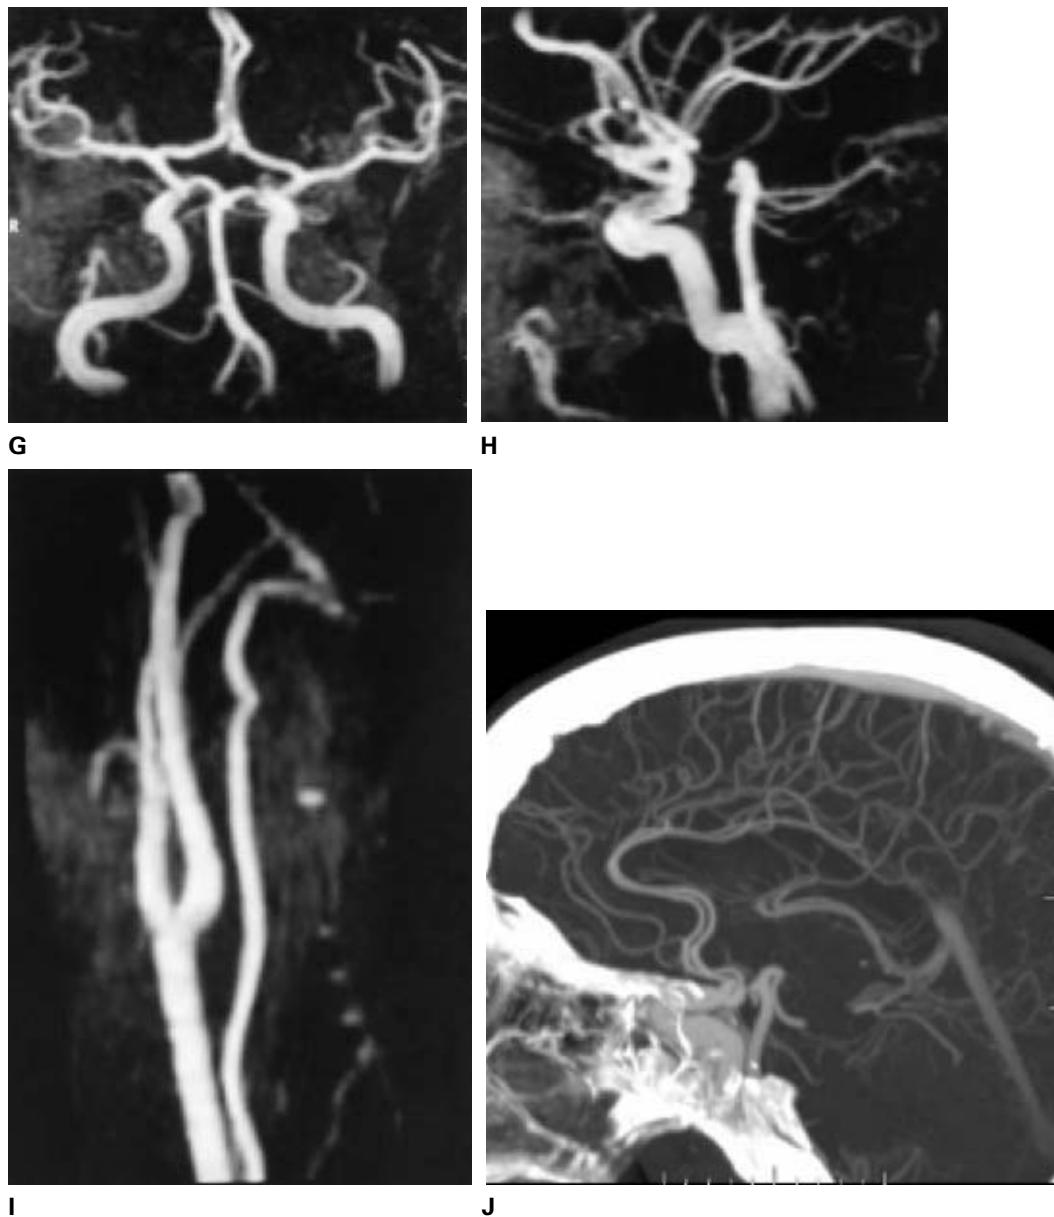

Figure 2-2 (Continued). *G.* Magnetic resonance angiogram (MRA) of the intracranial vessels (anteroposterior projection). Visualized are the large carotid arteries ascending on either side of the smaller vertebral arteries, which join to form the basilar artery in the midline. This technique allows resolution of the middle and anterior cerebral arteries beyond their first branchings. *H.* Lateral views of the MRA, showing the two large carotid arteries superimposed on each other anteriorly, giving rise to the middle and anterior cerebral arteries, and the vertebral and basilar arteries posteriorly, giving rise to the posterior cerebral arteries. *I.* Normal MRA of the cervical portions of the common, internal and external carotid arteries, and the lone, smaller vertebral artery. *J.* CT angiogram performed by injection of intravenous dye showing intracranial vessels.

mainly in the form of worsening of a pre-existent vascular lesion or from complications at the site of artery puncture. Occasionally a frank ischemic lesion is produced, probably the result of particulate atheromatous material that is dislodged by the catheter or, less often, by dissection due to the catheter. The patient may be left hemiplegic, quadriplegic, or blind; for these reasons the procedure should not be undertaken unless it is deemed necessary to obtain a clear diagnosis or in anticipation of surgery that requires a definition of the location of the vessels. A cervical myelopathy is an infrequent but disastrous complication of vertebral artery dye

injection; the problem is heralded by pain in the back of the neck immediately after injection. Progressive cord ischemia from an ill-defined vascular pathology ensues over the following hours. This same complication may occur at other levels of the cord following visceral angiography.

With current refinements of radiologic technique that use digital computer processing of radiologic data to produce images of the major cervical and intracranial arteries, the vessels can be visualized with relatively small amounts of dye that are introduced through smaller catheters than those used previously.

Magnetic Resonance and Computed Tomographic (Spiral, Helical) Angiography

These are noninvasive techniques for visualizing the main intracranial arteries that can reliably detect intracranial vascular lesions and extracranial carotid artery stenosis. They approach but have not yet reached the radiographic resolution of invasive angiography for distal vessels and for the fine detail of occlusive lesions, but they are very useful in gauging the patency of the large cervical and basal vessels (Fig. 2-2G to I). Visualization of the cerebral veins is also possible. Unlike MR angiography, the CT technique requires the injection of intravenous dye but has the great advantage of showing blood vessels and their anomalies in relation to adjacent brain and bone (Fig. 2-2J). The use of these and other methods for the investigation of carotid artery disease (ultrasound Doppler flow and imaging techniques) is discussed further below and in Chap. 34, on cerebral vascular disease.

Positron Emission Tomography

This technique, commonly known as PET, measures the regional cerebral concentration of systemically administered radioactive tracers. Positron-emitting isotopes (usually ^{11}C , ^{18}F , ^{13}N , and ^{15}O) are produced in a cyclotron or linear accelerator and incorporated into biologically active compounds in the body. The concentration of the tracers in various parts of the brain is determined noninvasively, by detectors outside the body, and tomographic images are constructed by techniques similar to those used in CT and MRI.

Local patterns of cerebral blood flow, oxygen uptake, and glucose utilization can be measured by PET scanning, and the procedure has proved to be of value in grading primary brain tumors, distinguishing tumor tissue from radiation necrosis, localizing epileptic foci, and differentiating types of dementing diseases. The ability of the technique to quantitate neurotransmitters and their receptors promises to be of importance in the study of Parkinson disease and other degenerative diseases. This technology is found in relatively few medical centers and requires costly facilities and support staff; it is therefore not utilized for routine diagnosis.

Single-Photon Emission Computed Tomography (SPECT)

This technique, which has evolved from PET, utilizes isotopes that do not require a cyclotron for their production. Here also radioligands (usually containing iodine) are incorporated into biologically active compounds, which, on decay, emit only a single photon. This procedure allows the study of regional cerebral blood flow under conditions of cerebral ischemia or during intense tissue metabolism. The restricted anatomic resolution provided by SPECT has limited its clinical usefulness, but its wider availability makes it appealing for clinical use. This has proved particularly true in helping to distinguish between Alzheimer dementia and a number of focal cerebral (lobar) atrophies and in the localization of epileptic foci in patients who are candidates for cortical resection. Once injected, the isotope localizes rapidly in the brain, with regional absorption proportional to blood flow, and is then stable for an hour or more. It is thus possible to inject the isotope at the time of the seizure onset, while the patient is undergoing video and electroencephalographic monitoring, and to scan the patient later. As with PET, the clinical potential of this technique has yet to be fully realized.

Ultrasound Scanning

In recent years this technique has been refined to the point where it has become a principal methodology for clinical study of the fetal and neonatal brain and an important ancillary test for the cerebral vessels and the heart in adults. The instrument for this application consists of a transducer capable of converting electrical energy to ultrasound waves of a frequency ranging from 5 to 20 kHz. These are transmitted through the intact skull into the brain. The different tissues have a variable acoustic impedance and send echoes back to the transducer, which displays them as waves of variable height or as points of light of varying intensity. In this way, one can obtain images of choroid plexuses, ventricles, and central nuclear masses. Usually several coronal and parasagittal views are obtained by placing the transducer over open fontanelles or the thin calvarium of an infant. Intracerebral and subdural hemorrhages, mass lesions, and congenital defects can readily be visualized.

Similar instruments are used to insonate the basal vessels of the circle of Willis ("transcranial Doppler"), the cervical carotid and vertebral arteries, and the temporal arteries for the study of cerebrovascular disease. Their greatest use is in detecting and estimating the degree of stenosis of the origin of the internal carotid artery. In addition to providing a sound image of the vascular structures, the Doppler frequency shift caused by flowing red blood cells creates a display of velocities at each site in a vessel. The two techniques combined have been called "carotid duplex"; they allow an accurate localization of the locus of maximal stenosis as reflected by the highest rates of flow and turbulence. The display scale for the Doppler shift is color-coded in order to make the insonated image and flow map easy to view and interpret.

The transcranial Doppler utilizes a 2-MHz pulsed signal that is able to transgress the calvarial bone in adults and then receives a frequency-shifted signal from the blood flowing in the lumen of the basal vessels. This allows the detection of vascular stenoses and the greatly increased blood flow velocity caused by vasospasm from subarachnoid hemorrhage.

This methodology has several advantages, notably that it is noninvasive, harmless (hence can be used repeatedly), convenient because of the portability of the instrument, and inexpensive. More specific applications of this technique are discussed in Chap. 38, on developmental diseases of the nervous system, and in Chap. 34, on stroke.

The related technique of echocardiography has also assumed a central role in the evaluation of stroke, as indicated in Chap. 34.

ELECTROENCEPHALOGRAPHY

The electroencephalographic examination, for many years a standard laboratory procedure in the study of all forms of cerebral disease, has to a large extent been supplanted by CT and MRI. Nevertheless, it continues to be an essential part of the study of patients with seizures and those suspected of having seizures. It is also used in evaluating the cerebral effects of many systemic metabolic diseases, in the study of sleep, and in the operating room to monitor cerebral activity in anesthetized patients. For a few diseases, such as subacute spongiform encephalopathy, it can be the defining laboratory test. It is described here in some detail, since it cannot suitably be assigned to any other single chapter.

The electroencephalograph records spontaneous electrical ac-

tivity generated in the cerebral cortex. This activity reflects the electrical currents that flow in the extracellular spaces of the brain, and these reflect the summated effects of innumerable excitatory and inhibitory synaptic potentials upon cortical neurons. This spontaneous activity of cortical neurons is much influenced and synchronized by subcortical structures, particularly the thalamus and high brainstem reticular formation. Afferent impulses from these deep structures are probably responsible for entraining cortical neurons to produce characteristic rhythmic brain-wave patterns, such as alpha rhythm and sleep spindles (see further on).

Electrodes, which are solder or silver-silver chloride discs 0.5 cm in diameter, are attached to the scalp by means of adhesive material such as collodion and conductive paste (or conductive paste alone). The electroencephalograph has 8 to 24 or more amplifying units capable of recording from many areas of the scalp at the same time. The amplified brain rhythms are strong enough to move an ink-writing pen, which produces waveforms of brain activity in the frequency range of 0.5 to 30 Hz (cycles per second) on paper moving at a standard speed of 3 cm/s. Alternatively, and more often now, the signal is digitally processed and displayed on a computer screen. The resulting electroencephalogram (EEG), essentially a *voltage-versus-time graph*, is recorded as a number of parallel wavy lines, or "channels" (Fig. 2-3A). Each channel represents the electrical potential between two electrodes (a common or ground electrode may be used as one recording site, but the channel still represents a bipolar recording). The channels are arranged for viewing into standard montages that generally compare the activity from one region of the cerebral cortex to that from the corresponding region of the opposite side. Conventional ink-written EEGs are gradually being replaced by a digital format, in which the digitized waveforms are viewed on the computer screen. As mentioned, the digital electroencephalograph has the great advantage of providing many more channels than the earlier type as well as flexibility in viewing the result, and it requires practically no storage space.

Patients are usually examined with their eyes closed and while relaxed in a comfortable chair or bed. The ordinary EEG, therefore, represents the electrocerebral activity that is recorded under restricted circumstances, usually during the waking state, from several parts of the cerebral convexities during an almost infinitesimal segment of the person's life.

In addition to the resting record, a number of so-called activating procedures are usually employed.

1. The patient is asked to breathe deeply 20 times a minute for 3 min. Hyperventilation, through a mechanism yet to be determined, may activate characteristic seizure patterns or other abnormalities.
2. A powerful strobe light is placed about 15 in. from the patient's eyes and flashed at frequencies of 1 to 20/s with the patient's eyes open and closed. The occipital EEG leads may then show waves corresponding to each flash of light (photic driving, Fig. 2-3B) or abnormal discharges (Fig. 2-3C).
3. The EEG is recorded after the patient is allowed to fall asleep naturally or following sedative drugs given by mouth or by vein. Sleep is extremely helpful in bringing out abnormalities, especially where temporal lobe epilepsy and certain other seizures are suspected.

Through the medium of lengthy EEG recordings as described in Chap. 19, many abnormalities associated with sleep can be dem-

onstrated and EEG activity synchronized with videographically recorded seizure activity. Also important clinically are EEGs recorded by small tape recorders or telemetry from freely moving ambulatory patients with suspected seizure disorders. These techniques are discussed more fully in Chap. 16.

The standard EEG consists of 150 to 300 or more pages, each representing 10 s in time. It is obtained by a technician who is primarily responsible for the entire procedure, including notation of movements or other events responsible for artifacts and successive modifications of technique based upon what the record shows. Certain precautions are necessary if electroencephalography is to be most useful. The patient should not be sedated (except as noted above) and should not have been without food for a long time, for both sedative drugs and relative hypoglycemia may modify the normal EEG pattern. The same may be said of mental concentration and extreme nervousness or drowsiness, all of which tend to suppress the normal alpha rhythm and increase muscle and other artifacts. When dealing with patients who are suspected of having epilepsy and are already being treated for it, most physicians prefer to record the EEG while the patient continues to receive anticonvulsant drugs. Under special circumstances these drugs may be omitted for a day or two in order to increase the chance of recording a seizure discharge.

The proper interpretation of EEGs involves the recognition of the characteristic normal and abnormal patterns and background rhythms (in accordance with the age of the patient), the detection of asymmetries and periodic changes in rhythm, and, importantly, the differentiation of artifacts from genuine abnormalities.

Types of Normal Recordings

The normal record in adults shows somewhat asymmetrical 8- to 12-per-second 50-mV sinusoidal *alpha* waves in both occipital and parietal regions. These waves wax and wane spontaneously and are attenuated or suppressed completely with eye opening or mental activity (see Fig. 2-3A). The frequency of the alpha rhythm is invariant for an individual patient, although the rate may slow during aging. Also, waves faster than 12 Hz and of lower amplitude (10 to 20 mV), called *beta* waves, are recorded from the frontal regions symmetrically. When the normal subject falls asleep, the alpha rhythm slows symmetrically and characteristic waveforms (vertex sharp waves and sleep spindles) appear (see Fig. 19-1); if sleep is induced by barbiturate or benzodiazepine drugs, an increase in the fast frequencies occurs and is considered to be normal. A small amount of theta (4- to 7-Hz) activity may normally be present over the temporal regions, somewhat more so in persons over 60 years of age. Delta (1- to 3-Hz) activity is not present in the normal waking adult.

During stroboscopic stimulation, an occipital response to each flash of light may normally be seen (*photic* or *occipital driving*). The visual response arrives in the calcarine cortex 20 to 30 ms after the flash of light. The presence of such a response indicates that the patient can at least perceive light, and if there is a claim to the contrary, the patient is either hysterical or malingering. The evoked visual responses (see further on) are an even more sensitive means of detecting hysterical blindness than occipital driving, since the latter may be absent in normal persons. Spread of the occipital response to photic stimulation, with the production of abnormal waves, provides evidence of abnormal excitability (Fig. 2-3B and C). Seizure patterns may be produced during this type of EEG testing, accompanied by gross myoclonic jerks of the face, neck, and limbs (*pho-*

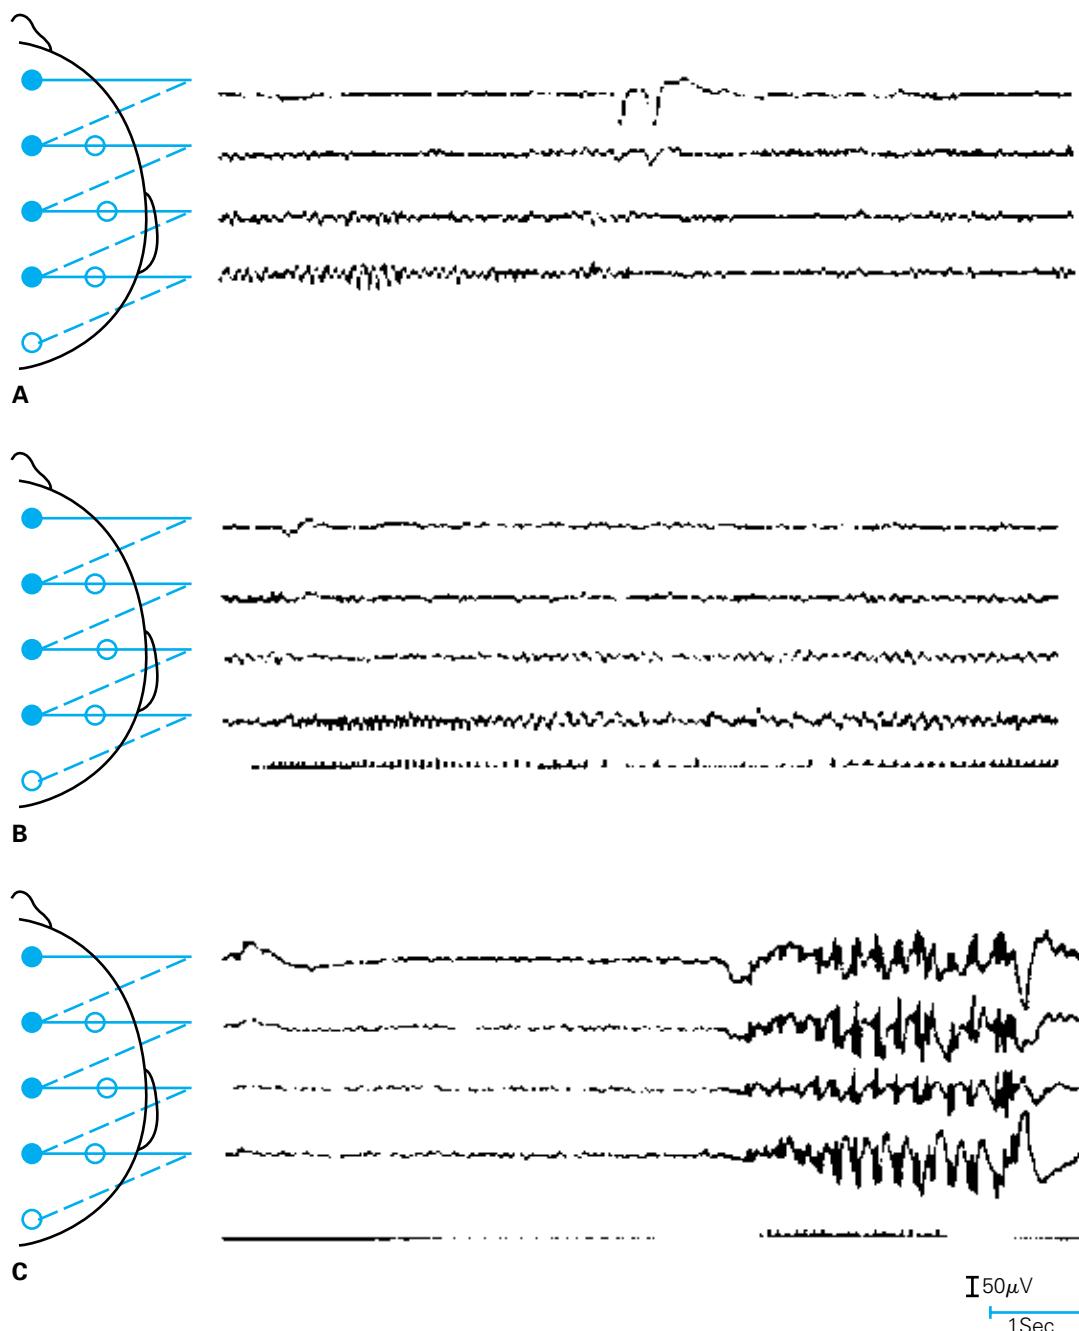

Figure 2-3. *A.* Normal alpha (9 to 10 per second) activity is present posteriorly (bottom channel). The top channel contains a large blink artifact. Note the striking reduction of the alpha rhythm with eye opening. *B.* Photic driving. During stroboscopic stimulation of a normal subject, a visually evoked response is seen posteriorly after each flash of light (signaled on the bottom channel). *C.* Stroboscopic stimulation at 14 flashes per second (bottom channel) has produced a photoparoxysmal response in this epileptic patient, evidenced by the abnormal spike and slow-wave activity toward the end of the period of stimulation.

tomyogenic or photomyoclonic response) or by major convulsions (photoparoxysmal or photoconvulsive response). Such effects occur with some regularity during periods of withdrawal from alcohol and other sedative drugs. These responses are to be differentiated from purely myoclonic ones that are produced by contracting scalp muscles and are often visible in the routine EEG.

Children and adolescents are more sensitive than adults to

all the activating procedures mentioned. It is customary for children to develop slow activity (3 to 4 Hz) during the middle and latter parts of a period of overbreathing. This activity, referred to as "breakdown," disappears soon after hyperventilation has stopped. The frequency of the dominant rhythms in infants is normally about 3 Hz, and they are very irregular. With maturation, there is a gradual increase in frequency and regularity of

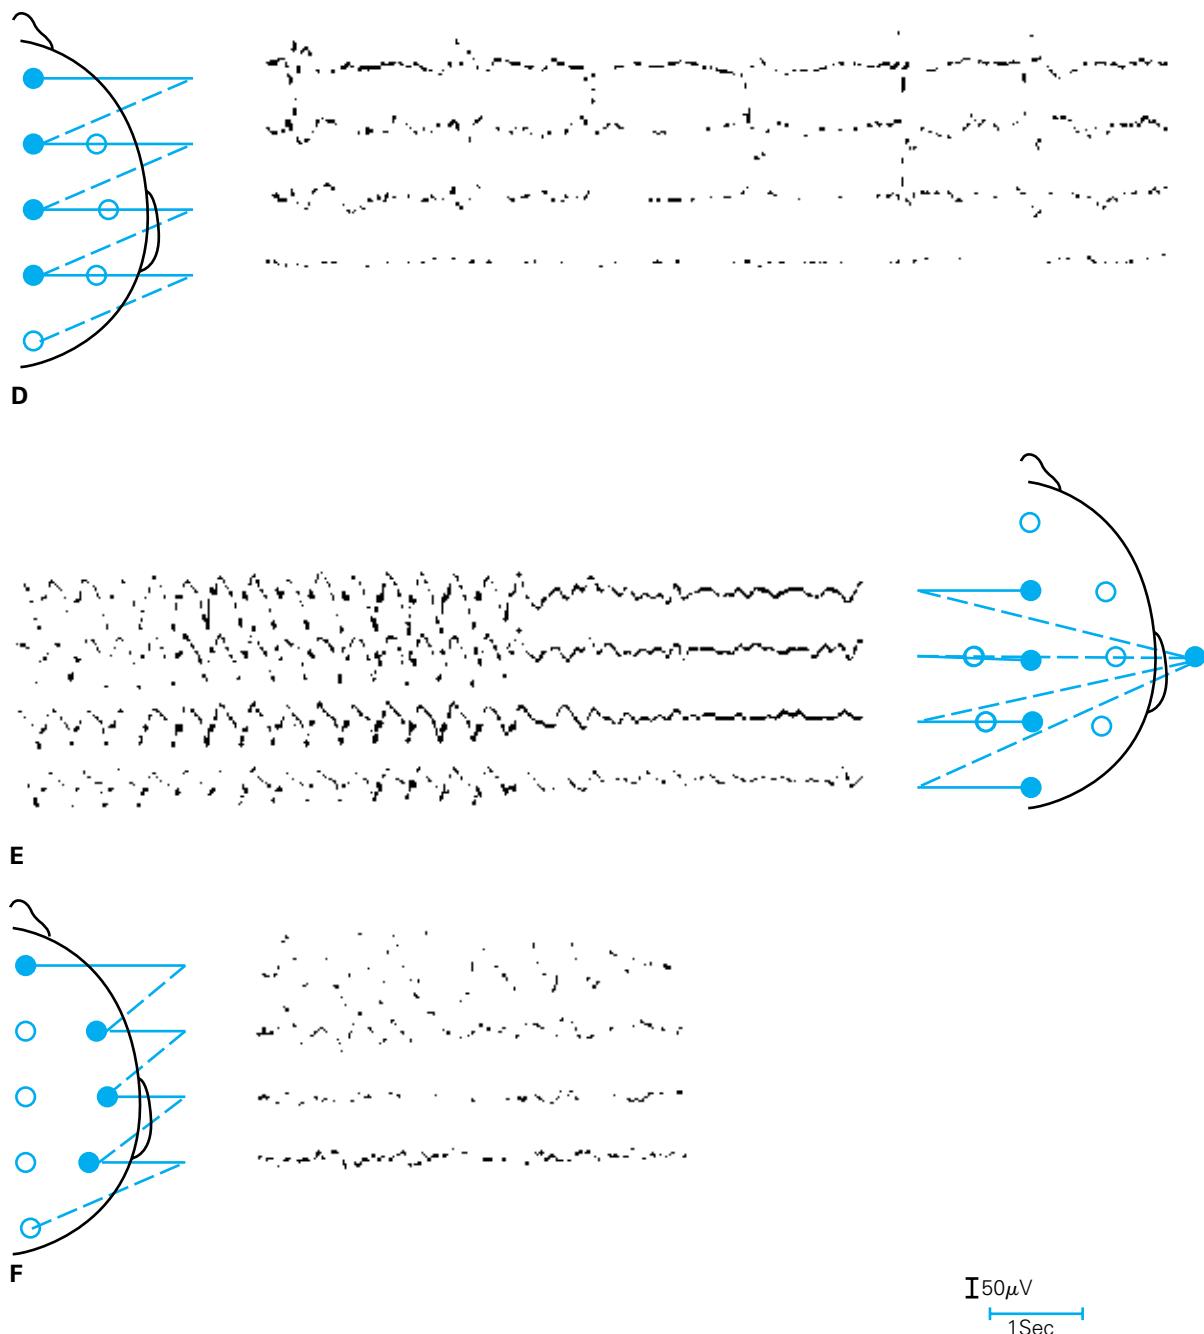

Figure 2-3 (Continued). *D.* An EEG from a patient with focal motor seizures of the left side. Note focal spike-and-wave discharge in right frontal region (channels 1 to 3). The activity from the left hemisphere (not shown here) was relatively normal. *E.* Absence seizures, showing generalized 3-per-second spike-and-wave discharge. The abnormal activity ends abruptly and normal background activity appears. *F.* Large, slow, irregular delta waves are seen in the right frontal region (channels 1 and 2). In this case a glioblastoma was found in the right cerebral hemisphere, but the EEG picture does not differ basically from that produced by a stroke, abscess, or contusion.

these occipital rhythms; by the age of 12 to 14 years, normal alpha waves are the dominant pattern (see Chap. 28 for further discussion of maturation of the brain as expressed in the EEG). The interpretation of records of infants and children require considerable experience because of the wide range of normal patterns at each age period (see Hahn and Tharp). Nevertheless,

asymmetrical records or records with seizure patterns are clearly abnormal in children of any age. Also, normal patterns in the fetus, from the seventh month onward, have been established. Certain changes in these patterns, as described by Stockard-Pope et al and by deWeerd, are clearly indicative of a developmental disorder or disease.

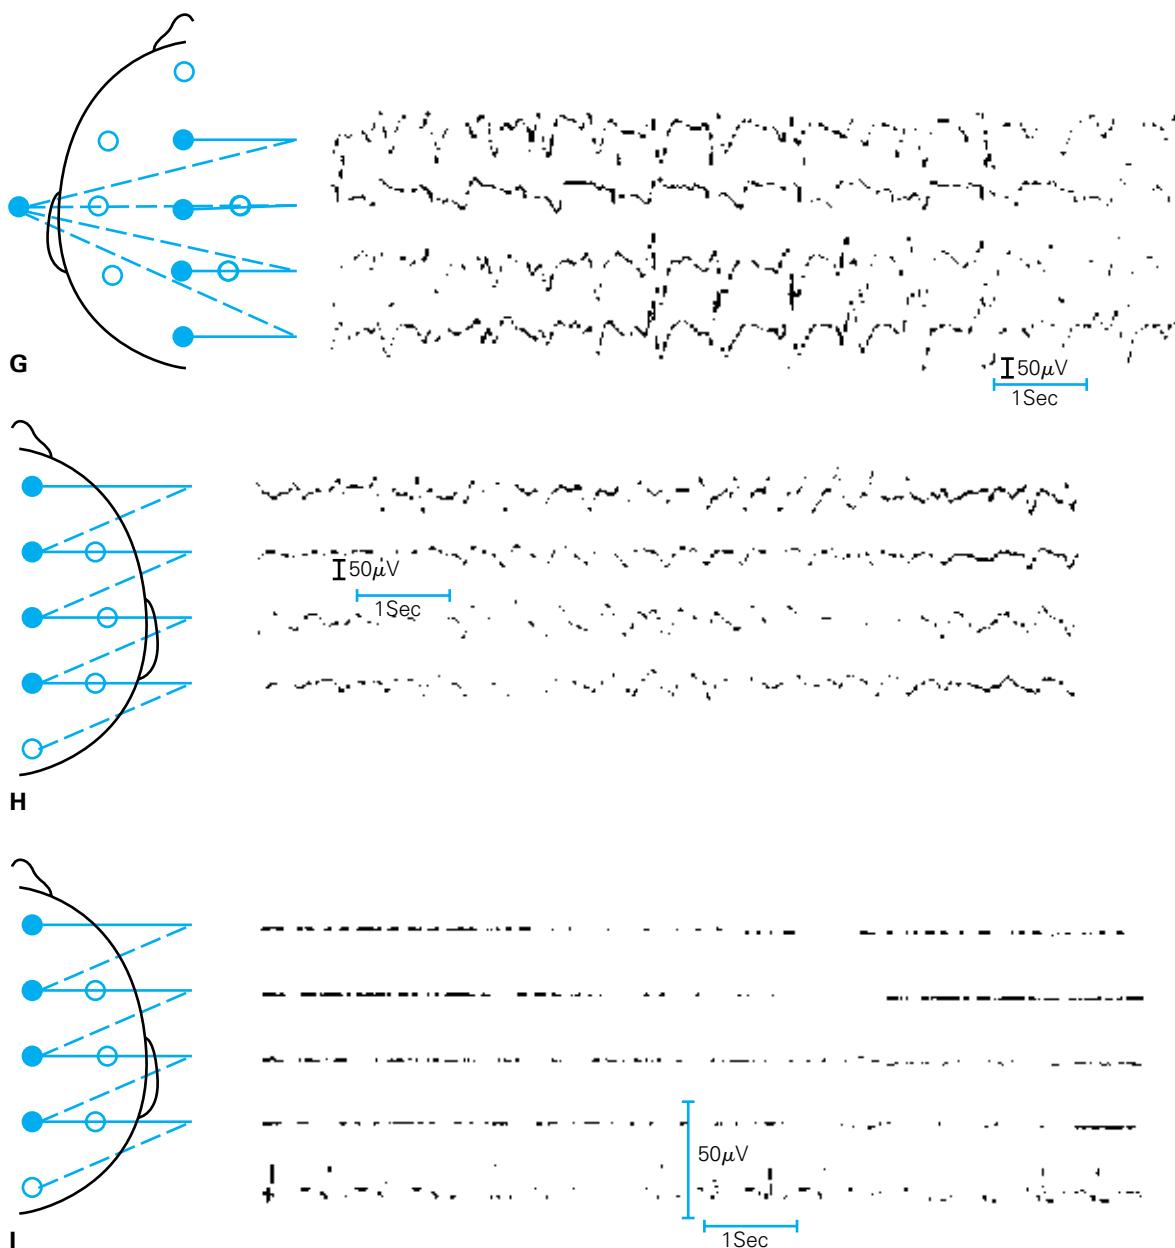

Figure 2-3 (Continued). *G*. Grossly disorganized background activity interrupted by repetitive “pseudoperiodic” discharges consisting of large, sharp waves from all leads about once per second. This pattern is characteristic of Creutzfeldt-Jakob disease. *H*. Advanced hepatic coma. Slow (about 2 per second) waves have replaced the normal activity in all leads. This record demonstrates the triphasic waves sometimes seen in this disorder (channel 1). *I*. Deep coma following cardiac arrest, showing electrocerebral silence. With the highest amplification, ECG and other artifacts may be seen, so that the record is not truly “flat” or isoelectric. However, no cerebral rhythms are visible. Note the ECG (channel 5). (Illustrations courtesy of Dr. Susan Chester.)

Types of Abnormal Recordings

Localized regions of greatly diminished or absent brain waves may be seen when there is a particularly large area of infarction, traumatic necrosis, or tumor or when an extensive clot lies between the cerebral cortex and the electrodes. With such a finding, the EEG localization of the abnormality is reasonably precise—but, of course, the nature of the lesion is not disclosed. However, most such lesions are not large enough, relative to the recording arrangement, to abolish the brain waves, and the EEG may then record

abnormal slow waves arising from functioning though damaged brain at the borders of the lesion.

Two types of abnormal waves, already mentioned, are of lower frequency and higher amplitude than normal. Waves below 4 Hz with amplitudes from 50 to 350 mV are called *delta* waves (Fig. 2-3*G* and *H*); those with a frequency of 4 to 7 Hz are called *theta* waves. Fast (*beta*) activity tends to be prominent frontally and usually reflects the effects of sedative drugs or, if focal, an immediately underlying skull defect (bone filters the normally abundant fast activity of the cortex). *Spikes* or *sharp waves* are

transient high-voltage waveforms that have a pointed peak at conventional paper speeds and a duration of 20 to 70 ms (Fig. 2-3D). Spikes or sharp waves that occur interictally in epileptics or in individuals with a genetic disposition to seizures are referred to as *epileptiform discharges*.

These abnormal fast and slow waves may be combined, and when a series of them interrupts relatively normal EEG patterns in a paroxysmal fashion, they are highly suggestive of epilepsy. The ones associated with *absence seizures* are 3-per-second spike-and-wave complexes that characteristically appear in all leads of the EEG simultaneously and disappear almost as suddenly at the end of the seizure (Fig. 2-3E). This finding led to the theoretic localization of a pacemaker for primary generalized seizure discharges in the thalamus or other deep gray structures (“centrencephalic seizures”), but such a center has not been verified anatomically or physiologically.

The most pathologic finding of all is the replacement of the normal EEG pattern by “electrocerebral silence,” meaning that the electrical activity of the cortical mantle, recorded from the scalp, is absent. Artifacts of various types should be seen as the amplifier gains are increased; if not, there is a risk that the leads are not properly connected to the machine. Acute intoxication with high levels of drugs such as barbiturates can produce this sort of iso-electric EEG (Fig. 2-3I). Moreover, in the absence of nervous system depressants or extreme degrees of hypothermia, a record that is “flat” (less than 2 mV except for artifacts) over all parts of the head is almost always a result of profound cerebral hypoxia or ischemia or of trauma and raised intracranial pressure. Such a patient—without EEG activity, brainstem reflexes, and spontaneous respiratory or muscular activity of any kind for 6 h or more—is said to be “brain dead.” The brain of such a patient is largely necrotic, and there is no chance of neurologic recovery. The topic of brain death is discussed further in Chap. 17.

Neurologic Conditions Causing Abnormal Electroencephalograms

Epilepsy All types of generalized epileptic seizures (grand mal and typical and atypical absence—see Chap. 16) are associated with some abnormality in the EEG provided that it is being recorded at the time of the seizure. Also, the EEG is usually abnormal during more restricted types of seizure activity. Rare exceptions are seizure states that originate in deep temporal, mesial, or orbital frontal foci, from which the discharge fails to reach the scalp in sufficient amplitude to be seen against the normal background activity of the EEG, particularly if there is well-developed alpha rhythm. In these cases, extra scalp leads in the anterior frontal and temporal regions (which are the most free of alpha frequencies) may pick up the discharge, especially during sleep. In some such cases, the only way in which this deep activity can be sampled is by inserting an electrode into the substance of the brain or placing a grid of electrodes in the subdural space, but this procedure is applicable only to the relatively few patients who are undergoing craniotomy. Occasionally one may fail to record an EEG abnormality in the course of one of the types of focal seizure (sensory, jacksonian, partial complex, epilepsia partialis continua) or in polymyoclonus. Presumably this means that the neuronal discharge is too deep, discrete, fast, or asynchronous to be transmitted by volume conduction through the skull and recorded via the EEG electrode, which is some 2 cm from the cortex. More often, a completely normal EEG during a convulsion indicates a “pseudoseizure.”

Some of the different types of seizure patterns are shown in Fig. 2-3C, D, and E. The absence, myoclonic, and grand mal patterns correlate closely with the clinical seizure type and may be present in milder form in the interictal EEG.

A fact of importance is that, between seizures, a single EEG recording will show a normal pattern in as many as 30 percent of patients with absence seizures and 50 percent of those with grand mal epilepsy (this percentage is less with repeated recordings). Anticonvulsant therapy also tends to diminish the interictal EEG abnormalities. The records of another 30 to 40 percent of epileptics, though abnormal between seizures, are nonspecifically so; therefore the diagnosis of epilepsy can be made only by the correct interpretation of clinical data in relation to the EEG abnormality.

Brain Tumor, Abscess, Subdural Hematoma, and Encephalitis Intracranial mass lesions are associated with characteristic abnormalities in the EEG, depending on their type and location, in some 90 percent of patients. In addition to diffuse changes, the classic abnormalities comprise focal or localized slow-wave activity (usually delta, as in Fig. 2-3F) or, occasionally, seizure activity and decreased amplitude and synchronization of normal rhythms. Although the EEG may be diagnostically helpful in cases of brain tumor or abscess, particularly when integrated with the other laboratory and clinical findings, reliance is now placed almost exclusively on CT and MRI.

However, the EEG remains of considerable value in the diagnosis of herpes simplex encephalitis in which periodic high-voltage sharp waves and slow-wave complexes at intervals of 2 to 3 per second in the temporal regions are characteristic. The other infectious encephalitides are often associated with sharp or spike activity, particularly if there have been seizures. The highly characteristic pattern of sharp waves that are almost periodic in Creutzfeldt-Jakob disease is shown in Fig. 2-3G.

Cerebrovascular Disease The EEG is now little used in the differential diagnosis of stroke. Its main practical value lies in the ability to distinguish an acute lesion in the distribution of the internal carotid or other major cerebral artery, which produces an area of slowing in the appropriate region, from lacunar infarction deep in the cerebrum or brainstem in which the surface EEG is usually normal despite prominent clinical abnormalities. After 3 to 6 months, in roughly 50 percent of patients with infarction in the territory of the middle cerebral artery, the EEG becomes normal. Perhaps half these patients will have had normal EEGs even in the week or two following the stroke. A persistent abnormality is generally associated with a poor prognosis for further recovery. Large lesions of the diencephalon or midbrain produce bilaterally synchronous slow waves, but those of the pons and medulla (i.e., below the mesencephalon) are usually associated with a normal or near-normal EEG pattern despite catastrophic clinical changes.

Cerebral Trauma A brief episode of cerebral concussion in animals is accompanied by a transitory disturbance in the EEG, but in humans this is usually no longer evident by the time a recording can be made. Large cerebral contusions produce EEG changes similar to those described for cerebral infarction. Diffuse changes often give way to focal ones, especially if the lesions are on the superolateral surfaces of the brain, and these, in turn, usually disappear over a period of weeks or months. Sharp waves or spikes sometimes emerge as the focal slow-wave abnormality resolves and may precede the occurrence of posttraumatic epilepsy; serial EEGs may

be of prognostic value in this regard. They may also aid in evaluating patients for subdural hematoma, but cerebral imaging has largely supplanted EEG for this purpose.

Diseases that Cause Coma and States of Impaired Consciousness The EEG is abnormal in almost all conditions in which there is impairment of the level of consciousness. There is a fairly close correspondence between the severity of acute anoxic damage from cardiac arrest and the degree of EEG slowing. The mildest forms are associated with generalized theta activity, intermediate forms with widespread delta waves and the loss of normal background activity, and the most severe forms with "burst suppression," in which the recording is almost isoelectric for several seconds, followed by high-voltage sharp and irregular delta activity. The latter pattern usually progresses to electrocerebral silence, a condition discussed earlier.

The term *alpha coma* refers to a unique EEG pattern in which an apparent alpha activity in the 8- to 12-Hz range is distributed widely over the hemispheres rather than in its normal location posteriorly. When analyzed carefully, this apparent alpha activity, unlike the normal monorhythmic alpha, is found to vary slightly in frequency within a narrow band. This is usually a transitional pattern after global anoxia; less often, alpha coma is seen with large acute pontine lesions. With severe *hypothyroidism*, the brain waves are normal in configuration but usually of decreased frequency.

In altered states of alertness, the more profound the depression of consciousness, in general, the more abnormal the EEG recording. In states of deep stupor or coma, the slow (delta) waves are bilateral and of high amplitude and tend to be more conspicuous over the frontal regions (Fig. 2-3H). This pertains in such differing conditions as acute meningitis or encephalitis and disorders that severely derange blood gases, glucose, electrolytes, and water balance; uremia; diabetic coma; and impairment of consciousness accompanying the large cerebral lesions discussed above. In *hepatic coma*, the degree of abnormality in the EEG corresponds closely with the degree of confusion, stupor, or coma. Characteristic of hepatic coma are paroxysms of bilaterally synchronous large, sharp "triphasic waves" (Fig. 2-3H), although such waveforms may also be seen with encephalopathies related to renal or pulmonary failure and with acute hydrocephalus.

An EEG may also be of help in the diagnosis of coma when the pertinent history is unavailable. Perhaps its greatest value in this situation is the disclosure of status epilepticus in the absence of obvious convulsions ("spike-wave stupor," epileptic fugue state). It may also point to an otherwise unexpected cause, such as hepatic encephalopathy, intoxication, thrombotic thrombocytopenic purpura, with barbiturates or other sedative-hypnotic drugs, the effects of diffuse anoxia-ischemia, or hysteria (in which case the EEG is normal).

Diffuse Degenerative Diseases Alzheimer disease and other degenerative diseases that cause serious impairment of cerebrocortical function are accompanied by relatively slight degrees of diffuse slow-wave abnormality in the theta (4- to 7-Hz) range; many recordings are normal in the early and mid-stages of illness. More rapidly progressive disorders—such as subacute sclerosing panencephalitis (SSPE), Creutzfeldt-Jakob disease, and to a lesser extent the cerebral lipidoses—often have, in addition, very characteristic and almost pathognomonic EEG changes consisting of periodic bursts of high-amplitude sharp waves, usually bisynchronous and symmetrical as already mentioned (Fig. 2-3G). In a negative sense,

a normal EEG in a patient who is profoundly apathetic is a point in favor of the diagnosis of catatonia, an affective disorder, or schizophrenia (see below).

Other Diseases of the Cerebrum Many disorders of the brain cause little or no alteration in the EEG. Multiple sclerosis and other demyelinating diseases are examples, though as many as 50 percent of advanced cases will have an abnormal record of nonspecific type (focal or diffuse slowing). Delirium tremens and Wernicke-Korsakoff disease, despite the dramatic nature of the clinical picture, cause little or no change in the EEG. Some degree of slowing usually accompanies confusional states that have been designated by some clinicians as hypokinetic delirium (Chap. 20). Interestingly, the neuroses, psychoses (such as manic-depressive disorders or schizophrenia), intoxication with hallucinogenic drugs such as LSD, and the majority of cases of mental retardation are associated either with no modification of the normal record or with only minor nonspecific abnormalities unless seizures are present.

Clinical Significance of Minor EEG Abnormalities

The gross EEG abnormalities discussed above are by themselves clearly abnormal, and any formulation of the patient's clinical state should attempt to account for them. These abnormalities include seizure discharges, generalized and extreme slowing, definite slowing with a clear-cut asymmetry or focal slowing or suppression of amplitude, and absence of normal rhythms. Lesser degrees of these abnormalities form a continuum between the undoubtedly abnormal and the completely normal and are of correspondingly minor significance. Findings such as 14- and 6-per-second positive spikes or small sharp waves during sleep, scattered 5- or 6-per-second slowing, minor voltage asymmetries, and persistence of "breakdown" for a few minutes after hyperventilation are interpreted as *borderline* abnormalities. The latter abnormalities may be meaningful, but only if correlated with particular clinical phenomena. Whereas borderline deviations in an otherwise entirely normal person have no clinical significance, the same minimal EEG findings associated with particular clinical signs and symptoms become important. The significance of a normal or "negative" EEG in certain patients suspected of having a cerebral lesion has been discussed above.

In summary, the results of the EEG, like those of the EMG and electrocardiogram, are meaningful only in relation to the illnesses under consideration and the clinical state of the patient at the time the recordings were made.

Evoked Potentials

The stimulation of sense organs or peripheral nerves evokes an electrical response in the corresponding cortical receptive areas and in a number of subcortical relay stations. However, one cannot place a recording electrode near the nuclear relay stations, nor can one detect tiny potentials of only a few microvolts among the much larger background activity in the EEG or EMG. The use of averaging methods, introduced by Dawson in 1954, and the subsequent development of computer techniques have provided the means of overcoming these problems. Initially, emphasis was on the study of late waves (over 75 ms after the stimulus) because they are of high amplitude and easy to record. However, there is more clinical utility in recording the much smaller, so-called short-latency waveforms, which are received at each nuclear relay within the main

sensory systems. These waveforms are maximized by the computer to a point where their latency and voltage can easily be measured. One of the most remarkable properties of evoked potentials is their resistance to anesthesia, sedative drugs, and—in comparison with EEG activity—even damage of the cerebral hemispheres. This permits their use for monitoring the integrity of cerebral pathways in situations that render the EEG useless. The details of these techniques are reviewed in Chiappa's monograph.

The interpretation of evoked potentials (visual, auditory, and somatosensory) is based on the prolongation of the latencies of the waveforms after the stimulus, the interwave latencies, and asymmetries in timing. Norms have been established, but it is still advisable to confirm these in each laboratory. Typically 2.5 or 3 standard deviations above the mean latency for any measurement is taken as the definition of abnormality (Table 2-4). The amplitudes of the waves are less informative.

Visual Evoked Potentials For many years it had been known that a light stimulus flashing on the retina often initiates a discern-

ible waveform over the occipital lobes. In the EEG, such responses to fast rates of stimulation are referred to as the *occipital driving response* (Fig. 2-3B and C). In 1969, Regan and Heron observed that a visual evoked response could be produced by the sudden change of a viewed checkerboard pattern. The responses produced by rapidly repeating the pattern reversal, were easier to detect and measure than flash responses and more consistent in waveform from one individual to another. It became apparent that this type of stimulus, applied first to one eye and then to the other, could demonstrate conduction delays in the visual pathways of patients who had formerly suffered a disease of the optic nerve—even when there were no residual signs of reduced visual acuity, visual field abnormalities, alterations of the optic nerve head, or changes in pupillary reflexes.

This procedure, called *pattern-shift visual evoked responses* (PSVER, or VER) or pattern-reversal visual evoked potentials, has been widely adopted as one of the most delicate tests of lesions in the visual system. Figure 2-4 illustrates the normal PSVER and two types of delayed responses. Usually, abnormalities in the amplitude and duration of PSVER accompany the abnormally prolonged latencies, but they are difficult to quantify. The expected latency for the positive polarity PSVER is near 100 ms (thus the term “P 100”); an absolute latency over approximately 118 ms or a difference in latencies of greater than 9 ms between the two eyes signifies involvement of one optic nerve (Table 2-4). Bilateral prolongation of latencies, demonstrated by separate stimulation of each eye, can be due to lesions in both optic nerves, the optic chiasm, or the visual pathways posterior to the chiasm.

Table 2-4
Main sensory evoked potential latencies from stimulus, milliseconds^a

TYPE OF EVOKED POTENTIAL	MEAN	UPPER LIMIT (MEAN + 3 SD)
PSVER (70-min check size)		
P100 absolute latency	104	118
Intereye difference	2	8
BAER (60 dB SL, 10/s monaural stimuli)		
Interwave latency		
I–III	2.1	2.6
III–V	1.9	2.4
I–V	4.0	4.7
Interside difference for most latencies	0.1	0.4
SEP—median nerve (wrist stimulation)		
Absolute latency		
Erb's point	9.7	12.0
P/N 13 (cervicomedullary)	13.5	16.3
N 19/P 21 (cortical)	19.0	22.1
Interwave latency		
Erb's-P/N 13	3.8	5.2
P/N 13–N 19	5.5	6.8
Interside difference		
P/N 13–N 19	0.3	1.1
SEP—tibial nerve (ankle stimulation; Fz-Cz recording; 165-cm height; absolute latencies are shorter for stimulation at the knee)		
Absolute latency		
Lumbar point (cauda equina)	20	25
N/P 37 (cortex)	36	42.5
Interwave latency		
Lumbar–N/P 37	16.4	21.6
Interside difference		
Lumbar–N/P 37	0.7	1.9

Norms must be verified in each laboratory; in most instances they are sensitive to the technique and stimulus used and height of the patient in the cases of limb stimulation. PSVER, pattern shift visual evoked response; BAER, brainstem auditory evoked response; SSEP, somatosensory evoked response.

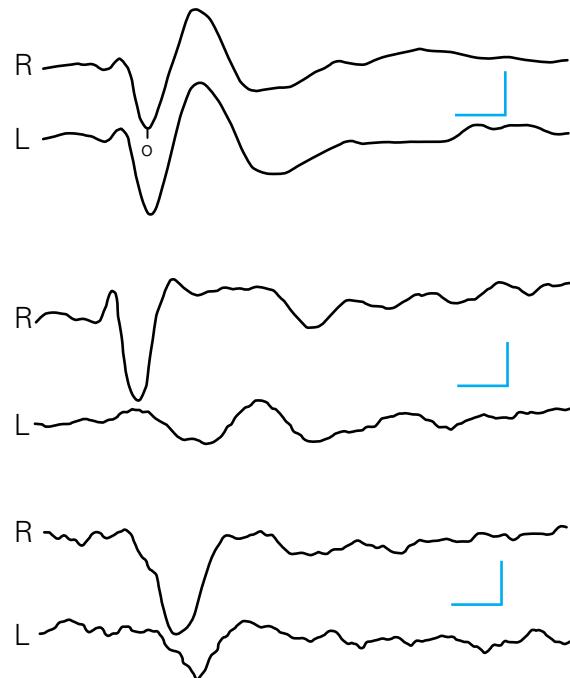

Figure 2-4. Pattern-shift visual evoked responses (PSVERs). Latency measured to first major positive peak (termed “P100” because of its latency from the stimulus of approximate 100 msec). Upper two tracings: These, from the right and left eyes, are normal. Middle tracings: PSVER from the right eye is normal but the latency of the response from the left eye is prolonged and its duration is increased. Lower tracings: PSVER from both eyes show abnormally prolonged latencies, somewhat greater on the left than on the right. Calibration: 50 ms, 2.5 mV. (Adapted by permission from Shahrokh et al.)

As indicated above, PSVER is especially valuable in proving the existence of active or residual disease of an optic nerve. Examinations of large numbers of patients who were known to have had retrobulbar (optic) neuritis has shown that only a small proportion will have normal latencies. Furthermore, similar abnormalities of PSVER are found in about one-third of multiple sclerosis patients who have no history or clinical evidence of optic nerve involvement. This acquires significance in that the finding of abnormal PSVER in a patient with a clinically apparent lesion elsewhere in the CNS may usually be taken as evidence of multiple sclerosis.

A compressive lesion of an optic nerve will have the same effect as a demyelinative one. Many other diseases of the optic nerves—including toxic and nutritional amblyopias, ischemic optic neuropathy, and the Leber type of hereditary optic neuropathy—show abnormalities of the PSVER. Glaucoma and other diseases involving structures anterior to the retinal ganglion cells may also produce increased latencies. Impaired visual acuity has little effect on the latency but does correlate well with the amplitude of the PSVER (a property that is exploited in computerized testing for visual acuity). By presenting the pattern-shift stimulus to one hem-

field, it is sometimes possible to isolate a lesion to an optic tract or radiation, or one occipital lobe, but with less precision than that provided by the usual monocular test.

Brainstem Auditory Evoked Potentials The effects of auditory stimuli can be studied in the same way as visual ones by a procedure called *brainstem auditory evoked responses* or *potentials* (BAERs or BAEPs). Between 1000 and 2000 clicks, delivered first to one ear and then to the other, are recorded through scalp electrodes and maximized by computer. A series of seven waves appears at the scalp within 10 ms after each stimulus. On the basis of depth recordings and the study of lesions produced in cats as well as pathologic studies of the brainstem in humans, it has been determined that each of the first five waves is generated by the brainstem structures indicated in Fig. 2-5. The generators of waves VI and VII are uncertain. Clinical interpretations of BAERs are based mainly on latency measurements of waves I, III, and V. The most important are the interwave latencies between I and III and III and V (see Table 2-4). The presence of wave I and its absolute latency are of particular value in testing the integrity of the auditory nerve.

A lesion that affects one of the relay stations or its immediate

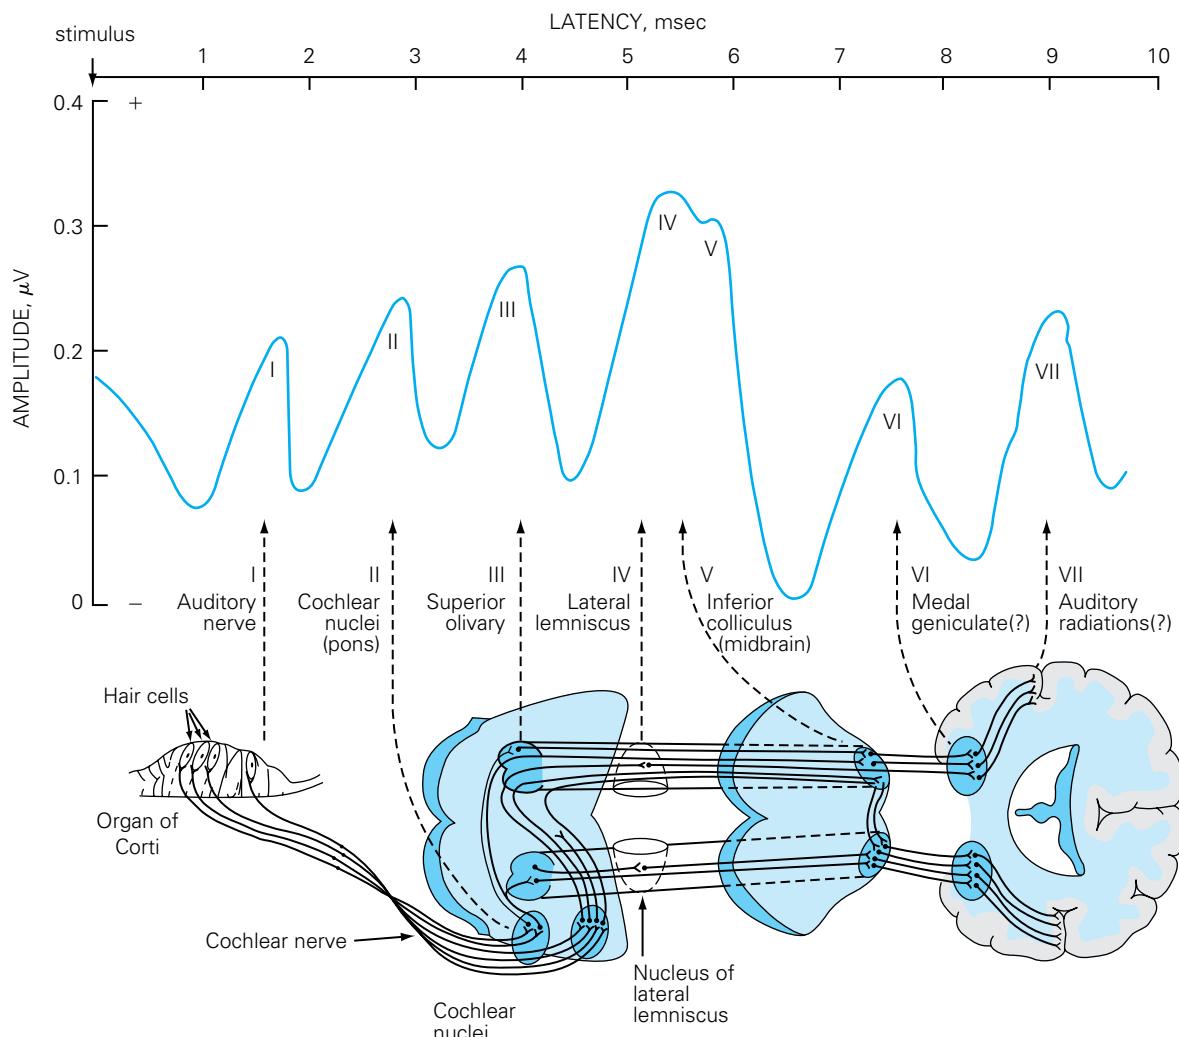

Figure 2-5. Short-latency brainstem auditory evoked responses (BAERs). Diagram of the proposed electro-physiologic-anatomic correlations in human subjects. Waves I through V are the ones measured in clinical practice.

connections manifests itself by a delay in its appearance and an absence or reduction in amplitude of subsequent waves. These effects are more pronounced on the side of the stimulated ear than contralaterally. This is difficult to understand, since a majority of the cochlear-superior olivary-lateral lemniscal-medial geniculate fibers cross to the opposite side. It is also surprising that a severe lesion of one relay station would allow impulses, even though delayed, to continue their ascent and be recordable in the cerebral cortex.

As indicated above, BAEPs are a particularly sensitive means of detecting lesions of the eighth cranial nerve (acoustic neuroma and other tumors of the cerebellopontine angle) and of the auditory pathways of the brainstem. Almost one-half of patients with definite multiple sclerosis and a lesser number with a possible or probable diagnosis of this disease will show abnormalities of the BAEPs (usually a prolongation of interwave latencies I to III or III to V), even in the absence of clinical symptoms and signs of brainstem disease. The BAEPs are also useful in assessing hearing in infants who have been exposed to ototoxic drugs, in young children who cannot cooperate with audiometry, and in hysterical patients who feign deafness.

Somatosensory Evoked Potentials *Somatosensory evoked potentials* (SEPs) are used in most clinical neurophysiology laboratories to confirm lesions in the somatic sensory systems. The technique consists of applying 5-per-second painless transcutaneous electrical stimuli to the median, peroneal, and tibial nerves and recording the evoked potentials (for the upper limb) as they pass the brachial plexus over Erb's point above the clavicle, over the C2 vertebra and over the opposite parietal cortex, and (for the lower limb) sequentially over the lumbar roots of the cauda equina, the nuclei over the cervical spine, and the opposite parietal cortex. The impulses generated in large touch fibers by 500 or more stimuli and averaged by computer can be traced through the peripheral nerves, spinal roots, and posterior columns to the nuclei of Burdach and Goll in the lower medulla, through the medial lemniscus to the contralateral thalamus, and thence to the sensory cortex of the parietal lobe. Delay between the stimulus site and Erb's point or lumbar spine indicates peripheral nerve disease; delay from Erb's point (or lumbar spine) to C2 implies an abnormality in the appropriate nerve roots or more frequently in the posterior columns; the presence of lesions in the medial lemniscus and thalamoparietal pathway can be inferred from delays of subsequent waves recorded from the parietal cortex (Fig. 2-6). The normal waveforms are designated by the symbols P (positive) and N (negative), with a number indicating the interval of time in milliseconds from stimulus to recording (e.g., N 11, N 13, P 13, P 22, etc.). As shorthand for the polarity and approximate latency, the summed wave that is recorded at the cervicomедullary junction is termed *N/P 13*, and the cortical potential from median nerve stimulation is seen in two contiguous waves of opposite polarity is called *N 19–P 22*. The corresponding cortical wave after tibial or peroneal nerve stimulation is called *N/P 37*.

For purposes of clinical interpretation, the SEPs are assumed to be linked in series, so that interwave abnormalities in latency indicate a conduction defect between the generators of the two peaks involved (Chiappa and Ropper). Normal values are shown in Table 2-4. Recordings with pathologically verified lesions at these levels are to be found in the monograph by Chiappa. This test has been most helpful in establishing the existence of lesions in spinal roots, posterior columns, and brainstem in disorders such

as the Guillain-Barré syndrome, ruptured lumbar and cervical discs, multiple sclerosis, and lumbar and cervical spondylosis when the clinical data are uncertain. The central counterpart also pertains—namely, that obliteration of the cortical waves (assuming that all preceding waves are unaltered) reflects profound damage to the somatosensory pathways in the hemisphere or to the cortex itself. As corollaries, the bilateral absence of cortical somatosensory waves after cardiac arrest is a powerful predictor of a poor clinical outcome; the persistent absence of a cortical potential after stroke usually indicates such profound damage that only a limited clinical recovery is to be expected.

Evoked potential techniques have also been used in the experimental study of olfactory sensation (see Chap. 12).

Transcranial Motor Cortex Stimulation

It is now possible, by using single-pulse high-voltage magnetic stimulation, to directly activate the motor cortex and cervical spine segments and to detect delays or lack of conduction in descending motor pathways. This technique, introduced by Marsden and associates, painlessly stimulates only the largest motor neurons (presumably Betz cells) and the fastest-conducting axons. Cervical cord stimulation is believed to activate the anterior roots. The difference in time between the motor cortical and cervical activation of hand or forearm muscles reflects the conduction velocity of the cortical–cervical cord motor neurons. Berardelli and colleagues, who have applied the technique to 20 hemiplegic patients with cerebrovascular lesions, found that in 15 there was no descending influence in comparison with the normal side. Although the degree of functional deficit does not correlate with the degree of electrophysiologic change, one expects that refinements of this technique will be useful in evaluating the status of the corticospinal motor system as well as other cortically based functions.

Endogenous Event-Related Evoked Potentials

Among the very late brain electrical potentials (>100-ms latency), which can be extracted from background activity by computer methods, are a group that cannot be classified as sensory or motor but rather as psychophysical responses to environmental stimuli. These responses are of very low voltage, often fleeting and inconsistent, and of unknown anatomic origin. The most studied types occur approximately 300 ms (P 300) after an attentive subject identifies an unexpected or novel stimulus that has been inserted into a regular train of stimuli. Almost any modality can be used and the potential occurs even when a stimulus has been omitted from a regular pattern. The amplitude of the response depends on the difficulty of the task and has an inverse relationship to the frequency of the unexpected or “odd” event; the latency depends on the task difficulty and other features of testing. There is therefore no single P 300; instead, there are numerous types, depending on the experimental paradigm. A prolongation of the latency is found with aging and in dementia as well as with degenerative diseases such as Parkinson disease, progressive supranuclear palsy, and Huntington chorea. The amplitude is reduced in schizophrenia and depression. The potential has been interpreted by some as a reflection of the subject's orienting behavior or attention and by others, including Donchin, who discovered the phenomenon, as related to an updating of the brain's

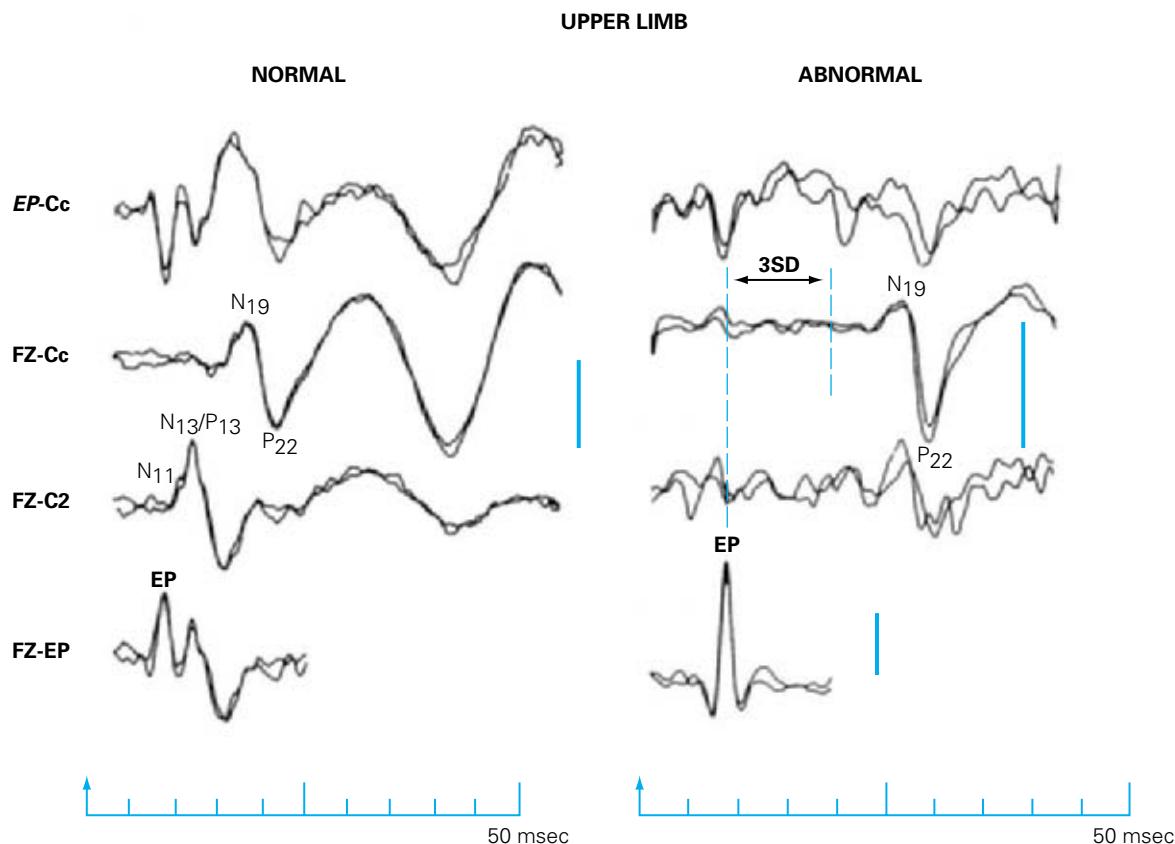

Figure 2-6. Short-latency SSEPs produced by stimulation of the **median nerve** at the wrist. The set of responses shown at left is from a normal subject; the set at right is from a patient with multiple sclerosis who had no sensory symptoms or signs. In the patient, note the preservation of the brachial-plexus component (EP), the absence of the cervical-cord (N 11) and lower-medullary components (N/P 13), and the latency of the thalamocortical components (N 19 and P 22), prolonged markedly above the normal mean 13 S.D. for the separation from the brachial plexus. Unilateral stimulation occurred at a frequency of 5 per second. Each trace is the averaged response to 1024 stimuli; the superimposed trace represents a repetition to demonstrate waveform consistency. Recording electrode locations are as follows: FZ denotes midfrontal; EP, Erb's point (the shoulder); C2, the middle back of the neck over the C2 cervical vertebra; and Cc, the scalp overlying the sensoriparietal cortex contralateral to the stimulated limb.

Relative negativity at the second electrode caused an upward trace deflection. Amplitude calibration marks denote 2 mV. (Reproduced by permission from Chiappa and Ropper.)

representation of the environment. The P 300 remains a curiosity for the clinical neurologist, because abnormalities are detected only when large groups are compared to normals, and the technique is hardly as standardized as the conventional evoked potentials. A review of the subject can be found in sections by Altenmüller and Gerloff and by Polich in the Niedermeyer and Lopes DaSilva text on electroencephalography.

Electromyography and Nerve Conduction Studies

These are discussed in Chap. 45.

Psychometry, Perimetry, Audiometry, and Tests of Labyrinthine Function

These methods are used in quantitating and defining the nature of the special psychologic or sensory deficits produced by disease of the nervous system. They are performed most often to obtain con-

firmation of a disorder of function in particular parts of the nervous system or to quantitate more precisely, by subsequent examinations, the progression of the underlying illness. A description of these methods and their clinical use will be found in the chapters dealing with cerebral function (Chap. 22), developmental disorders of the cerebrum (Chap. 28), dementia (Chap. 21), and disorders of vision (Chap. 13) and of hearing and equilibrium (Chap. 15).

Genetic Testing

Numerous genetic markers of heredofamilial disease have become available to the clinician and greatly advanced both diagnosis and categorization of hitherto obscure causes of disease. The main examples are analyses of DNA extracted from blood or other cells for the identification of mutations (e.g., muscular dystrophy, spinocerebellar atrophies, and genetically determined polyneuropathies) and the quantification of abnormally long repetitions of certain trinucleotide sequences, most often used for the diagnosis of Huntington chorea.

Biopsy of Muscle, Nerve, Skin, Temporal Artery, Brain, and Other Tissue

The application of light, phase, and electron microscopy to the study of these tissues may be highly informative. The findings are discussed in Chaps. 45 (muscle), 46 (nerve), and 37 (skin and conjunctivum in the diagnosis of storage diseases). Temporal artery biopsy is indicated when giant cell arteritis is suspected. Brain biopsy, aside from its main use in the direct sampling of a suspected neoplasm, may be diagnostic in cases of granulomatous angiitis,

some forms of encephalitis, subacute spongiform encephalopathy (biopsy now performed infrequently because of the risk of transmitting the infectious agent), and a number of other rare diseases. An important advance in recent years has been the use of CT- or MRI-guided stereotactic biopsy, which is particularly valuable in tumor diagnosis and exposes the patient to less risk than does a craniotomy and open biopsy. In choosing to perform a biopsy in any of these clinical situations, the paramount issue is the likelihood of establishing a definitive diagnosis—one that would permit successful treatment or otherwise enhance the management of the disease.

PART 2

CARDINAL MANIFESTATIONS OF NEUROLOGIC DISEASE

This page intentionally left blank.

SECTION 1

DISORDERS OF MOTILITY

The control of motor function, to which much of the human nervous system is committed, is accomplished through the integrated action of a vast array of segmental and suprasegmental motor neurons. As originally conceived by Hughlings Jackson in 1858, purely on the basis of clinical observations, the motor system is organized hierarchically in three levels, each higher level controlling the one below. It was Jackson's concept that the spinal and brainstem neurons represent the lowest, simplest, and most closely organized motor centers; that the motor neurons of the posterior frontal region represent a more complex and less closely organized second motor center; and that the prefrontal parts of the cerebrum are the third and highest motor center. This scheme is still regarded as being essentially correct, though Jackson failed to recognize the importance of the parietal lobe and basal ganglia in motor control.

Since Jackson's time, physiologists have repeatedly analyzed these three levels of motor organization and have found their relationships to be remarkably complex. Motor and sensory systems, although separated for practical clinical purposes, are not independent entities but are closely integrated. Without sensory feedback, motor control is ineffective. And at the higher cortical levels of motor control, motivation, planning, and other frontal lobe activities that subserve volitional movement are always preceded and modulated by activity in the parietal sensory cortex.

Motor activities include not only those that alter the position of a limb or other part of the body (isotonic contraction) but also those that stabilize posture (isometric contraction). Movements that are performed slowly are called *ramp movements*. Very rapid movements are called *ballistic* (they are too fast for sensory control). Another way of classifying movements, stressed by Hughlings Jackson, is in terms of their automaticity: reflex movements are the most automatic, willed movements the least. Physiologic studies, cast in their simplest terms, indicate that the following parts of the nervous system are engaged primarily in the control of movement and, in the course of disease, yield a number of characteristic derangements.

1. *The large motor neurons in the anterior horns of the spinal cord and the motor nuclei of the brainstem.* The axons of these nerve cells comprise the anterior spinal roots, the spinal nerves, and the cranial nerves, and they innervate the skeletal muscles. These nerve cells and their axons constitute the primary, or lower, motor neurons, complete lesions of which result in a loss of all movement—voluntary, automatic, postural, and reflex. The lower motor neurons are the *final common path* by which all neural impulses are transmitted to muscle.
2. *The motor neurons in the frontal cortex adjacent to the rolandic fissure* connect with the spinal motor neurons by a system of fibers known, because of the shape of its fasciculus in the medulla, as the *pyramidal tract*. Since the motor fibers that extend from the cerebral cortex to the spinal cord are not confined to the pyramidal tract, they are more accurately designated as *the corticospinal tract*, or, alternatively, as *the upper motor neurons*, to distinguish them from the lower motor neurons.
3. *Several brainstem nuclei that project to the spinal cord, notably the pontine and medullary reticular nuclei, vestibular nuclei, and red nuclei.* These nuclei and their descending fibers subserve the neural mechanisms of posture and movement, particularly when movement is highly automatic and repetitive. Certain of these brainstem nuclei are influenced by the motor or premotor regions of the cortex, e.g., via corticoreticulospinal relays.
4. *Two subcortical systems, the basal ganglia (striatum, pallidum, and related structures, including the substantia nigra and subthalamic nucleus) and the cerebellum.* Each system plays an important role in the control of muscle tone, posture, and coordination

- of movement by virtue of its connections, via thalamocortical fibers, with the corticospinal system and other descending cortical pathways.
5. *Several other parts of the cerebral cortex, particularly the premotor and supplementary motor cortices.* These structures are involved in the programming (i.e., the sequencing and modulation) of voluntary movement.
 6. *The prefrontal cortex. These parts are involved in the planning and initiation of willed movement.* Fibers from the prefrontal cortex project to the supplementary and premotor cortex and provide the input to these more strictly motor areas. Similarly, certain *parietal cortical areas (superior parietal lobule)* supply the somatic sensory information that activates the premotor and supplementary motor cortices and leads to directed movement. In addition, other parts of the nervous system concerned with tactile, visual, and auditory sensation are connected by fiber tracts with the motor cortex. These association pathways provide their own sensory regulation of motor function.

The impairments of motor function that result from lesions in these various parts of the nervous system may be subdivided into (1) paralysis due to an interruption of lower motor neurons, (2) paralysis due to dysfunction of upper motor (corticospinal) neurons, (3) apraxic or nonparalytic disturbances of purposive movement due to involvement of association pathways in the cerebrum, (4) involuntary movements and abnormalities of posture due to disease of the basal ganglia, and (5) abnormalities of coordination (ataxia) due to lesions in the cerebellum. The first two types of motor disorder and the apraxic disorders of movement are discussed in Chap. 3; “extrapyramidal” motor abnormalities are discussed in Chap. 4; and disorders of coordination, in Chap. 5. A miscellaneous group of movement disorders—tremor, myoclonus, spasms, and tics—and disorders of stance and gait are considered in Chaps. 6 and 7. Impairment or loss of motor function due to primary disease of peripheral nerves and striated muscle or to a failure of neuromuscular transmission forms the subject matter of Chaps. 46 to Chap. 55.

CHAPTER 3

MOTOR PARALYSIS

Definitions

The term *paralysis* is derived from the Greek words *para*, “beside, off, amiss,” and *lysis*, a “loosening” or “breaking up.” In medicine it has come to refer to an abolition of function, either sensory or motor. When applied to motor function, *paralysis* means loss of voluntary movement due to interruption of one of the motor pathways at any point from the cerebrum to the muscle fiber. A lesser degree of paralysis is spoken of as *paresis*, but in everyday medical parlance *paralysis* may stand for either partial or complete loss of function. The word *plegia* comes from a Greek word meaning “to strike,” and the word *palsy* from an old French word that has the same meaning as *paralysis*. All these words are used interchangeably, though generally one uses *paralysis* or *plegia* for severe or complete loss of motor function and *paresis* for partial loss.

THE LOWER MOTOR NEURON

Anatomic and Physiologic Considerations

Each spinal and cranial motor nerve cell, through the extensive arborization of the terminal part of its efferent fiber, comes into contact with only a few or up to 1000 or more muscle fibers; together, the nerve cell, its axons, and the muscle fibers they subserve constitute *the motor unit*. All variations in the force, range, rate, and type of movement are determined by the number and size of motor units called into action and the frequency and sequence of firing of each motor unit. Feeble movements involve relatively few small motor units; powerful movements recruit many more units of increasing size.

Within a few days after interruption of a motor nerve, the individual denervated muscle fibers begin to contract spontaneously. This isolated activity of individual muscle fibers is called *fibrillation*. Inability of the isolated fiber to maintain a stable membrane potential is the likely explanation. Fibrillation is so fine that it cannot be seen through the intact skin, but it can be recorded as a small, repetitive, short-duration potential in the electromyogram (EMG) (Chap. 45). When a motor neuron becomes diseased, as in progressive spinal muscular atrophy, it may manifest increased irritability, i.e., the axon is unstable and capable of ectopic impulse generation, and all the muscle fibers that it controls may discharge sporadically, in isolation from other units. The result of contraction of one or several such motor units is a visible twitch, or *fasciculation*, that appears in the EMG as a large spontaneous muscle action potential. Simultaneous or sequential spontaneous contractions of multiple motor units cause a rippling of muscle, a condition known as *myokymia*. If the motor neuron is destroyed, all the muscle fibers that it innervates undergo profound atrophy—termed *denervation atrophy*.

The motor nerve fibers of each ventral root intermingle with those of neighboring roots to form plexuses, and although the muscles are innervated roughly according to segments of the spinal cord, each large muscle comes to be supplied by two or more roots. In contrast, a single peripheral nerve usually provides the complete

motor innervation of a muscle or group of muscles. For this reason, paralysis due to disease of the anterior horn cells or anterior roots has a different pattern than paralysis following interruption of a peripheral nerve. These patterns follow the distribution shown in Table 46-1, page 1118. For example, section of the L5 motor root causes paralysis of the extensors of the foot and a foot drop, while a lesion of the peroneal nerve does the same but does not affect the invertors of the foot that are also innervated by L5 but via the tibial nerve.

All motor activity, even the most elementary reflex type, requires the synchronous activity of many muscles. Analysis of a relatively simple movement, such as clenching the fist, conveys some idea of the complexity of the underlying neuromuscular arrangements. In this act the primary movement is a contraction of the flexor muscles of the fingers, the flexor digitorum sublimis and profundus, the flexor pollicis longus and brevis, and the abductor pollicis brevis. In the terminology of Beevor, these muscles act as *agonists*, or *prime movers*. For flexion to be smooth and forceful, the extensor muscles (*antagonists*) must relax at the same rate as the flexors contract (reciprocal innervation, or Sherrington’s law). The muscles that flex the fingers also flex the wrist; since it is desired that only the fingers flex, the extensors of the wrist must be brought into play to prevent its flexion; they are *synergists*. Lastly, during this action of the hand, appropriate flexor and extensor muscles stabilize the wrist, elbow, and shoulder; muscles that accomplish this serve as *fixators*. The coordination of agonists, antagonists, synergists, and fixators is effected mainly by segmental spinal reflexes under the guidance of proprioceptive sensory stimuli. In general, the more delicate the movement, the more precise must be the coordination between agonist and antagonist muscles.

All voluntary ballistic (phasic) movements to a target are effected by the activation of ensembles of motor neurons, large ones supplying large motor units and small ones, small motor units. The smaller ones are more efficiently activated by sensory afferents from muscle spindles, more tonically active, and more readily recruited in reflex activities, postural maintenance, walking, and running. The large motor units participate mainly in phasic movements, which are characterized by an initial burst of activity in the agonist muscles, then a burst in the antagonists, followed by a third burst in the agonists. The strength of the initial agonist burst determines the speed and distance of the movement, but there is always the same triphasic pattern of agonist, antagonist, and agonist activity (Hallett et al.). The basal ganglia and cerebellum set the pattern and timing of the muscle action in any projected motor performance. These points are discussed further in Chaps. 4 and 5.

Unlike the phasic movements just described, certain basic motor activities do not involve reciprocal innervation. In support of the body in an upright posture, when the legs must act as rigid pillars, and in shivering, agonists and antagonists contract simultaneously. Locomotion requires that the extensor pattern of reflex standing be inhibited and that the coordinated pattern of alternating stepping movements be substituted; the latter is accomplished by multisegmental spinal and brainstem reflexes, the so-called locomotor centers. Suprasegmental control of the axial and proximal

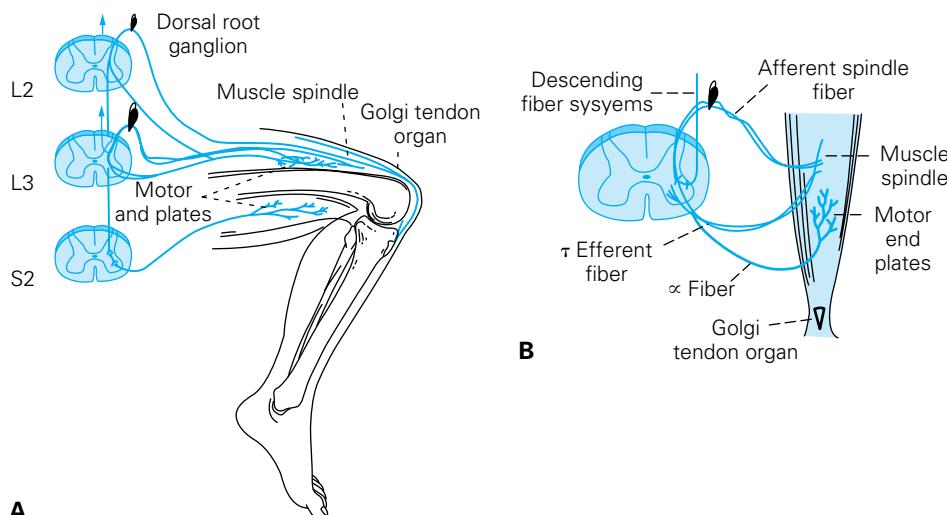

Figure 3-1. A. Patellar tendon reflex. Sensory fibers of the femoral nerve (spinal segments L2 and L3) mediate this myotatic reflex. The principal receptors are the muscle spindles, which respond to brisk stretching of the muscle effected by tapping the patellar tendon. Afferent fibers from muscle spindles are shown entering only the L3 spinal segment, while afferent fibers from the Golgi tendon organ are shown entering only the L2 spinal segment. In this monosynaptic reflex, afferent fibers entering spinal segments L2 and L3 and efferent fibers issuing from the anterior horn cells of these and lower levels complete the reflex arc. Motor fibers shown leaving the S2 spinal segment and passing to the hamstring muscles demonstrate the disynaptic pathway by which inhibitory influences are exerted upon an antagonistic muscle group during the reflex.

B. The gamma loop is illustrated. Gamma efferent fibers pass to the polar portions of the muscle spindle. Contractions of the intrafusal fibers in the polar parts of the spindle stretch the nuclear bag region and thus cause an afferent impulse to be conducted centrally. The afferent fibers from the spindle synapse with many alpha motor neurons. Because the alpha motor neurons innervate extrafusal muscle fibers, excitation of the alpha motor neurons by spindle afferents causes a cocontraction of the muscle. In this way, both gamma and alpha fibers can simultaneously activate muscle contraction. Both alpha and gamma motor neurons are influenced by descending fiber systems from supraspinal levels. (Adapted by permission from Carpenter MB, Sutin J: *Human Neuroanatomy*, 8th ed. Baltimore, Williams & Wilkins, 1983.)

limb musculature (antigravity postural mechanisms) is mediated primarily by the reticulospinal and vestibulospinal tracts and manipulatory movements of the distal extremity muscles, by the rubrospinal and corticospinal tracts. These aspects of motor function are also elaborated further on.

Tendon reflex activity and muscle tone depend on the status of the large motor neurons of the anterior horn (the *alpha motor neurons*), the muscle spindles and their afferent fibers, and the small anterior horn cells (*gamma neurons*), whose axons terminate on the small intrafusal muscle fibers within the spindles. Each anterior horn cell has on its surface membrane approximately 10,000 receptive synaptic terminals. Some of these terminals are excitatory, others inhibitory; in combination, they determine the activity of the neuron. *Beta motor neurons* effect cocontraction of both spindle and nonspindle fibers, but the physiologic significance of this innervation is not fully understood. Some of the gamma neurons are tonically active at rest, keeping the intrafusal (nuclear chain) muscle fibers taut and sensitive to active and passive changes in muscle length.

A tap on a tendon stretches or perhaps causes a vibration of the spindle and activates its nuclear bag fibers. Afferent projections from these fibers synapse directly with alpha motor neurons in the same and adjacent spinal segments; these neurons, in turn, send impulses to the skeletal muscle fibers, resulting in the familiar monosynaptic muscle contraction or monophasic (myotatic) stretch reflex, commonly referred to as the tendon reflex or “tendon jerk” (Fig. 3-1). All this occurs within 25 ms of sudden stretch. The alpha

neurons of antagonist muscles are simultaneously inhibited, but through disynaptic rather than monosynaptic connections. This is accomplished in part by inhibitory interneurons (*reciprocal inhibition*), which also receive input from descending pathways. Renshaw cells also participate by providing negative feedback through inhibitory synapses of alpha motor neurons (*recurrent inhibition*).

Thus the setting of the spindle fibers and the state of excitability of the alpha and gamma neurons (influenced greatly by descending fiber systems) determine the level of activity of the tendon reflexes and muscle tone (the responsiveness of muscle to stretch.) Other mechanisms, of an inhibitory nature, involve the Golgi tendon organs, for which the stimulus is tension produced by active contraction of muscle. These encapsulated receptors, which lie in the tendinous and aponeurotic insertions of muscle, activate afferent fibers that end on internuncial cells, which, in turn, project to alpha motor neurons, thus forming a disynaptic reflex arc. Golgi tendon receptors are silent in relaxed muscle and during passive stretch; they serve, together with muscle spindles, to monitor or calibrate the length and force of muscle

contraction under different naturally occurring limb movements, particularly in locomotion.

The alpha neurons of the medial parts of the anterior horn supply trunk or axial muscles, and neurons of the lateral parts supply the appendicular muscles. The largest neurons, in Rexed layer IX (see Fig. 8-1B), innervate large muscles with large motor units. Smaller anterior horn cells innervate small muscles and control more delicate movements, particularly those in the fingers and hand. Both groups of alpha neurons receive projections from neurons in the intermediate Rexed layers (V to VIII) and from propriospinal neurons in the fasciculi proprii of adjacent spinal segments (see Fig. 8-1B). All the facilitatory and inhibitory influences supplied by cutaneous and proprioceptive afferent and descending suprasegmental neurons are coordinated at segmental levels in such activities as phasic and tonic reflexes, flexor withdrawal and crossed extensor reflexes, postural support, tonic neck and lumbar reflexes, and more complex synergies such as rhythmic stepping (e.g., the reflex stepping of neonates). For further details the reader may consult Burke and Lance and also Davidoff (1992).

There is considerable information concerning the pharmacology of motor neurons. The large neurons of the anterior horns of the spinal cord contain high concentrations of choline acetyltransferase and utilize acetylcholine as their transmitter at the neuromuscular junction. The main neurotransmitters of the descending corticospinal tract, in so far as can be determined in humans, are aspartate and glutamate. Glycine is the neurotransmitter released by Renshaw cells, which are responsible for recurrent inhibition,

and by interneurons that mediate reciprocal inhibition during reflex action. Gamma-aminobutyric acid (GABA) serves as the inhibitory neurotransmitter of interneurons in the posterior horn. L-glutamate and L-aspartate are released by primary afferent terminals and interneurons and act specifically on excitatory amino acid receptors. There are also descending cholinergic, adrenergic, and dopaminergic axons, which play a less well defined role in reflex functions.

Paralysis Due to Lesions of the Lower Motor Neurons

If all or practically all peripheral motor fibers supplying a muscle are interrupted, all voluntary, postural, and reflex movements of that muscle are abolished. The muscle becomes lax and soft and does not resist passive stretching, a condition known as *flaccidity*. Muscle tone—the slight resistance that normal relaxed muscle offers to passive movement—is reduced (*hypotonia* or *ataxia*). The denervated muscle undergoes extreme atrophy, being reduced to 20 or 30 percent of its original bulk within 3 to 4 months. The reaction of the muscle to sudden stretch, as by tapping its tendon, is lost (*areflexia*). Damage restricted to only a portion of the motor fibers supplying the muscle results in partial paralysis, or *paresis*, and a proportionate diminution in the force and speed of contraction. The atrophy will be less and the tendon reflex reduced instead of lost. The electrodiagnosis of denervation depends upon finding fibrillations, fasciculations, and other abnormalities on needle electrode examination. However, some of these abnormalities do not appear until several days or a week or two after nerve injury (see Chap. 45).

Lower motor neuron paralysis is the direct result of loss of function or destruction of anterior horn cells or their axons in anterior roots and nerves. The signs and symptoms vary according to the location of the lesion. In any individual case, the most important clinical question is whether sensory changes coexist. The combination of a flaccid, areflexic paralysis and sensory changes usually indicates involvement of mixed motor and sensory nerves or of both anterior and posterior roots. If sensory changes are absent, the lesion must be situated in the anterior gray matter of the spinal cord, in the anterior roots, in a purely motor branch of a peripheral nerve, or in motor axons alone (or in the muscle itself). At times it may be impossible to distinguish between nuclear (spinal) and anterior root (radicular) lesions.

Preserved and often heightened tendon reflexes and spasticity in muscles weakened by lesions of the corticospinal systems attest to the integrity of the spinal segments below the level of the lesion. However, acute and profound spinal cord lesions and, to a lesser extent, corticospinal lesions in the brainstem and cerebrum may temporarily abolish spinal myotatic reflexes ("spinal shock"; see Chap. 44). This is due to the interruption of descending tonic excitatory impulses, which normally maintain a sufficient level of excitation in spinal motor neurons to permit the peripheral activation of segmental reflexes.

THE UPPER MOTOR NEURON

Anatomic and Physiologic Considerations

The terms *pyramidal*, *corticospinal*, and *upper motor neuron* are often used interchangeably, although they are not altogether synonymous. The pyramidal tract, strictly speaking, designates only

those fibers that course longitudinally in the pyramid of the medulla oblongata. Of all the fiber bundles in the brain, the pyramidal tract has been known for the longest time, the first accurate description having been given by Turck in 1851. It descends from the cerebral cortex; traverses the subcortical white matter (corona radiata), internal capsule, cerebral peduncle, basis pontis (ventral pons), and pyramid of the upper medulla; decussates in the lower medulla; and continues its caudal course in the lateral funiculus of the spinal cord—hence the alternative name *corticospinal tract*. This is the only *direct* long-fiber connection between the cerebral cortex and the spinal cord (Fig. 3-2). The *indirect* pathways through which the cortex influences spinal motor neurons are the rubrospinal, reticulospinal, vestibulospinal, and tectospinal; these tracts do not run in the pyramid. All of these pathways, direct and indirect, are embraced by the term *upper motor neuron*.

A major source of confusion about the pyramidal tract stems from the traditional view, formulated at the turn of the century, that it originates entirely from the large motor cells of Betz in the fifth layer of the precentral convolution (the primary motor cortex, or area 4 of Brodmann) (Figs. 3-3 and 22-1). However, there are only some 25,000 to 35,000 Betz cells, whereas the medullary pyramid contains about 1 million axons (Lassek). The pyramidal tract, therefore, contains many fibers that arise from cortical neurons other than Betz cells, particularly in Brodmann's areas 4 and 6 (the frontal cortex immediately rostral to area 4, including the medial portion of the superior frontal gyrus, i.e., the supplementary motor area); in the primary somatosensory cortex (Brodmann's areas 3, 1, and 2); and in the superior parietal lobule (areas 5 and 7). Data concerning the origin of the pyramidal tract in humans are scanty, but in the monkey, by counting the pyramidal axons that remained after cortical excisions and long survival periods, Russell and DeMyer found that 40 percent of the descending axons arose in the parietal lobe, 31 percent in motor area 4, and the remaining 29 percent in premotor area 6. Studies of retrograde transport of tracer substance in the monkey have confirmed these findings.

Fibers from the motor and premotor cortices (Brodmann's areas 4 and 6, Fig. 22-1), supplementary motor cortex, and portions of parietal cortex (areas 1, 3, 5, and 7) converge in the corona radiata and descend through the posterior limb of the internal capsule, basis pedunculi, basis pontis, and medulla. As the corticospinal tracts descend in the cerebrum and brainstem, they send collaterals to the striatum, thalamus, red nucleus, cerebellum, and reticular formations. Accompanying the corticospinal tracts in the brainstem are the corticobulbar tracts, which are distributed to motor nuclei of the cranial nerves ipsilaterally and contralaterally (Fig. 3-2). It has been possible to trace the direct projection of axons of cortical neurons to the trigeminal, facial, ambiguus, and hypoglossal nuclei (Iwatsubo et al). No axons were seen to terminate directly in the oculomotor, trochlear, abducens, or vagal nuclei. Insofar as the corticobulbar and corticospinal fibers have a similar origin and the motor nuclei of the brainstem are the homologues of the motor neurons of the spinal cord, the term *upper motor neurons* may suitably be applied to both these systems of fibers.

The corticospinal tracts *decussate* at the lower end of the medulla, although some of their fibers may cross above this level. The proportion of crossed and uncrossed fibers varies to some extent from one person to another. Most textbooks state that 75 to 80 percent of the fibers cross and that the remainder descend ipsilaterally, mostly in the uncrossed ventral corticospinal tract. In exceptional cases, these tracts cross completely; equally rarely, they remain uncrossed. These variations are probably of functional sig-

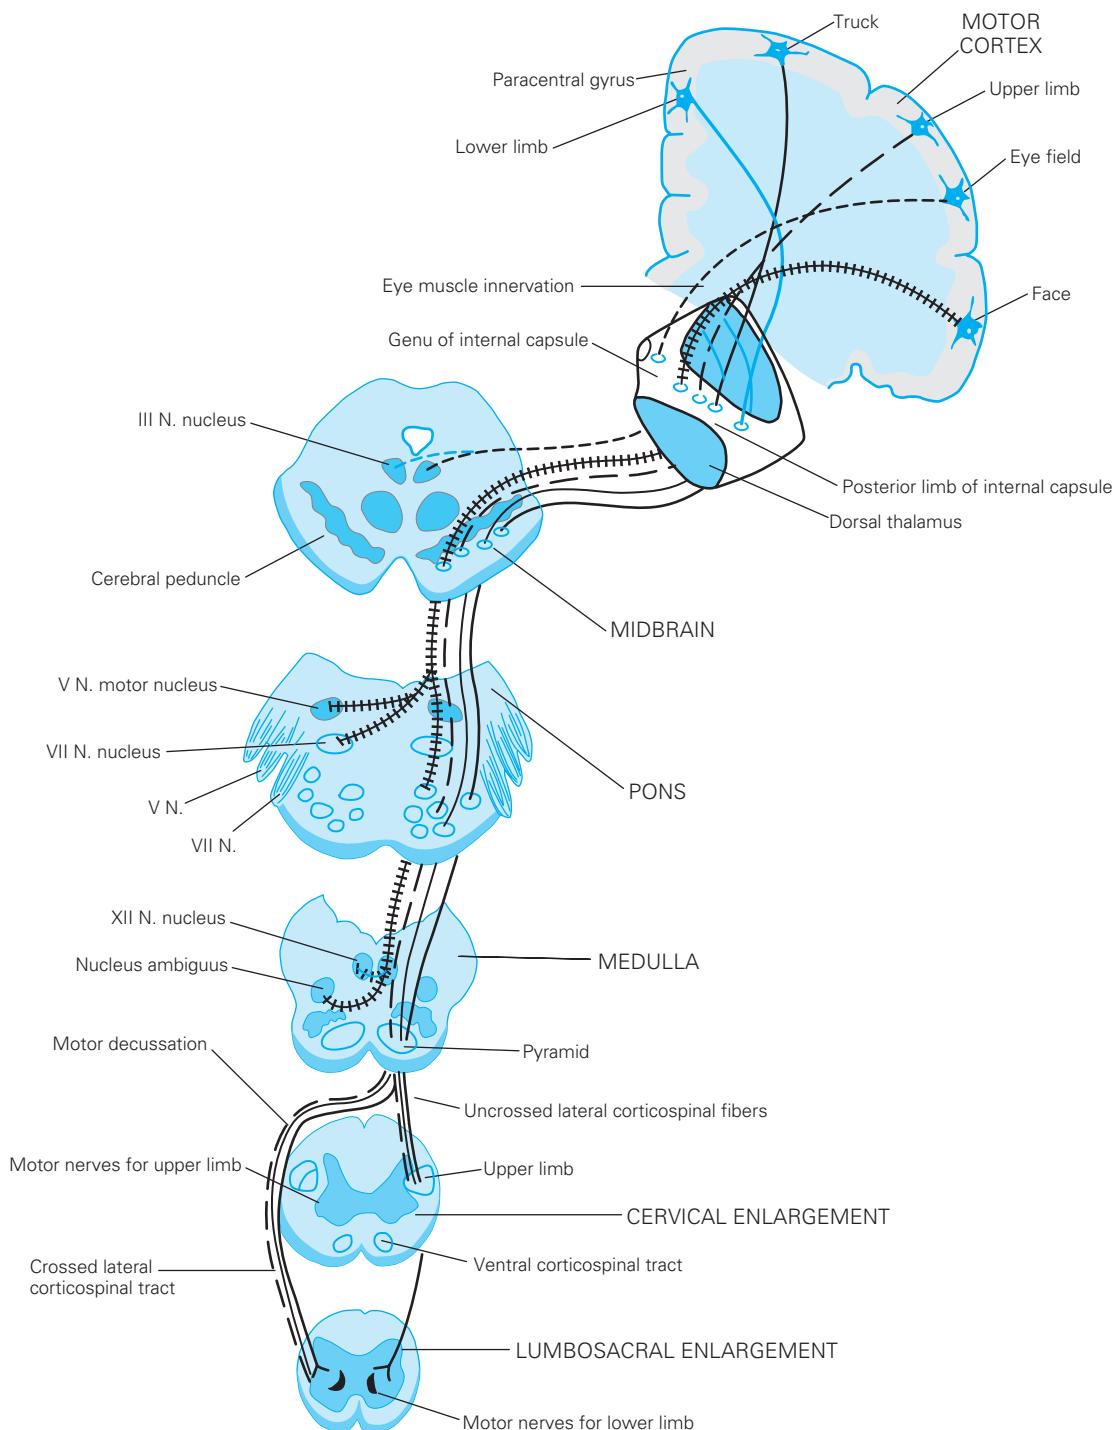

Figure 3-2. Corticospinal and corticobulbar tracts. The various lines indicate the trajectories of these pathways, from their origin in particular parts of the cerebral cortex to their nuclei of termination.

nificance in determining the amount of neurologic deficit that results from a unilateral lesion such as capsular infarction.

Beyond their decussation, the corticospinal pathways descend as well-defined bundles in the anterior and posterolateral columns of white matter (funiculi) of the spinal cord (Fig. 3-2). The course of the noncorticospinal motor pathways (vestibulospinal, reticulospinal, and descending propriospinal) have been traced in man by Nathan and his colleagues. The lateral vestibulospinal tract lies at

the periphery of the cord, where it occupies the most anterolateral portion of the anterior funiculus. The medial vestibulospinal fibers mingle with those of the medial longitudinal fasciculus. Reticulospinal fibers are less compact; they descend bilaterally, and most of them come to lie just anterior to the lateral corticospinal tract. The descending propriospinal pathway consists of a series of short fibers (one or two segments long) lying next to the gray matter.

The *somatotopic organization* of the corticospinal system is

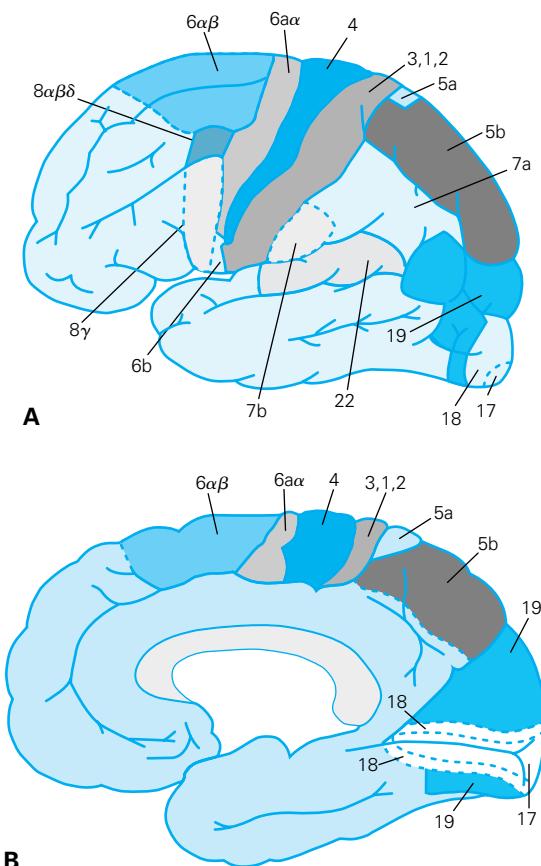

Figure 3-3. Lateral (A) and medial (B) surfaces of the human cerebral hemispheres, showing the areas of excitable cortex, i.e., areas, numbered according to the scheme of Brodmann, from which movement can be elicited by electrical stimulation. (Reprinted with permission from House EL, Pansky B: *A Functional Approach to Neuroanatomy*, 2nd ed. New York, McGraw-Hill, 1967.) See also Fig. 22-1.

of importance in clinical work, especially in relation to certain stroke syndromes. As the descending axons subserving limb and facial movements emerge from the cortical motor strip, they maintain the anatomic specificity of the overlying cortex; therefore a discrete cortical-subcortical lesion will result in a restricted weakness of the hand and arm or the foot and leg. More caudally, the descending motor fibers converge and are collected in the posterior limb of the internal capsule, so that even a small lesion there may cause a “pure motor hemiplegia,” in which the face, arm, hand, leg and foot are affected to more or less the same degree (page 682). The axons subserving facial movement are situated rostrally in the posterior limb of the capsule, those for hand and arm in the central portion, and those for the foot and leg caudally (see Brodal).

This topographic distribution is more or less maintained in the cerebral peduncle, where the corticospinal fibers occupy approximately the middle of the peduncle, the fibers destined to innervate the facial nuclei lying most medially. More caudally, in the basis pontis (base, or ventral part of the pons), the descending motor tracts separate into bundles that are interspersed with masses of pontocerebellar neurons and their cerebellopetal fibers. A degree of somatotopic organization can be recognized here as well, exemplified by selective weakness of the face and hand with dysarthria, or of the leg, which may occur with pontine lacunar infarctions. Anatomic studies in nonhuman primates indicate that arm-leg

distribution of fibers in the rostral pons is much the same as in the cerebral peduncle; in the caudal pons this distinction is less well defined. In man, a lack of systematic study leaves the precise somatotopic organization of corticospinal fibers in the pons uncertain.

A point of some uncertainty has been the course of fibers that descend through the lower pons and upper medulla and then ascend again to innervate the facial motor nucleus on the opposite side. Such a connection must exist to explain occasional instances of facial palsy from brainstem lesions caudal to the midpons. A discussion of the various hypothesized sites of this pathway, including a recurrent bundle attached to the name of Pick, can be found in the report by Terao and colleagues. They conclude from imaging studies that corticobulbar fibers destined for the facial nucleus descend in the ventromedial pons to the level of the upper medulla, where they decussate and then ascend again; but there is considerable variability between individuals in this configuration.

The descending pontine bundles, now devoid of their corticopontine fibers, reunite to form the medullary pyramid. The brachial-crural pattern may persist in the pyramids and is certainly reconstituted in the lateral columns of the spinal cord (Fig. 8-3), but it should be emphasized that the topographic separation of motor fibers at cervical, thoracic, lumbar, and sacral levels is not as discrete as usually shown in schematic diagrams of the spinal cord.

The corticospinal tracts and other upper motor neurons terminate mainly in relation to nerve cells in the intermediate zone of spinal gray matter (internuncial neurons), from which motor impulses are then transmitted to the anterior horn cells. Only 10 to 20 percent of corticospinal fibers (presumably the thick, rapidly conducting axons derived from Betz cells) establish direct synaptic connections with the large motor neurons of the anterior horns.

The Motor, Premotor, and Supplementary Motor Cortex and the Cerebral Control of Movement

The *motor area of the cerebral cortex* is defined physiologically as the region of electrically excitable cortex from which isolated movements can be evoked by stimuli of minimal intensity (Fig. 3-3). The muscle groups of the contralateral face, arm, trunk, and leg are represented in the primary motor cortex (area 4), those of the face being in the most inferior part of the precentral gyrus on the lateral surface of the cerebral hemisphere and those of the leg in the paracentral lobule on the medial surface of the cerebral hemisphere. The parts of the body capable of the most delicate movements have, in general, the largest cortical representation, as displayed in the motor homunculus diagram shown in Fig. 3-4.

Area 6, the *premotor area*, is also electrically excitable but requires more intense stimuli than area 4 to evoke movements. Stimulation of its caudal aspect (area 6aa) produces responses that are similar to those elicited from area 4. These responses are probably effected by transmission of impulses from area 6a to area 4 (since they cannot be obtained after ablation of area 4). Stimulation of the rostral premotor area (area 6ab) elicits more general movement patterns, predominantly of proximal limb musculature. The latter movements are effected via pathways other than those derived from area 4 (hence, “extrapyramidal”). Very strong stimuli elicit movements from a wide area of premotor frontal and parietal cortex, and the same movements may be obtained from several widely

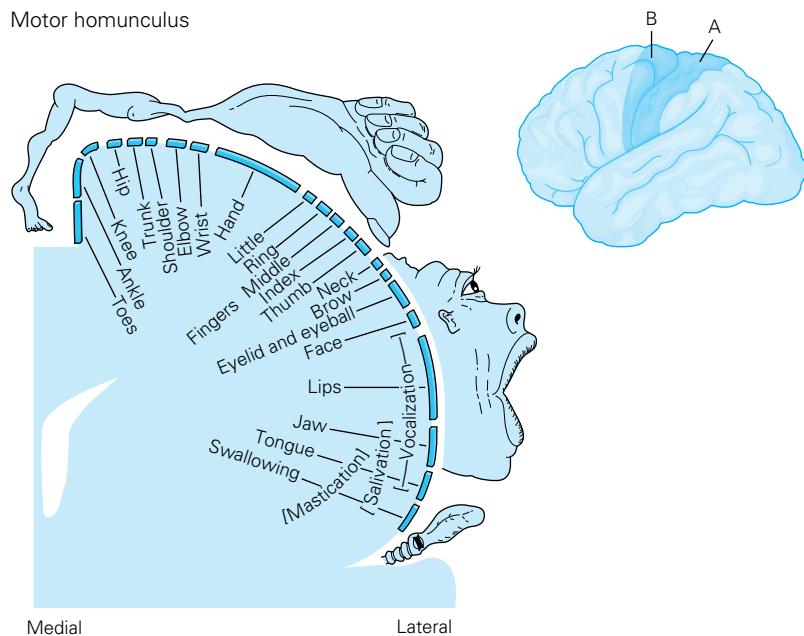

Figure 3-4. The representation of body parts in the motor cortex, commonly called the “*motor homunculus*.” The large area of cortex devoted to motor control of the hand, lips, and face is evident. *B* in the smaller diagram represents the motor cortex; *A* is the sensory cortex.

separated points. From this it may be assumed, as Ash and Georgopoulos point out, that the premotor cortex includes several anatomically distinct subregions with different afferent and efferent connections. In general, it may be said that the motor-premotor cortex is capable of synthesizing agonist actions into an infinite variety of finely graded, highly differentiated patterns. These are directed by visual (area 7) and tactile (area 5) sensory information and supported by appropriate postural mechanisms.

The *supplementary motor area* is the most anterior portion of area 6 on the medial surface of the cerebral hemisphere. Stimulation of this area may induce relatively gross homolateral or contralateral movements, bilateral tonic contractions of the limbs, contraversive movements of the head and eyes with tonic contraction of the contralateral arm, and sometimes inhibition of voluntary motor activity and vocal arrest.

Precisely how the motor cortex controls movements is still a controversial matter. The traditional view, based on the interpretations of Hughlings Jackson and of Sherrington, is that the motor cortex is organized not in terms of individual muscles but of movements, i.e., the coordinated contraction of groups of muscles. Jackson visualized a widely overlapping representation of muscle groups in the cerebral cortex on the basis of his observation that a patient could recover the use of a limb following destruction of the limb area as defined by cortical stimulation. This view was supported by Sherrington's observations that stimulation of the cortical surface activated not solitary muscles but a combination of muscles, and always in a reciprocal fashion—i.e., in a manner that maintained the expected relationship between agonists and antagonists. He also noted the inconstancy of stimulatory effects; the stimulation of a given cortical point that initiated flexion of a part on one occasion might initiate extension on another.

These interpretations must be viewed with circumspection, as must all observations based on the electrical stimulation of the surface of the cortex. It has been shown that to stimulate motor cells from the surface, the electric current has to penetrate the cor-

tex to layer V, where these neurons are located, inevitably activating a large number of other cortical neurons. The elegant experiments of Asanuma and of Evarts and his colleagues, who stimulated the depths of the cortex with microelectrodes, demonstrated the existence of discrete zones of efferent neurons that control the contraction of individual muscles; moreover, the continued stimulation of a given efferent zone often facilitated rather than inhibited the contraction of the antagonists. These investigators have also shown that cells in the efferent zone receive afferent impulses from the particular muscle to which the efferent neurons project. When the effects of many stimulations at various depths were correlated with the exact sites of each penetration, cells that projected to a particular pool of spinal motor neurons were found to be arranged in radially aligned columns about 1 mm in diameter. The columnar arrangement of cells in the sensorimotor cortex had been appreciated for many years; the wealth of radial interconnections between the cells in these columns led Lorente de Nò to suggest that these “vertical chains” of cells were the elementary functional units of the cortex. On the sensory side, this notion received strong support from Mountcastle's observations that all the neurons in a somatosensory

column receive impulses of the same sensory modality, from the same part of the body. In regard to the functional organization of the columns of motor neurons, it is still not entirely clear whether they contribute to a movement as units or whether individual cells within many columns are selectively activated to produce a movement. The evidence for these disparate views has been summarized by Henneman and by Asanuma.

The role of cerebrocortical motor neurons in sensory evoked or planned movement has also been elucidated by Evarts and his colleagues. Using single-cell recording techniques, they showed that pyramidal cells fire about 60 ms prior to the onset of a movement in a sequence determined by the required pattern and force of the movement. But other, more complex properties of the pyramidal cells were also noted. Some of them received a somatosensory input trans cortically from the parietal lobe (areas 3, 1, and 2), which could be turned on or off or gated according to whether the movement was to be controlled, i.e., guided, by sensory input. Many neurons of the supplementary and premotor parts of the motor cortical area were activated in a “set discharge” that preceded (anticipated) a planned movement. Thus, pyramidal (area 4) motor neurons were prepared for the oncoming activation; i.e., they were triggered by a number of trans cortical impulses from the parietal, prefrontal, premotor, and auditory and visual areas of the cortex. This set signal could occur in the absence of any segmental activity in the spinal cord and muscles. The source of this set signal was found to be mainly in the supplementary motor cortex, which appears to be under the direct influence of the readiness stimuli (*Bedürfnis* potential) reaching it from the prefrontal areas (for planned movements) and the posterior parietal cortex (for motor activities initiated by visual, tactile, and auditory perceptions). Also, there are fibers that reach the motor area from the limbic system, presumably subserving motivation and attention. The blood flow to each of the cortical motor zones increases with an increase in their synaptic activity, and the measurement of blood flow has been used to follow these neural events (Roland).

Thus the prefrontal cortex, supplementary motor cortex, premotor cortex, and motor cortex are all responsive to various afferent stimuli and are involved in set discharges prior to and in coordinated fashion with a complex movement. And, as remarked later on, the striatopallidum and cerebellum, which project to these cortical areas, are also activated prior to or concurrently with the discharge of corticospinal neurons (see Thach and Montgomery for a critical review of the physiologic data).

Termination of the Corticospinal and Other Descending Motor Tracts

This has been studied in the monkey by interrupting the descending motor pathways in the medulla and more rostral parts of the brainstem and tracing the distribution of the degenerating elements in the spinal gray matter. On the basis of such experiments and other physiologic data, Lawrence and Kuypers proposed that the functional organization of the descending cortical and subcortical pathways is determined more by their patterns of termination and the motor capacities of the internuncial neurons upon which they terminate than by the location of their cells of origin. Three groups of motor fibers were distinguished according to their differential terminal distribution: (1) The corticospinal and corticobulbar tracts, which project to all levels of the spinal cord and brainstem, terminating diffusely throughout the nucleus proprius of the dorsal horn and the intermediate zone. A portion of these connect directly with the large motor neurons that innervate the muscles of the fingers, face, and tongue; this system provides the capacity for a high degree of fractionation of movements, as exemplified by independent finger movements. As alluded to above, a large fraction of the fibers in the corticospinal originate from the sensory cortex and appear to function in the modulation of movement by afferent neurons. (2) A *ventromedial pathway*, which arises in the tectum (*tectospinal tract*), vestibular nuclei (*vestibulospinal tract*), and pontine and medullary reticular cells (*reticulospinal tract*) and terminates principally on the internuncial cells of the ventromedial part of the spinal gray matter. This system is mainly concerned with axial movements—the maintenance of posture, integrated movements of body and limbs, and total limb movements. (3) A *lateral pathway*, which is derived mainly from the magnocellular part of the red nucleus and terminates in the dorsal and lateral parts of the internuncial zone. This pathway adds to the capacity for independent use of the extremities, especially of the hands.

Reference has already been made to the corticomesencephalic, corticopontine, and corticomедullary fiber systems that project onto the reticulospinal, vestibulospinal, rubrospinal, and tectospinal nuclei. These control stability of the head (via labyrinthine reflexes) and of the neck and body in relation to the head (tonic neck reflexes) as well as postures of the body in relation to limb movements. Lesions in these systems are less well understood than those of the corticospinal system. They cause no paralysis of muscles but result in the liberation of unusual postures (e.g., hemiplegic dystonia), heightened tonic neck and labyrinthine reflexes, and decerebrate rigidity. In a strict sense these are all “extrapyramidal,” as discussed in the next two chapters.

Paralysis Due to Lesions of the Upper Motor Neurons

The corticospinal pathway may be interrupted by a lesion at any point along its course—at the level of the cerebral cortex, subcor-

tical white matter, internal capsule, brainstem, or spinal cord. Usually, when hemiplegia is severe and permanent as a consequence of disease, much more than the long, direct corticospinal pathway is involved. In the cerebral white matter (corona radiata) and internal capsule, the corticospinal fibers are intermingled with corticostriate, corticothalamic, corticorubral, corticopontine, cortico-olivary, and corticoreticular fibers. It is noteworthy that thalamocortical fibers, which are a vital link in an ascending fiber system from the basal ganglia and cerebellum, also pass through the internal capsule and cerebral white matter. Thus lesions in these parts simultaneously affect both corticospinal and extrapyramidal systems. Attribution of a capsular hemiplegia solely to a lesion of the corticospinal or pyramidal pathway is therefore not entirely correct. The term *upper motor neuron paralysis*, which recognizes the involvement of several descending fiber systems that influence and modify the lower motor neuron, is more appropriate.

In primates, lesions limited to area 4 of Brodmann, the motor cortex, cause mainly hypotonia and weakness of the distal limb muscles. Lesions of the premotor cortex (area 6) result in weakness, spasticity, and increased stretch reflexes (Fulton). Lesions of the supplementary motor cortex lead to involuntary grasping. Resection of cortical areas 4 and 6 and subcortical white matter causes complete and permanent paralysis and spasticity (Laplane et al). These clinical effects have not been as clearly defined in humans as in monkeys.

The one place where corticospinal fibers are entirely isolated is the pyramidal tract in the medulla. In humans there are a few documented cases of a lesion more or less confined to this location. The result of such lesions has been an initial flaccid hemiplegia (with sparing of the face), from which there is considerable recovery. Similarly in monkeys—as shown by Tower in 1940 and subsequently by Lawrence and Kuypers and by Gilman and Marco—interruption of both pyramidal tracts results in a hypotonic paralysis; ultimately, these animals regain a wide range of movements, though slowness of all movements and loss of individual finger movements remain as permanent deficits. Also, the cerebral peduncle has been sectioned in patients in an effort to abolish involuntary movements (Bucy et al); in some of these patients, a slight degree of weakness or only a Babinski sign was produced but no spasticity developed. These observations and those in monkeys indicate that a pure pyramidal tract lesion does not result in spasticity and that control over a wide range of voluntary movements depends at least in part on nonpyramidal motor pathways. Animal experiments suggest that the corticoreticulospinal pathways are particularly important in this respect, since their fibers are arranged somatotopically and are able to influence stretch reflexes. Further studies of human disease are necessary to settle problems related to volitional movement and spasticity. The motor organization of the cat and even of the monkey is so different from that of humans, and the range of volitional activity and motor skills is so much less in animals, that direct comparisons are not justified.

The distribution of the paralysis due to upper motor neuron lesions varies with the locale of the lesion, but certain features are characteristic of all of them. A group of muscles is always involved, never individual muscles, and if any movement is possible, the proper relationships between agonists, antagonists, synergists, and fixators are preserved. On careful inspection, the paralysis never involves all the muscles on one side of the body, even in the severest forms of hemiplegia. Movements that are invariably bilateral—such as those of the eyes, jaw, pharynx, upper face, larynx, neck, thorax, diaphragm, and abdomen—are affected little or not

at all. This comes about because these muscles are bilaterally innervated; i.e., stimulation of either the right or left motor cortex results in contraction of these muscles on both sides of the body. Upper motor neuron paralysis is rarely complete for any long period of time; in this respect it differs from the absolute paralysis due to destruction of anterior horn cells or interruption of their axons.

Upper motor neuron lesions are characterized further by certain peculiarities of residual movement. There is decreased voluntary drive on spinal motor neurons (fewer motor units are recruitable and their firing rates are slower), resulting in a slowness of movement. There is also an increased degree of cocontraction of antagonistic muscles, reflected in a decreased rate of rapid alternating movements. These abnormalities probably account for the greater sense of effort and the manifest fatigability in effecting voluntary movement of the weakened muscles. Another phenomenon is the activation of paralyzed muscles as parts of certain automatisms (synkinesias). The paralyzed arm may move suddenly during yawning and stretching. Attempts by the patient to move the hemiplegic limbs may result in a variety of associated movements. Thus, flexion of the arm may result in involuntary pronation and flexion of the leg or in dorsiflexion and eversion of the foot. Also, volitional movements of the paretic limb may evoke imitative (mirror) movements in the normal one or vice versa. In some patients, as they recover from hemiplegia, a variety of movement abnormalities emerge, such as tremor, ataxia, athetosis, and chorea on the affected side. These are expressions of damage to basal ganglionic and thalamic structures and are discussed in Chap. 4.

If the upper motor neurons are interrupted above the level of the facial nucleus in the pons, hand and arm muscles are affected most severely and the leg muscles to a lesser extent; of the cranial musculature, only muscles of the tongue and lower part of the face are involved to any significant degree. Since Broadbent was the first to call attention to this distribution of facial paralysis, it is sometimes referred to as "Broadbent's law." The precise course taken by fibers that innervate the facial nucleus is still somewhat uncertain, as described earlier, under "Anatomic and Physiologic Considerations"; but it is clear that some descend to the upper medulla and then ascend recurrently to the pons. This accounts for the mild facial weakness that is seen with lesions of the lower pons and upper medulla.

At lower levels, such as the cervical cord, complete acute lesions of the upper motor neurons not only cause a paralysis of voluntary movement but also abolish temporarily the spinal reflexes subserved by segments below the lesion. This is the condition referred to above as *spinal shock*, a state of acute flaccid paralysis that is replaced later by *spasticity*. A comparable state of shock may occur with acute cerebral lesions but is less sharply defined than is the spinal state. With some acute cerebral lesions, spasticity and paralysis develop together; in others, especially with parietal lesions, the limbs remain flaccid but reflexes are retained.

Spasticity, Hyperreflexia, and the Babinski Sign A predilection for involvement of certain muscle groups, a specific pattern of response of muscles to passive stretch (where resistance increases linearly in relation to velocity of stretch), and a manifest exaggeration of tendon reflexes are the identifying characteristics of *spasticity*. The antigravity muscles—the flexors of the arms and the extensors of the legs—are predominantly affected. The arm tends to assume a flexed and pronated position and the leg an extended and adducted one, indicating that certain spinal neurons are reflexly

more active than others. At rest, with the muscles shortened to midposition, they are flaccid to palpation and electromyographically silent. If the arm is extended or the leg flexed very slowly, there may be little or no change in muscle tone. By contrast, if the muscles are briskly stretched, the limb moves freely for a very short distance (free interval), beyond which there is an abrupt catch and then a rapidly increasing muscular resistance up to a point; then, as passive extension of the arm or flexion of the leg continues, the resistance melts away. This sequence constitutes the classic "clasp-knife" phenomenon. With the limb in the extended or flexed position, a new passive movement may not encounter the same sequence; this entire pattern of response constitutes the lengthening and shortening reaction. Thus the essential feature of spasticity is a velocity-dependent increase in the resistance of muscles to a passive stretch stimulus.

Although a clasp-knife relaxation following peak resistance is highly characteristic of cerebral hemiplegia, it is by no means found consistently. In some cases, the arm flexors and leg extensors are spastic, while the antagonist muscles show an even resistance throughout the range of passive movement—i.e., rigidity (discussed in Chap. 4); or rigidity may be more prominent than spasticity in all muscles. This plastic or rigid resistance, in Denny-Brown's view, is the mild form or precursor of an altered posture that he called *dystonic* (the term is used differently now) and considered to be a characteristic feature of hemiplegic spasticity. Nor is there a constant relationship between spasticity and weakness. In some cases, severe weakness may be associated with only the mildest signs of spasticity, detectable as a "catch" in the pronators on passive supination of the forearm and in the flexors of the hand on extension of the wrist. Contrariwise, the most extreme degrees of spasticity, observed in certain patients with cervical spinal cord disease, may so vastly exceed paresis of voluntary movement as to indicate that these two states depend on separate mechanisms. Indeed, the selective blocking of small gamma neurons is said to abolish spasticity as well as hyperactive segmental tendon reflexes but to leave motor performance unchanged.

Until recently, it was taught that the heightened myotatic or stretch reflexes ("tendon jerks") of the spastic state are "release" phenomena—the result of interruption of descending inhibitory pathways. This appears to be only a partial explanation. Animal experiments have demonstrated that this aspect of the spastic state is also mediated through spindle afferents (increased tonic activity of gamma motor neurons) and, centrally, through reticulospinal and vestibulospinal pathways that act on alpha motor neurons. The clasp-knife phenomenon appears to derive at least partly from a lesion (or presumably a change in central control) of a specific portion of the reticulospinal system.

P. Brown, in a discussion of the pathophysiology of spasticity, has emphasized the importance of two systems of fibers: (1) the dorsal reticulospinal tract, which has inhibitory effects on stretch reflexes, and (2) the medial reticulospinal and vestibulospinal tracts, which together facilitate extensor tone. He postulates that in cerebral and capsular lesions, cortical inhibition is weakened, resulting in spastic hemiplegia. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal tract is usually involved as well. If the latter tract is spared, only paresis, loss of support reflexes, and possibly release of flexor reflexes (Babinski phenomenon) occur. Pantano and colleagues have suggested that primary involvement of the lentiform nucleus and thalamus is the feature that determines the persistence of flaccidity after stroke, but the anatomic and physiologic evidence for this view is insecure.

The classic and most sensitive indication of an upper motor neuron lesion is the sign described by Babinski in 1896. Numerous monographs and articles have been written about the sign: a quite comprehensive one, by van Gijn, and a classic but more arcane one by Fulton and Keller. A movement resembling the Babinski sign is present in normal infants, but its definite persistence or emergence in late infancy and childhood or later in life is an invariable indicator of a lesion at some level of the corticospinal tract. In its essential form, the sign consists of extension of the large toe and extension and fanning of the other toes during and immediately after stroking the lateral plantar surface of the foot. The stimulus is applied along the dorsum of the foot from the lateral heel and sweeping upward and across the ball of the foot. The stimulus must be firm but not necessarily painful. Several dozen surrogate responses (with numerous eponyms) have been described over the years, most utilizing alternative sites and types of stimulation, but all have the same significance as the classic response. Clinical and electrophysiologic observations indicate that the extension movement of the toe is a component of a larger synergistic flexion or shortening reflex of the leg—i.e., toe extension when viewed from a physiologic perspective is a flexor protective (nocifensive) response.

The *nociceptive spinal flexion reflexes*, of which the Babinski sign is a part, are common accompaniments but not essential components of spasticity. They, too, are exaggerated because of disinhibition or release of motor programs of spinal origin. Important characteristics of these responses are their capacity to be induced by weak superficial stimuli (such as a series of pinpricks) and their tendency to persist after the stimulation ceases. In their most complete form, a nocifensive flexor synergy occurs, involving flexion of the knee and hip and dorsiflexion of the foot and big toe (*triple flexion response*). With incomplete suprasegmental lesions, the response may be fractionated; for example, the hip and knee may flex but the foot may not dorsiflex, or vice versa. In the more chronic stages of hemiplegia, the upper limb is characteristically held stiffly in partial flexion.

The hyperreflexic state that characterizes spasticity may take the form of *clonus*, a series of rhythmic involuntary muscular contractions occurring at a frequency of 5 to 7 Hz in response to an abruptly applied and sustained stretch stimulus. It is usually designated in terms of the part of the limb to which the stimulus is applied (e.g., patella, ankle). The frequency is constant within 1 Hz and is not appreciably modified by altering peripheral or central nervous system activities. Clonus depends for its elicitation on an appropriate degree of muscle relaxation, integrity of the spinal stretch reflex mechanisms, sustained hyperexcitability of alpha and gamma motor neurons (suprasegmental effects), and synchronization of the contraction-relaxation cycle of muscle spindles. The cutaneomuscular abdominal and cremasteric reflexes are usually abolished in these circumstances, and a Babinski sign is usually but not invariably present.

Spread, or irradiation of reflexes, is regularly associated with spasticity, although the latter phenomenon may be observed to a slight degree in normal persons with brisk tendon reflexes. Tapping of the radial periosteum, for example, may elicit a reflex contraction not only of the brachioradialis but also of the biceps, triceps, or finger flexors. This spread of reflex activity is probably due not to an irradiation of impulses in the spinal cord, as is often taught, but to the propagation of a vibration wave from bone to muscle, stimulating the excitable muscle spindles in its path (Lance). The same mechanism is probably operative in other manifestations of the

hyperreflexic state, such as the Hoffmann sign and the crossed adductor reflex of the thigh muscles. Also, reflexes may be “inverted,” as in the case of a lesion of the fifth or sixth cervical segment; here the biceps and brachioradialis reflexes are abolished and only the triceps and finger flexors, whose reflex arcs are intact, respond to a tap over the distal radius.

In addition to hyperactive *phasic myotatic reflexes* (“tendon jerks”), certain lesions, particularly of the cervical segments of the spinal cord, may result in great enhancement of *tonic myotatic reflexes*. These are stretch reflexes in which a stimulus produces a prolonged asynchronous discharge of motor neurons, causing sustained muscle contraction. As the patient stands or attempts voluntary movement, the entire limb may become involved in intense muscular spasm, sometimes lasting for several minutes. During this period the limb is quite useless. Presumably there is both an interruption of lateral reticulospinal inhibitory influences on the anterior horn cells and a release of the medial reticulospinal facilitatory effects needed in antigravity support (Henneman).

With bilateral cerebral lesions, exaggerated stretch reflexes can be elicited in cranial as well as limb and trunk muscles because of interruption of the corticobulbar pathways. These are seen as easily triggered masseter contractions in response to a brisk downward tap on the chin (jaw jerk) and brisk contractions of the orbicularis oris muscles in response to tapping the philtrum or corners of the mouth. In advanced cases, weakness or paralysis of voluntary movements of the face, tongue, larynx, and pharynx are added (bulbar spasticity or “pseudobulbar” palsy; see pages 426 and 445).

There have been many investigations of the biochemical changes that underlie spasticity and the mechanisms of action of antispasticity drugs. These have been reviewed by Davidoff. Since glutamic acid is the neurotransmitter of the corticospinal tracts, one would expect its action on inhibitory interneurons to be lost. As mentioned earlier, gamma-aminobutyric acid (GABA) and glycine are the major inhibitory transmitters in the spinal cord; GABA functions as a presynaptic inhibitor, suppressing sensory signals from muscle and cutaneous receptors. Baclofen, a derivative of GABA, as well as diazepam and pro gabide, are thought to act by reducing the release of excitatory transmitter from the presynaptic terminals of primary afferent terminals. Actually, none of these agents is entirely satisfactory in the treatment of spasticity when administered orally; the administration of baclofen intrathecally may have a more beneficial effect. Glycine is the transmitter released by inhibitory interneurons and is measurably reduced in quantity, uptake, and turnover in the spastic animal. There is some evidence that the oral administration of glycine reduces experimentally induced spasticity, but its value in patients is uncertain. Interruption of descending noradrenergic, dopaminergic, and serotonergic fibers is undoubtedly involved in the genesis of spasticity, although the exact mode of action of these neurotransmitters on the various components of spinal reflex arcs remains to be defined.

Table 3-1 summarizes the main attributes of upper motor neuron lesions and contrasts them with those of the lower motor neuron.

Motor Disturbances Due to Lesions of the Parietal Lobe

As indicated earlier in this section, a significant portion of the pyramidal tract originates in neurons of the parietal cortex. Also, the parietal lobes are important sources of visual and tactile informa-

Table 3-1**Differences between upper and lower motor neuron paralysis**

UPPER MOTOR NEURON, OR SUPRANUCLEAR PARALYSIS	LOWER MOTOR NEURON, OR NUCLEAR-INFRANUCLEAR PARALYSIS
Muscles affected in groups; never individual muscles	Individual muscles may be affected
Atrophy slight and due to disuse	Atrophy pronounced; up to 70% of total bulk
Spasticity with hyperactivity of the tendon reflexes and extensor plantar reflex (Babinski sign)	Flaccidity and hypotonia of affected muscles with loss of tendon reflexes
Fascicular twitches absent	Plantar reflex, if present, is of normal flexor type
Normal nerve conduction studies; no denervation potentials in EMG	Fasciculations may be present
	Abnormal nerve conduction studies; denervation potentials (fibrillations, fasciculations, positive sharp waves) in EMG

tion necessary for the control of movement. Pause and colleagues have described the motor disturbances due to lesions of the parietal cortex. The patient is unable to maintain stable postures of the outstretched hand when his eyes are closed and cannot exert a steady contraction. Exploratory movements and manipulation of small objects are impaired, and the speed of tapping is diminished. Posterior parietal lesions (involving areas 5 and 7) are more detrimental in this respect than anterior ones (areas 1, 3, and 5), but both regions are affected in patients with the most severe deficits.

APRAXIA AND OTHER NONPARALYTIC DISORDERS OF MOTOR FUNCTION

All that has been said about the cortical and spinal control of the motor system gives one only a limited idea of human motility. Viewed objectively, the conscious and sentient human organism is continuously active—fidgeting, adjusting posture and position, sitting, standing, walking, running, speaking, manipulating tools, or performing the intricate sequences of movements involved in athletic or musical skills. Some of these activities are relatively simple, automatic, and stereotyped. Others have been learned and mastered through intense conscious effort and with long practice have become habitual—i.e., reduced to an automatic level—a process not at all understood physiologically. Still others are complex and voluntary, parts of a carefully formulated plan, and demand continuous attention and thought. What is more remarkable, one can be occupied in several of these variably conscious and habitual activities simultaneously, such as driving through heavy traffic while dialing a cellular phone and engaging in animated conversation. Moreover, when an obstacle prevents a particular sequence of movements from accomplishing its goal, a new sequence can be undertaken automatically for the same purpose. As stated above, these activities, in the scheme of Hughlings Jackson, represent the third and highest level of motor function.

How is all this possible? Neuropsychologists, on the basis of studies of large numbers of patients with lesions of different parts of the cerebrum, believe that the planning of complex activities,

conceptualizing their final purpose, and continuously modifying the individual components of a motor sequence until the goal is achieved are initiated and directed by the frontal lobes. Lesions of the frontal lobes have the effect of reducing the impulse to think, speak, and act (i.e., abulia, or reduced “cortical tone,” to use Luria’s expression), and a complex activity will not be initiated or sustained long enough to permit its completion.

The term *apraxia* is applied to a state in which a clear-minded patient with no weakness, ataxia, or other extrapyramidal derangement, and no defect of the primary modes of sensation, loses the ability to execute highly complex and previously learned skills and gestures. This was the meaning given to *apraxia* by Liepmann, who introduced the term in 1900. It was his view, on the basis of case studies, that apraxia could be subdivided into three types—ideational, ideomotor, and kinetic. His anatomic data indicated that planned or commanded action is normally developed not in the frontal lobe, where the impulse to action arises, but in the parietal lobe of the dominant hemisphere, where visual, auditory, and somesthetic information is integrated. Presumably the formation of ensembles of skilled movements depends on the integrity of this part of the brain; if it is damaged, the patterns cannot be activated at all or the movements are faltering and inappropriate. The failure to conceive or formulate an action, either spontaneously or to command, was referred to by Liepmann as *ideational apraxia*. Involved are connections from sensory areas 5 and 7 in the dominant parietal lobe and the supplementary and premotor cortices of both cerebral hemispheres, wherein reside the innervatory mechanisms for patterned movement. Or, the patient may know and remember the planned action, but because these areas or their connections are interrupted, he cannot actually execute it with either hand. This was Liepmann’s concept of *ideomotor apraxia*. Certain tasks are said to differentiate ideomotor from ideational apraxia, as discussed further on, but the distinction is so subtle at times that it has largely eluded us. A third disorder, *kinetic limb apraxia*, involves clumsiness and maladroitness of a limb, usually the right, or dominant, hand, in the performance of a skilled act that cannot be accounted for by paresis, ataxia, or sensory loss (see also Chap. 22). It is often obscured by paralysis on the same side. A historical perspective that outlines the development of these concepts is given by Faglioni and Basso. These high-order abnormalities of learned movement patterns have several unique features. Seldom are they evident to the patient himself, and therefore they are not sources of complaint; or, if they are appreciated by the patient, he has difficulty describing the problem except in narrow terms of the activity that is impaired, such as using a phone or dressing. For this reason they are often overlooked by the examining physician. Their evocation requires special types of testing that may be difficult because of the presence of other neurologic deficits. Obviously, if the patient is confused or aphasic, spoken or written requests to perform an act will not be understood and one must find ways of persuading him to imitate the movements of the examiner. Moreover, the patient must be able to recognize and name the articles that he attempts to manipulate; i.e., there must not be an agnosia.

In practical terms, the lesion responsible for *ideomotor apraxia that affects both arms* usually resides in the left parietal region. Kertesz and colleagues have provided evidence that the lesions responsible for aphasia and apraxia are different, though the two conditions are frequently associated because of their origin in the left hemisphere.. The exact location of the parietal lesion, whether in the supramarginal gyrus or in the superior parietal lobe (areas 5 and 7) and whether subcortical or cortical, is still uncertain.

Geschwind accepted Liepmann's proposition that a lesion of a subcortical tract (presumably the arcuate fasciculus) disconnects the parietal from the left frontal cortex, accounting for the ideomotor apraxia of the right limbs, and that the left limb apraxia is due to a callosal disconnection of the left and right premotor association cortices.

But in a right-handed person there is also the situation of a left limb apraxia from a lesion in the left frontal lobe that includes Broca's area, the left motor cortex, and the deep underlying white matter. Clinically there is a motor speech disorder, a right hemiparesis, and this type of apraxia of the nonparalyzed hand, which has been termed *sympathetic apraxia*. If the lesion in the deep white matter separates the language areas from the right motor cortex but not from the left, the patient can write with the right hand but not with the left, or he may write correctly with the right hand and aphasically with the left. That such a syndrome is attributable to interruption of a pathway that traverses the genu of the corpus callosum, as depicted by Geschwind, is questionable, insofar as sympathetic apraxia has not been observed in patients with lesions (or surgical sections) confined to the anterior third of the corpus callosum (see page 395). The disconnection syndromes are discussed further in Chaps. 22 and 23. Perhaps surprisingly, there are but a few cases of apraxia of any type with proven prefrontal lesions.

Of a somewhat different nature is *a facial-oral apraxia*, which is probably the most common of all apraxias in practice. It may occur with lesions that undercut the left supramarginal gyrus or the left motor association cortex and may or may not be associated with the apraxia of the limbs described above. Such patients are unable to carry out facial movements to command (lick the lips, blow out a match, etc.), although they may do better when asked to imitate the examiner or when holding a lighted match. With lesions that are restricted to the facial area of the left motor cortex, the apraxia will be limited to the facial musculature and may be associated with a verbal apraxia or cortical dysarthria (page 418). So-called apraxia of gait is considered in Chap. 7. The terms *dressing apraxia* and *constructional apraxia* are used to describe certain manifestations of parietal lobe disease. These abnormalities are not apraxias in the strict sense of a loss of previously learned behavior but are instead symptoms of contralateral extinction or neglect of the body schema and of extrapersonal space (anosognosia, page 401).

Testing for apraxia is carried out in several ways. First, one observes the actions of the patient as he engages in such tasks as dressing, washing, shaving, and using eating utensils. Second, the patient is asked to carry out familiar symbolic acts—wave goodbye, salute the flag, shake a fist as though angry, or blow a kiss. If he fails, he is asked to imitate such acts made by the examiner. Finally, he is asked to show how he would hammer a nail, brush his teeth, take a comb out of his pocket and comb his hair, cross himself, and so forth, or to execute a more complex act, such as lighting and smoking a cigarette or opening a bottle of soda, pouring some into a glass, and drinking it. These last actions, involving more complex sequences, are said to be tests of ideational apraxia; the simpler and familiar acts are called tests of ideomotor apraxia. To perform these tasks in the absence of the tool or utensil is always more demanding because the patient must mentally formulate a plan of action rather than engage in a habitual motor sequence. The patient may fail to carry out a commanded or suggested activity (e.g., to take a pen out of his pocket), yet a few minutes later he may perform the same motor sequence automatically. One may

think of such an ideomotor deficit, if it can be singled out from confusion or a defect in comprehension, as a kind of amnesia for certain learned patterns of movement, analogous to the amnesia for words in aphasia.

Children with cerebral diseases that retard mental development are often unable to learn the sequences of movement required in hopping, jumping over a barrier, hitting or kicking a ball, or dancing. They suffer a developmental motor apraxia. Certain tests quantitate failure in these age-linked motor skills (see Chap. 28).

In the authors' opinion, the time-honored division of apraxia into ideational, ideomotor (idiokinetic), and kinetic types is unsatisfactory. It is more helpful to think of the apraxias in an anatomic sense, as disorders of association between different parts of the cerebral cortex, as described above. We have been unable to confidently separate ideomotor from ideational apraxia. The patient with a severe ideomotor apraxia nearly always has difficulty at the ideational level and, in any case, similarly situated left parietal lesions give rise to both types. Furthermore, in view of the complexity of the motor system, we are frequently uncertain whether the clumsiness or ineptitude of a hand in performing a motor skill represents a kinetic apraxia or some other fault in the intrinsic organization of hand control.

A related but poorly understood disorder of movement has been termed the *alien hand*. In the absence of volition, the hand and arm undertake complex and seemingly purposeful movements such as reaching into a pocket or handbag, placing the hand behind the head, and tugging on the opposite hand or other body part; these activities may occur even during sleep. The patient is aware of the movements but has the sense that the actions are beyond his control, and there is often an impression that the hand is estranged, as if commanded by an external agent (although the limb is recognized as one's own—there is no anosognosia); a grasp reflex and a tendency to grope are usually added. Most instances arise as a result of infarction in the territory of the opposite anterior cerebral artery, including the corpus callosum. When the callosum is involved, Feinberg and colleagues find that there frequently appears to be a conflict between the actions of the hands, the normal one sometimes even restraining the alien one. Damage in the left supplementary motor area from any cause as well as in the disease called corticobasal ganglionic degeneration (page 928) are associated with a similar alien hand syndrome. A form that results from a stroke in the posterior cerebral artery territory with associated sensory loss has also been observed by Ay and colleagues.

Finally, it should be remarked once again that the complexity of motor activity is almost beyond imagination. Reference was made earlier to the reciprocal innervation involved in an act as simple as making a fist. Scratching one's shoulder has been estimated to recruit about 75 muscles. But what must be involved in playing a piano concerto? Over a century ago Hughlings Jackson commented that "There are, we shall say, over thirty muscles in the hand; these are represented in the nervous centers in thousands of different combinations, that is, as very many movements; it is just as many chords, musical expressions and tunes can be made out of a few notes." The execution of these complex movements, many of them learned and habitual, is made possible by the cooperative activities of not just the motor and sensory cortices but integrally of the basal ganglia, cerebellum, and reticular formation of the brainstem. All are continuously integrated and controlled by feedback mechanisms from the sensory and spinal motor neurons. Even the spinal stretch reflex has connections with the motor cor-

tex. These points, already touched upon in this chapter, are elaborated in the following three chapters.

PATTERNS OF PARALYSIS AND THEIR DIAGNOSIS

The diagnostic considerations in cases of paralysis can be simplified by utilizing the following subdivision, based on the location and distribution of the muscle weakness:

1. *Monoplegia* refers to weakness or paralysis of all the muscles of one leg or arm. This term should not be applied to paralysis of isolated muscles or groups of muscles supplied by a single nerve or motor root.
2. *Hemiplegia*, the commonest form of paralysis, involves the arm, the leg, and sometimes the face on one side of the body. With rare exceptions, mentioned further on, hemiplegia is attributable to a lesion of the corticospinal system on the side opposite to the paralysis.
3. *Paraplegia* indicates weakness or paralysis of both legs. It is most often the result of diseases of the thoracic spinal cord, cauda equina, or peripheral nerves, and rarely, both medial frontal cortices.
4. *Quadriplegia (tetraplegia)* denotes weakness or paralysis of all four extremities. It may result from disease of the peripheral nerves, muscles, or myoneural junctions; gray matter of the spinal cord; or the upper motor neurons bilaterally in the cervical cord, brainstem, or cerebrum. *Diplegia* is a special form of quadriplegia in which the legs are affected more than the arms. *Triplegia* occurs most often as a transitional condition in the development of or partial recovery from tetraplegia.
5. Isolated paralysis of one or more muscle groups.
6. Nonparalytic disorders of movement (apraxia, ataxia, etc.).
7. Muscular paralysis without visible changes in motor neurons, roots, or nerves.
8. Hysterical paralysis.

Monoplegia

The examination of patients who complain of weakness of one limb often discloses an asymptomatic weakness of another, and the condition is actually a hemiparesis or paraparesis. Or, instead of weakness of all the muscles in a limb, only isolated groups are found to be affected. Ataxia, sensory disturbances, or reluctance to move the limb because of pain must not be misinterpreted as weakness. Parkinsonism may give rise to the same error, as can rigidity or bradykinesia of other causation or a mechanical limitation due to arthritis and bursitis. The presence or absence of atrophy of muscles in a monoplegic limb is of particular diagnostic help, as indicated below.

Monoplegia without Muscular Atrophy This is most often due to a lesion of the cerebral cortex. Only infrequently does it result from a subcortical lesion that interrupts the motor pathways. A cerebral vascular lesion (thrombotic or embolic infarction) is the commonest cause; a circumscribed tumor or abscess may have the same effect. A small cortical lesion may paralyze half the hand or even just the thumb. Multiple sclerosis and spinal cord tumor, early in their course, may cause weakness of one limb, usually the leg. Monoplegia due to a lesion of the upper motor neuron is usually

accompanied by spasticity, increased reflexes, and an extensor plantar reflex (Babinski sign); exceptionally, a small lesion of the motor cortex will not result in spasticity. In either event, nerve conduction studies are normal. In acute diseases of the lower motor neurons, the tendon reflexes are reduced or abolished, but atrophy may not appear for several weeks. Hence, before reaching an anatomic diagnosis, one must take into account the mode of onset and duration of the disease.

Monoplegia with Muscular Atrophy This is more frequent than monoplegia without muscular atrophy. Long-continued disuse of one limb may lead to atrophy, but it is usually of lesser degree than atrophy due to lower motor neuron disease (denervation atrophy). In disuse atrophy, the tendon reflexes are retained and nerve conduction studies are normal. With denervation of muscles, there may be visible fasciculations and reduced or abolished tendon reflexes in addition to paralysis. If the limb is partially denervated, the electromyogram shows reduced numbers of motor unit potentials (often of large size) as well as fasciculations and fibrillations. The location of the lesion (in nerves, spinal roots, or spinal cord) can usually be determined by the pattern of weakness, by the associated neurologic symptoms and signs, and by special tests—magnetic resonance imaging (MRI) of the spine, examination of the cerebrospinal fluid (CSF), and electrical studies of nerve and muscle.

A *complete atrophic brachial monoplegia* is uncommon; more often, only parts of a limb are affected. When present in an infant, it should suggest brachial plexus trauma from birth; in a child, poliomyelitis or other viral infection of the spinal cord; and in an adult, poliomyelitis, syringomyelia, amyotrophic lateral sclerosis, or a brachial plexus lesion. *Crural (leg) monoplegia* is more frequent than brachial monoplegia and may be caused by any lesion of the thoracic or lumbar cord—i.e., trauma, tumor, myelitis, multiple sclerosis, progressive muscular atrophy, late radiation effect, etc. These disorders rarely cause severe atrophy; neither does infarction in the territory of the anterior cerebral artery. A prolapsed intervertebral disc and the several varieties of mononeuropathy almost never paralyze all or most of the muscles of a limb. The effects of a centrally prolapsed disc or other compressive lesion of the cauda equina are rarely confined to one leg. However, a unilateral retroperitoneal tumor or hematoma may paralyze the leg by compressing the lumbosacral plexus. The mode of onset and temporal course differentiate these diseases.

Hemiplegia

This is the most frequent form of paralysis. With rare exceptions (a few unusual cases of poliomyelitis or motor system disease), this pattern of paralysis is due to involvement of the corticospinal pathways.

The site or level of the lesion—i.e., cerebral cortex, corona radiata, capsule, brainstem, or spinal cord—can usually be deduced from the associated neurologic findings. Diseases localized to the cerebral cortex, cerebral white matter (corona radiata), and internal capsule usually manifest themselves by weakness or paralysis of the leg, arm, and lower face on the opposite side. The occurrence of seizures or the presence of a language disorder (aphasia), a loss of discriminative sensation (astereognosis, impairment of tactile localization, etc.), anosognosia, or a homonymous visual field defect suggests a contralateral cortical or subcortical location.

Damage to the corticospinal and corticobulbar tracts in the upper portion of the brainstem also causes paralysis of the face,

arm, and leg of the opposite side (see Fig. 3-2). The lesion in such cases may in some patients be localized by the presence of a third nerve palsy (Weber syndrome) or other segmental abnormality on the same side as the lesion (opposite the hemiplegia). With low pontine lesions, an ipsilateral abducens or facial palsy is combined with a contralateral weakness or paralysis of the arm and leg (Millard-Gubler syndrome). Lesions in the medulla affect the tongue and sometimes the pharynx and larynx on one side and the arm and leg on the other. These “crossed paralyses,” so characteristic of brainstem lesions, are described further in Chap. 34.

Even lower in the medulla, a unilateral infarct in the pyramid causes a flaccid paralysis followed by slight spasticity of the contralateral arm and leg, with sparing of the face and tongue. Some motor function may be retained, as in the case described by Ropper and colleagues; interestingly, in this case and in others previously reported, there was considerable recovery of voluntary power even though the pyramid was almost completely destroyed.

Rarely, an ipsilateral hemiplegia may be caused by a lesion in the lateral column of the cervical spinal cord. In this location, however, the pathologic process more often induces bilateral signs, with resulting quadripareisis or quadriplegia. A homolateral paralysis that spares the face, if combined with a loss of vibratory and position sense on the same side and a contralateral loss of pain and temperature, signifies disease of one side of the spinal cord (*Brown-Séquard syndrome*, as discussed in Chap. 44).

As indicated above, muscle atrophy that follows upper motor neuron lesions never reaches the proportions seen in diseases of the lower motor neuron. The atrophy in the former cases is due to disuse. When the motor cortex and adjacent parts of the parietal lobe are damaged in infancy or childhood, normal development of the muscles as well as the skeletal system in the affected limbs is retarded. The limbs and even the trunk are smaller on one side than on the other. This does not happen if the paralysis occurs after puberty, by which time the greater part of skeletal growth has been attained. In hemiplegia due to spinal cord lesions, muscles at the level of the lesion may atrophy as a result of damage to anterior horn cells or ventral roots.

In the causation of hemiplegia, ischemic and hemorrhagic vascular diseases of the cerebrum and brainstem exceed all others in frequency. Trauma (brain contusion, epidural and subdural hemorrhage) ranks second. Other important causes, less acute in onset, are, in order of frequency, brain tumor, brain abscess, demyelinative diseases, and the vascular complications of meningitis and encephalitis. Most of these diseases can be recognized by their mode of evolution and characteristic clinical and laboratory findings, which are presented in the chapters on neurologic diseases. Alternating transitory hemiparesis may be due to a special type of migraine (see discussion in Chap. 10). From time to time, hysteria is found to be the cause of a hemiplegia, as discussed further on.

Paraplegia

Paralysis of both lower extremities may occur with diseases of the spinal cord, nerve roots, or, less often, the peripheral nerves. If the onset is acute, it may be difficult to distinguish spinal from neuropathic paralysis because of the element of spinal shock, which results in abolition of reflexes and flaccidity. In acute spinal cord diseases with involvement of corticospinal tracts, the paralysis or weakness affects all muscles below a given level; usually, if the white matter is extensively damaged, sensory loss below a partic-

ular level is conjoined (loss of pain and temperature sense due to spinothalamic tract damage, and loss of vibratory and position sense due to posterior column involvement). Also, in bilateral disease of the spinal cord, the bladder and bowel and their sphincters are usually affected. These abnormalities may be due to an intrinsic lesion of the cord or to an extrinsic mass that narrows the spinal canal, both types of lesion being evident on MRI.

In peripheral nerve diseases, motor loss tends to involve the distal muscles of the legs more than the proximal ones (exceptions are certain varieties of the Guillain-Barré syndrome and certain types of diabetic neuropathy and porphyria); sphincteric function is usually spared or impaired only transiently. Sensory loss, if present, is also more prominent in the distal segments of the limbs, and the degree of loss is often more for one modality than another.

For clinical purposes it is helpful to separate the acute paraplegias from the chronic ones and to divide the latter into two groups: those beginning in adult life and those occurring in infancy.

The most common cause of *acute paraplegia* (or *quadriplegia* if the cervical cord is involved) is spinal cord trauma, usually associated with fracture-dislocation of the spine. Less common causes are hematomyelia due to a vascular malformation, an arteriovenous malformation of the cord that causes ischemia by an obscure mechanism, or infarction of the cord due to occlusion of the anterior spinal artery or, more often, to occlusion of segmental branches of the aorta (due to dissecting aneurysm or atheroma, vasculitis, and nucleus pulposus embolism).

Paraplegia or quadriplegia due to postinfectious myelitis, demyelinative or necrotizing myelopathy, or epidural abscess or tumor with spinal cord compression tends to develop somewhat more slowly, over a period of hours, days, or longer. Epidural or subdural hemorrhage from bleeding diseases or warfarin therapy causes an acute or subacute paraplegia; in a few instances the bleeding has followed a lumbar puncture. Paralytic poliomyelitis and acute Guillain-Barré syndrome—the former a purely motor disorder with mild meningitis (now rare), the latter predominantly motor but often with sensory disturbances—must be distinguished from the acute and subacute myelopathies and from each other.

In adult life, multiple sclerosis and tumor account for most cases of *subacute and chronic spinal paraplegia*, but a wide variety of extrinsic and intrinsic processes may produce the same effect: protruded cervical disc and cervical spondylosis (often with a congenitally narrow canal), epidural abscess and other infections (tuberculous, fungal, and other granulomatous diseases), syphilitic meningomyelitis, motor system disease, subacute combined degeneration (vitamin B₁₂ deficiency), syringomyelia, and degenerative disease of the lateral and posterior columns of unknown cause. (See Chap. 44 for discussion of these spinal cord diseases.)

In pediatric practice, delay in starting to walk and difficulty in walking are common problems. These conditions may indicate a systemic disease (such as rickets), mental deficiency, or, more commonly, some muscular or neurologic process. Congenital cerebral disease due to periventricular leukomalacia accounts for a majority of cases of infantile diplegia (weakness predominantly of the legs, with minimal affection of the arms). Present at birth, it becomes manifest in the first months of life and may appear to progress, but actually the disease is stationary and the progression is only apparent, being exposed as the motor system develops; later there may seem to be slow improvement as a result of the normal maturation processes of childhood. These disorders fall under the heading of cerebral palsy, as discussed in Chap. 38. Congenital

malformation or birth injury of the spinal cord are other possibilities. Friedreich ataxia and familial paraplegia, muscular dystrophy, tumor, and the chronic varieties of polyneuropathy tend to appear later, during childhood and adolescence, and are slowly progressive. Transverse (demyelinative) myelitis is a cause of acute paraplegia in childhood.

Quadriplegia (Tetraplegia)

All that has been said about the spinal causes of paraplegia applies to quadriplegia, the lesion being in the cervical rather than the thoracic or lumbar segments of the spinal cord. If the lesion is situated in the low cervical segments and involves the anterior half of the spinal cord, as typified by the syndrome resulting from occlusion of the anterior spinal artery (but occurring also in some cases of myelitis and fracture-dislocations of the cervical spine). In all these processes, the paralysis of the arms may be flaccid and areflexic in type and that of the legs, spastic. There is usually pain in the neck and shoulders and numbness of the hands; elements of ataxia from posterior column lesions accompany the paraparesis. Compression of the C1 and C2 spinal cord segments is caused by dislocation of the odontoid process. Rheumatoid arthritis and Morquio disease are causes of special note; in the latter, there is pronounced dural thickening.

A progressive syndrome of monoparesis, biparesis, and then triparesis is caused by tumors and a variety of other compressive lesions in the region of the foramen magnum and high cervical cord. Bilateral infarction of the medullary pyramids from occlusion of the vertebral arteries or their anterior spinal branches is a very rare cause of quadriplegia. Repeated strokes affecting both hemispheres may lead to bilateral hemiplegia, usually accompanied by pseudobulbar palsy (see pages 426 and 445). In infants and young children, aside from developmental abnormalities and anoxia of birth, certain metabolic cerebral diseases (metachromatic and other forms of leukoencephalopathy, lipid storage disease) may be responsible for a quadripareisis or quadriplegia, but always with severe psychomotor retardation. Congenital forms of muscular dystrophy and muscular atrophy (Werdnig-Hoffmann disease) may be recognized soon after birth or later and may progress slowly.

Triplexia Paralysis that remains confined to three limbs is observed only rarely; more often the fourth limb is weak or hyperreflexic, and the syndrome is really an incomplete tetraparesis. As indicated earlier, this pattern of involvement is important, because it may signify an evolving lesion of the upper cervical cord or cervicomedullary junction. A meningioma of the foramen magnum, for example, may begin with spastic weakness of one limb, followed by sequential involvement of the other limbs in an "around the clock" pattern. There are usually bilateral Babinski signs early in the process, but there may be few sensory findings. We have also seen this pattern in patients with multiple sclerosis and other intrinsic inflammatory and neoplastic lesions. These same diseases may produce triplexia (or triparesis) by a combination of paraparesis from a thoracic spinal cord lesion and a separate unilateral lesion in the cervical cord or higher that results in a hemiparesis.

Paralysis of Isolated Muscle Groups

This condition usually indicates a lesion of one or more peripheral nerves or of several adjacent spinal roots. The diagnosis of an in-

dividual peripheral nerve lesion is made on the basis of weakness or paralysis of a particular muscle or group of muscles and impairment or loss of sensation in the distribution of the nerve. Complete or extensive interruption of a peripheral nerve is followed by atrophy of the muscles it innervates and by loss of tendon reflexes of the involved muscles; abnormalities of vasomotor and sudomotor functions and trophic changes in the skin, nails, and subcutaneous tissue may also occur.

Knowledge of the motor and sensory innervation of the peripheral nerve in question is needed for a satisfactory diagnosis. It is not practical to memorize the precise sensorimotor distribution of each peripheral nerve, and special manuals, such as *Aids to the Examination of the Peripheral Nervous System*, should be consulted (see also Table 46-1). In addition, it is important to decide whether the lesion is a temporary one of electrical conduction alone or whether there has been a structural interruption of nerve fibers, requiring nerve regeneration or corrective surgery for recovery. Electromyography and nerve conduction studies are of great value here.

If there is no evidence of upper or lower motor neuron disease but certain movements are nonetheless imperfectly performed, one should look for a disorder of position sense or cerebellar coordination or for rigidity with abnormalities of posture and movement due to disease of the basal ganglia (Chap. 4). In the absence of these disorders, the possibility of an apraxic disorder should be investigated by the methods outlined earlier.

Hysterical Paralysis

Hysterical paralysis may involve one arm or leg, both legs, or all or one side of the body. Tendon reflexes are retained and atrophy is lacking in hysterical paralysis, features that distinguish it from chronic lower motor neuron disease. Diagnostic difficulty arises only in certain acute cases of upper motor neuron disease that lack the usual changes in reflexes and muscle tone. The hysterical gait is often diagnostic (page 107). Sometimes there is loss of sensation in the paralyzed parts and loss of sight, hearing, and smell on the paralyzed side—a pattern of sensory changes that is never seen in organic disease of the nervous system. When the hysterical patient is asked to move the affected limbs, the movements tend to be slow, hesitant, and jerky, often with contraction of agonist and antagonist muscles simultaneously and intermittently ("give-way" weakness). Lack of effort is usually obvious, despite facial and other expressions to the contrary. Power of contraction improves with encouragement. The weakness is inconsistent; some movements are performed tentatively and moments later another movement involving the same muscles is performed naturally. Hoover's sign and the trunk-thigh sign of Babinski are helpful in distinguishing hysterical from organic hemiplegia. To elicit Hoover's sign, the examiner places both hands under the heels of the recumbent patient, who is asked to press the heels down forcefully. With organic hemiplegia, downward pressure will be felt from the nonparalyzed leg. The examiner then removes his hand from under the nonparalyzed leg, places it on top of the nonparalyzed one, and asks the patient to raise that leg. In true hemiplegia, no added pressure will be felt by the hand that remained beneath the heel of the paralyzed leg. In hysteria, the heel of the supposedly paralyzed leg may press down on the examiner's hand. Or, more useful in our experience, the normal leg fails to demonstrate downward pressure when the hysteric is asked to elevate the supposedly paralyzed one, thereby indicating a lack of voluntary effort. To carry out Babinski's trunk-thigh test, the examiner asks the recumbent patient to sit up while

keeping his arms crossed in front of his chest. In the patient with organic hemiplegia, there is an involuntary flexion of the paretic lower limb; in paraplegia, both limbs are flexed as the trunk is flexed; in hysterical hemiplegia, only the normal leg may be flexed; and in hysterical paraplegia, neither leg is flexed.

Muscular Paralysis and Spasm Unattended by Visible Changes in Nerve or Muscle

A discussion of motor paralysis would not be complete without some reference to a group of diseases in which muscle weakness may be profound but there are no overt structural changes in motor

nerve cells or nerve fibers. Almost any disease of the neuromuscular junction and many diseases of muscle may cause this combination. This group comprises myasthenia gravis; inflammatory myopathies, the muscular dystrophies, and myotonia congenita (Thomsen disease); familial periodic paralysis; disorders of potassium, sodium, calcium, and magnesium metabolism; tetany; tetanus; poisoning by *Clostridium botulinum*; black widow spider bite; and the thyroid and other endocrine myopathies. In these diseases, each with a fairly distinctive clinical picture, the abnormality is essentially biochemical; their investigation requires special biochemical and histochemical tests and electron microscopic study. These subjects are discussed in the sections on muscle disease later in this book.

CHAPTER 4

ABNORMALITIES OF MOVEMENT AND POSTURE DUE TO DISEASE OF THE BASAL GANGLIA

In this chapter, the disorders of the automatic, static, postural, and other less modifiable motor activities of the nervous system are discussed. They are believed, on good evidence, to be an expression of the *extrapyramidal* motor system, meaning—according to S. A. K. Wilson, who introduced this term—the motor structures of the basal ganglia and certain related thalamic and brainstem nuclei.

In health, the activities of the basal ganglia and the cerebellum are blended with and modulate the corticospinal and cortical-brainstem-spinal systems. The static postural activities of the former are indispensable to the voluntary movements of the latter. The close association of the basal ganglia and corticospinal systems becomes evident in the course of many forms of neurologic disease. Cerebral lesions that involve the corticospinal tracts result not only in a contralateral paralysis of volitional movements but also in a fixed posture or attitude in which the arm is flexed and the leg extended (predilection of Wernicke-Mann or hemiplegic dystonia of Denny-Brown). Also, as noted in Chap. 3, interruption of the motor projections by a lesion in the upper pons or midbrain may release a posture in which all four limbs or the arm and leg on one side are extended and the cervical and thoracolumbar portions of the spine are hyperextended (*decerebrate rigidity*). In these released motor patterns, one has evidence of labyrinthine, tonic neck, and other postural reflexes that are mediated through nonpyramidal bulbospinal and other brainstem motor systems. Observations such as these and the anatomic data presented in Chap. 3 have blurred the classic distinctions between pyramidal and extrapyramidal motor systems. Nevertheless, this division remains a useful if not an essential concept in clinical work, since it compels a distinction between several motor syndromes—one that is characterized by a loss of volitional movement accompanied by spasticity; a second by akinesia, rigidity, and tremor without loss of voluntary movement; a third by involuntary movements (choreoathetosis and dystonia); and yet another by incoordination (ataxia). The clinical differences between corticospinal and extrapyramidal syndromes are summarized in Table 4-1.

Much of the criticism of the pyramidal-extrapyramidal concept derives from the terms themselves. The ambiguity related to the term *pyramidal* was discussed in Chap. 3, in which it was pointed out that pure pyramidal lesions do not cause total paralysis; when the latter exists, there is always some degree of involvement of other descending motor pathways as well. The term *extrapyramidal* is equally imprecise. Strictly interpreted, it refers to all the motor pathways except the pyramidal one, making this term so all-embracing as to be practically meaningless. The concept of an extrapyramidal motor system becomes more meaningful if it is subdivided into two parts: (1) the striatopallidonigral system (basal ganglia) and (2) the cerebellum. These parts function very differently in the control of movement and posture, and disease in each

of them results in particular disturbances of movement and posture without paralysis. The basal ganglia and the symptoms that result when they are diseased are described in the pages that follow. The disorders of movement and posture due strictly to cerebellar disease are described in Chap. 5.

THE STRIATOPALLIDONIGRAL SYSTEM (BASAL GANGLIA)

Anatomic Considerations

As an anatomic entity, the basal ganglia have no precise definition. Principally they include the caudate nucleus and the lentiform nucleus with its two subdivisions, the putamen and globus pallidus. Insofar as the caudate nucleus and putamen are really a continuous structure (separated only incompletely by fibers of the internal capsule) and are cytologically and functionally distinct from the pallidum, it is more meaningful to divide these nuclear masses into the striatum (or neostriatum), comprising the caudate nucleus and putamen, and the paleostriatum or pallidum, which has a medial (internal) and a lateral (external) portion. The putamen and pallidum lie on the lateral aspect of the internal capsule, which separates them from the caudate nucleus, thalamus, subthalamic nucleus, and substantia nigra on its medial side (Figs. 4-1 and 4-2). By virtue

Table 4-1
Clinical differences between corticospinal and extrapyramidal syndromes

	CORTICOSPINAL	EXTRAPYRAMIDAL
<i>Character of the alteration of muscle tone</i>	Clasp-knife effect (spasticity)	Plastic, equal throughout passive movement (rigidity), or intermittent (cogwheel rigidity)
<i>Distribution of hypertonus</i>	Flexors of arms, extensors of legs	Generalized but predominates in flexors of limbs and of trunk
<i>Involuntary movements</i>	Absent	Presence of tremor, chorea, athetosis, dystonia
<i>Tendon reflexes</i>	Increased	Normal or slightly increased
<i>Babinski sign</i>	Present	Absent
<i>Paralysis of voluntary movement</i>	Present	Absent or slight

of their close connections with the caudate and lenticular nuclei, the subthalamic nucleus (nucleus of Luys) and the substantia nigra are usually considered as parts of the basal ganglia. The claustrum and amygdaloid nuclear complex, because of their largely different connections and functions, are usually excluded.

For reasons indicated further on, some physiologists have expanded the list of basal ganglionic structures to include the red nucleus, the intralaminar thalamic nuclei, and the reticular formations of the upper brainstem. These additional structures receive direct cortical projections and give rise to rubrospinal and reticulospinal tracts which run parallel to the corticospinal (pyramidal) ones; hence they were also once referred to as *extrapyramidal*. However, these nonpyramidal linkages are structurally independent of the major extrapyramidal circuits that include the striatum, pallidum, thalamus, and premotor and supplementary motor cortices. Insofar as the final links in this circuit—the premotor and supplementary motor cortices—ultimately project onto the motor cortex, the aforementioned circuit is more aptly referred to as *prepyramidal* (Thach and Montgomery).

Earlier views of basal ganglionic organization emphasized the serial connectivity of the basal ganglionic structures and the funneling of efferent projections to the ventrolateral thalamus and thence to the motor cortex (Fig. 4-3). This concept was based largely on the classic experimental work of Whittier and Mettler and of Carpenter, in the late 1940s. These investigators demonstrated, in monkeys, that a characteristic movement disorder, which they termed *choreoid dyskinesia*, could be brought about in the limbs of one side of the body by a lesion localized to the opposite subthalamic nucleus. They also showed that for such a lesion to provoke dyskinesia, the adjacent pallidum and pallidofugal fibers had to be preserved; that is, a secondary lesion—placed in the medial segment of the pallidum, in the fasciculus lenticularis, or in the ventrolateral thalamic nuclear group—abolished the dyski-

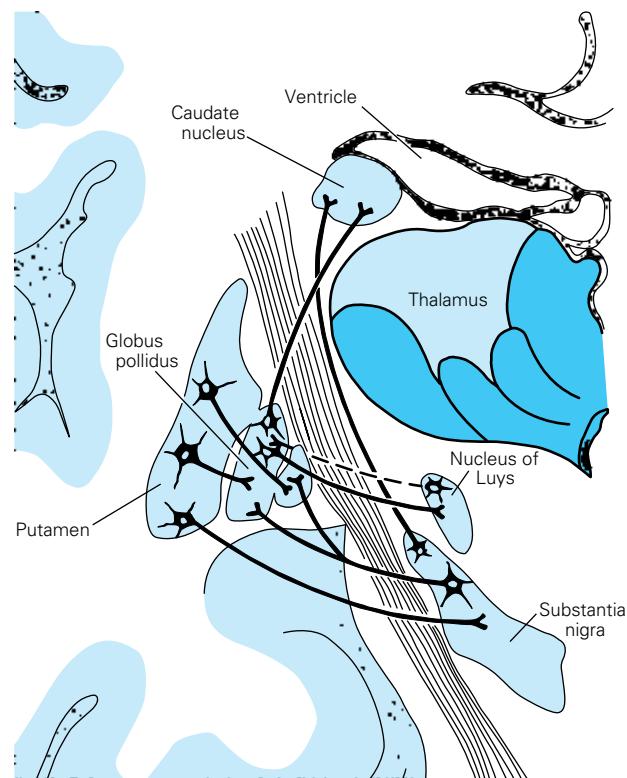

Figure 4-2. Diagram of the basal ganglia in the coronal plane, illustrating the main interconnections (see text for details). The pallidothalamic connections are illustrated in Fig. 4-3.

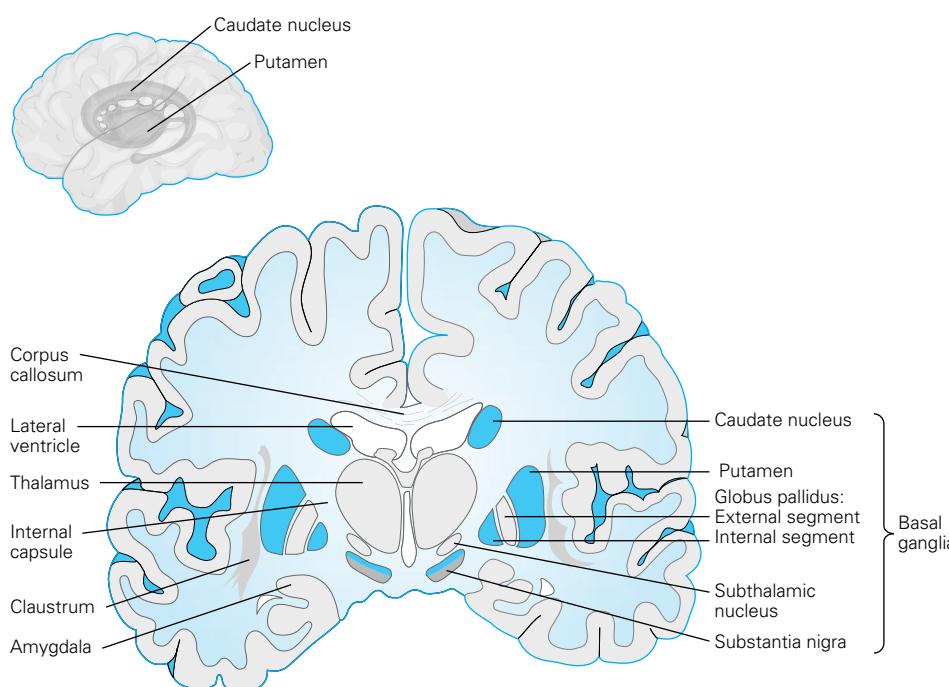

Figure 4-1. Overview of the components of the basal ganglia in coronal view. The main nuclei of the basal ganglia are represented in blue, as labeled on the right. nesia. This experimental hyperkinesia could also be abolished permanently by interruption of the lateral corticospinal tract but not by interruption of the other motor or sensory pathways in the spinal cord. These observations were interpreted to mean that the subthalamic nucleus normally exerts an inhibitory or regulating influence on the globus pallidus and ventral thalamus. Removal of this influence by selective destruction of the subthalamic nucleus is expressed physiologically by irregular choreoid activity, presumably arising from the intact pallidum and conveyed by pallidofugal fibers to the ventrolateral thalamic nuclei, thence by thalamocortical fibers to the ipsilateral premotor cortex, and from there, by short association fibers, to the motor cortex, all in a serial manner. New observations have made it apparent that there are instead a number of parallel circuits. Ultimately the abnormal movement is expressed via the lateral corticospinal tract, which in this instance functions as the final executive pathway.

A general principle that emerged and withstood the test of

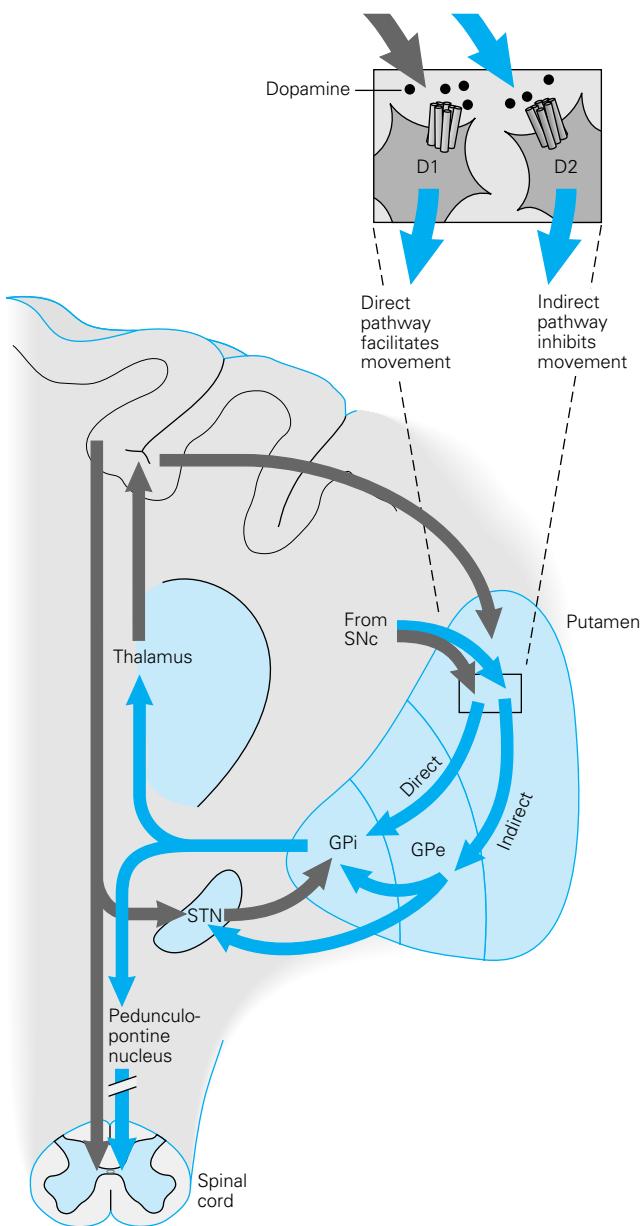

Figure 4-3. Schematic illustration of major efferent and afferent connections of the basal ganglia (see text for details; also Fig. 4-2). (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM: *Principles of Neural Science*, 4th ed. New York: McGraw-Hill, 2000.)

time was the central role of the ventrolateral and ventroanterior nuclei of the thalamus. Together, they form a vital link in an ascending fiber system, not only from the basal ganglia but also from the cerebellum to the motor and premotor cortex. Thus both basal ganglionic and cerebellar influences are brought to bear, via thalamocortical fibers, on the corticospinal system and on other descending pathways from the cortex. Direct descending pathways from the basal ganglia to the spinal cord are relatively insignificant.

The foregoing view of basal ganglionic organization has been broadened considerably, the result of new anatomic, physiologic, and pharmacologic data (see in particular the reviews of Gombar, of Crutcher, of DeLong, and of Penney and Young). Whereas earlier concepts emphasized the serial connectivity of the basal

ganglionic structures and the funneling of efferent projections to the ventrolateral thalamus and then to the motor cortex, current evidence indicates an organization into several parallel basal ganglionic–cortical circuits. Although these circuits run parallel to the premotor or prepyramidal pathway, they remain separate from it anatomically and physiologically. At least five such circuits have been described, each projecting to a different portion of the frontal lobe: (1) the prototypical motor circuit, converging on the premotor cortex; (2) the oculomotor circuit, on the frontal eye fields; two prefrontal circuits, (3) one on the dorsolateral prefrontal and (4) another on the lateral orbitofrontal cortex; and (5) a limbic circuit that projects to the anterior cingulate and medial orbitofrontal cortex.

An additional and essential feature of basal ganglionic structure, also relatively recently appreciated, is the nonequivalence of all parts of the striatum. Particular cell types and zones of cells within this structure appear to mediate different aspects of motor control and to utilize specific neurochemical transmitters, as detailed below under “Pharmacologic Considerations” (see Albin et al and DeLong). This specialization has taken on further importance with the observation that one or another cell type is found to be destroyed preferentially in degenerative diseases such as Huntington chorea.

The most important basal ganglionic connections and circuitry are indicated in Figs. 4-1, 4-2, and 4-3. Conventionally it has been taught that the striatum, mainly the putamen, is the *receptive part* of the basal ganglia, receiving topographically organized fibers from all parts of the cerebral cortex and from the pars compacta (pigmented neurons) of the substantia nigra, and that the *output* nuclei of the basal ganglia consist of the medial (internal) pallidum and the pars reticulata (nonpigmented portion) of the substantia nigra (Fig. 4-3).

It has been proposed—on the basis of physiologic, lesional, and pharmacologic studies—that there are two main efferent projections from the putamen; but these models, being quite incomplete, should be viewed as provisional. Nonetheless, there are reasons to conceptualize a *direct* efferent system from the putamen onto the medial (internal) pallidum and then onto the substantia nigra again, particularly to the pars reticulata (nonpigmented) cells, and an *indirect* system that traverses the lateral (external) pallidum and continues on to the subthalamic nucleus, with which it has strong to-and-fro connections. In most ways, the subthalamic nucleus and lateral pallidum operate as a single functional unit (at least in terms of the effects of lesions in those locations on parkinsonian symptoms and the neurotransmitters involved; see further on). The medial pallidum and reticular part of the nigra can be viewed in a similar unitary way, sharing the same input and output patterns. Within the indirect pathway, an internal loop is created by projections from the subthalamic nucleus to the medial segment of the pallidum and pars reticulata. A second offshoot of the indirect pathway, recently uncovered, consists of projections from the lateral pallidum to the medial pallidonigral output nuclei. These anatomic and physiologic concepts are continuously being revised on the basis of clinical and neurochemical observations. As already mentioned, a complete account of this intricate connectivity cannot be given; but the main themes outlined here seem to have been accepted. The relative importance of the direct and indirect pathways is being altered by recent experience, as discussed below.

From the internal pallidum, two bundles of fibers reach the thalamus—the ansa lenticularis and the fasciculus lenticularis. The

ansa sweeps around the internal capsule; the fasciculus traverses the internal capsule in a number of small fascicles and then continues medially and caudally to join the ansa in the prerubral field. Both of these fiber bundles join the thalamic fasciculus, which then contains not only the pallidothalamic projections but also mesothalamic, rubrothalamic, and dentatothalamic ones. These projections are directed to separate targets in the ventrolateral nucleus of the thalamus and to a lesser extent in the ventral anterior and intralaminar thalamic nuclei. The centromedian nucleus of the intralaminar group projects back to the putamen and, via the parafascicular nucleus, to the caudate. A major projection from the ventral thalamic nuclei to the ipsilateral premotor cortex completes the large *cortical-striatal-pallidal-thalamic-cortical* motor loop—the prepyramidal circuit, mentioned above—with conservation of the somatotopic arrangement of motor fibers, once again emphasizing the nexus at the thalamic nuclei.

Physiologic Considerations

Physiologic evidence indicates that a balanced functional architecture, one excitatory and the other inhibitory, is operative within the individual circuits. The *direct* striatomedial pallidonigral pathway is activated by *glutaminergic* projections from the sensorimotor cortex and by *dopaminergic* nigral (pars compacta)—striatal projections. Activation of this direct pathway inhibits the medial pallidum, which, in turn, disinhibits the ventrolateral and ventroanterior nuclei of the thalamus. As a consequence, thalamocortical drive is enhanced and cortically initiated movements are facilitated. The *indirect* circuit arises from putaminal neurons that contain *gamma-aminobutyric acid* (GABA) and smaller amounts of enkephalin. These striatal projections have an inhibitory effect on the lateral pallidum, which, in turn, disinhibits the subthalamic nucleus through GABA release, providing excessive subthalamic drive to the medial pallidum and substantia nigra pars reticulata. The net effect is thalamic inhibition that reduces thalamocortical input to the precentral motor fields and impedes voluntary movement. These complex, and in part still theoretical anatomic and physiologic relationships have been summarized in numerous schematic diagrams similar to Fig. 4-4 and those in Lang and Lozano and in Standaert and Young (see References).

Restated, enhanced conduction through the indirect pathway leads to hypokinesia (by increasing pallidothalamic inhibition), whereas enhanced conduction through the direct pathway results in hyperkinesia (by reducing pallidothalamic inhibition). The direct pathway is perceived by Marsden and Obeso as facilitating cortically initiated movements and the indirect pathway as suppressing potentially conflicting and unwanted motor patterns. In Parkinson disease, for example, loss of dopaminergic input from the substantia nigra diminishes activity in the direct pathway and increases activity in the indirect pathway; the net effect is to increase inhibition of the thalamic nuclei and to reduce excitation of the cortical motor system.

Further insight into Parkinson disease has come from the discovery that it can be faithfully reproduced in humans and primates by the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This toxin was discovered accidentally in drug addicts who self-administered an analogue of meperidine. The toxin binds with high affinity to monoamine oxidase (MAO), an extraneuronal enzyme that transforms it to a toxic metabolite—pyridinium. The latter is bound by melanin in the dopaminergic nigral neurons in

sufficient quantities to destroy the cells, probably by interfering with mitochondrial function. In monkeys made parkinsonian by the administration of MPTP, electrophysiologic studies have shown increased activity in the medial globus pallidus and decreased activity in the lateral globus pallidus, as predicted from the previously described models. This comes about because of the differential loss of activity of dopaminergic striatal neurons that project to each of these parts of the pallidum. The end result is increased inhibition of thalamocortical neurons. It is, however, difficult to explain why medial pallidal lesions do not regularly cause parkinsonism, as pointed out by Bhatia and Marsden. Perhaps it is because the subtle imbalance between the medial and lateral pallidal circuits that exists in Parkinson disease is not reproduced. This subtlety may also explain why crude lesions such as infarcts, hemorrhages, and tumors rarely produce the complete parkinsonian syndrome of tremor, bradykinesia, and rigidity without paralysis or reflex changes. Indeed, striking improvements in parkinsonian symptoms are obtained by placing lesions in the medial pallidum (pallidotomy), as discussed on page 924.

However, there are deficiencies in all current models, particularly as they relate to Parkinson disease and its treatment. For example, the abatement of drug-induced dyskinesias by a lesion in the subthalamic nucleus is an anomaly, and the effects of thalamic lesions are not easily explained (see Chap. 39). It is likely that the static model of inhibitory and excitatory pathways and the parsing of a direct and an indirect pathway, as useful as it is as a mnemonic, does not account for the dynamic activities of the basal ganglia. In particular, the activity of the neurons in these systems oscillate and influence the frequency of oscillations in other parts of the system, as well as bringing individual cells closer to firing. It has also been pointed out that currently conceived models do not account for the tremor of Parkinson disease. Furthermore, the various subtypes of dopamine receptors act in both excitatory and inhibitory ways under different circumstances depending on their location. The complexity of basal ganglionic interactions can hardly be explained in these simplified models, but they remain reasonable prototypes for understanding abnormal hyperkinetic and hypokinetic movements.

In more conventional but not yet antiquated physiologic terms, Denny-Brown and Yanagisawa, who studied the effects of ablation of individual extrapyramidal structures in monkeys, concluded that the basal ganglia function as a kind of clearinghouse where, during an intended or projected movement, one set of activities is facilitated and all other unnecessary ones are suppressed. They used the analogy of the basal ganglia as a brake or switch, the tonic inhibitory (“brake”) action of the basal ganglia preventing target structures from generating unwanted motor activity and the “switch” function referring to the capacity of the basal ganglia to select which of many available motor programs will be active at any given time. Still other theories focus on the role of the basal ganglia in the initiation, sequencing, and modulation of motor activity (“motor programming”). Also, it appears that the basal ganglia participate in the constant priming of the motor system, enabling the rapid execution of motor acts without premeditation—e.g., hitting a baseball. In most ways, these conceptualizations restate the same notions of balance and selectivity imparted to all motor actions by the basal ganglia. The manner in which excessive or depleted activity of various components of the basal ganglia gives rise to hypokinetic and hyperkinetic movement disorders is discussed further on, under “Symptoms of Basal Ganglia Disease.”

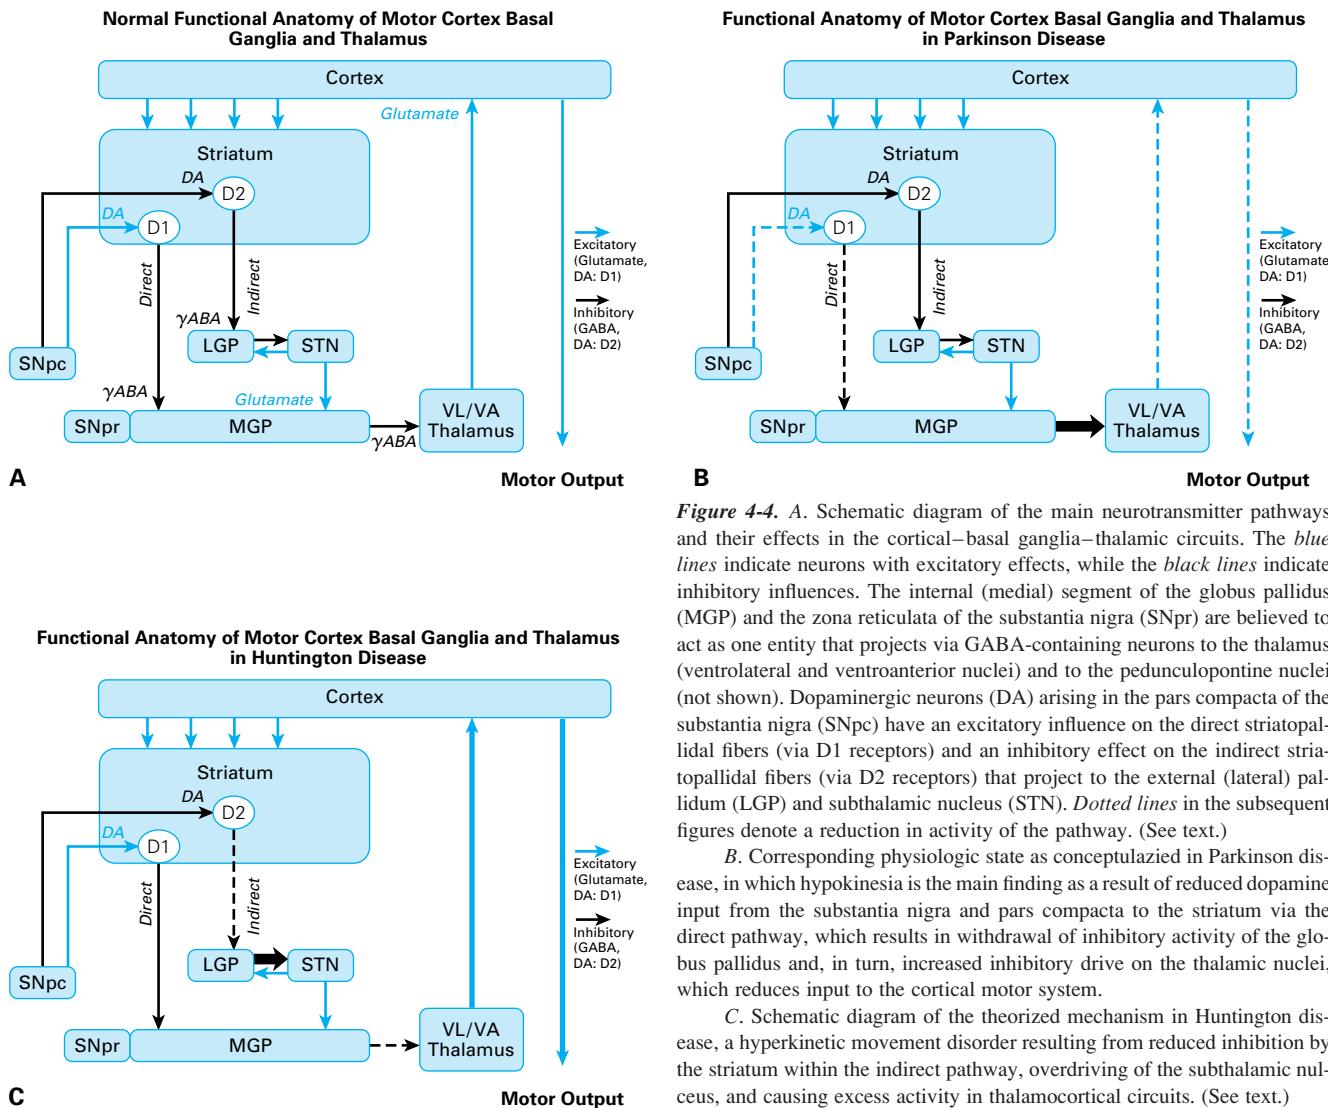

Figure 4-4. A. Schematic diagram of the main neurotransmitter pathways and their effects in the cortical–basal ganglia–thalamic circuits. The blue lines indicate neurons with excitatory effects, while the black lines indicate inhibitory influences. The internal (medial) segment of the globus pallidus (MGP) and the zona reticulata of the substantia nigra (SNpr) are believed to act as one entity that projects via GABA-containing neurons to the thalamus (ventrolateral and ventroanterior nuclei) and to the pedunculopontine nuclei (not shown). Dopaminergic neurons (DA) arising in the pars compacta of the substantia nigra (SNpc) have an excitatory influence on the direct striatopallidal fibers (via D1 receptors) and an inhibitory effect on the indirect striatopallidal fibers (via D2 receptors) that project to the external (lateral) pallidum (LGP) and subthalamic nucleus (STN). Dotted lines in the subsequent figures denote a reduction in activity of the pathway. (See text.)

B. Corresponding physiologic state as conceptualized in Parkinson disease, in which hypokinesia is the main finding as a result of reduced dopamine input from the substantia nigra and pars compacta to the striatum via the direct pathway, which results in withdrawal of inhibitory activity of the globus pallidus and, in turn, increased inhibitory drive on the thalamic nuclei, which reduces input to the cortical motor system.

C. Schematic diagram of the theorized mechanism in Huntington disease, a hyperkinetic movement disorder resulting from reduced inhibition by the striatum within the indirect pathway, overdriving of the subthalamic nucleus, and causing excess activity in thalamocortical circuits. (See text.)

Pharmacologic Considerations

During the past three decades, a series of pharmacologic observations—some mentioned above—have considerably enhanced our understanding of basal ganglionic function and led to a rational treatment of Parkinson disease and other extrapyramidal syndromes. Whereas physiologists had for years failed to discover the functions of the basal ganglia by stimulation and crude ablation experiments, clinicians became aware that the use of certain drugs, such as reserpine and the phenothiazines, regularly produced extrapyramidal syndromes (e.g., parkinsonism, choreoathetosis, dystonia). These observations greatly stimulated the study of central nervous system (CNS) transmitter substances in general. The current view is that the integrated basal ganglionic control of movement can be best understood by considering, in the context of the anatomy described above, the physiologic effects of neurotransmitters that convey the signals between cortex, striatum, globus pallidus, subthalamic nucleus, substantia nigra, and thalamus.

The most important neurotransmitter substances from the point of view of basal ganglionic function are glutamate, GABA, dopamine, acetylcholine, and serotonin. Their roles are sum-

marized in Fig. 4-4. A more complete account of this subject than is possible here may be found in the reviews of Penney and Young, Alexander and Crutcher, and of Rao referenced at the end of this chapter.

The following is what is known with a fair degree of certainty. Glutamate is the neurotransmitter of the excitatory projections from the cortex to the striatum and of the excitatory neurons of the subthalamic nucleus. GABA is the inhibitory neurotransmitter of striatal, pallidal, and substantia nigra (pars reticulata) projection neurons. Acetylcholine (ACh), long established as the neurotransmitter at the neuromuscular junction and the autonomic ganglia, is also physiologically active in the basal ganglia. The highest concentration of ACh as well as of the enzymes necessary for its synthesis and degradation (choline acetyl transferase and acetylcholinesterase) is in the striatum. Acetylcholine is synthesized and released by the large but sparse (Golgi type 2) nonspiny striatal neurons. It has a mixed but mainly excitatory effect on the more numerous spiny neurons within the putamen that constitute the main origin of the direct and indirect pathways described above. Dopamine, by contrast, has both inhibitory and excitatory effects on these neurons, as detailed below. It is likely that the effectiveness of atropinic

agents—which have been used empirically for many years in the treatment of Parkinson disease and dystonia—depends on their capacity to antagonize ACh at sites within the basal ganglia and in projections from the pedunculopontine nuclei. Acetylcholine appears also to act on the presynaptic membrane of striatal cells and to influence their release of neurotransmitters, as discussed below.

In addition, the basal ganglia contain other biologically active substances—substance P, enkephalin, cholecystokinin, somatostatin, and neuropeptide Y—which may enhance or diminish the effects of other neurotransmitters, i.e., they act as *neuromodulators*. The neurons utilizing these substances and the manner in which they operate are just now being identified.

Of the catecholamines, dopamine has the most pervasive role in the function of the basal ganglia. It can be said that it is among the most important in brain disease, since disturbances of dopamine signaling are essential abnormalities of several CNS disorders including Parkinsonism, schizophrenia, attention deficit disorder, and drug abuse. Within the basal ganglia, the areas richest in dopamine are the substantia nigra, where it is synthesized in the nerve cell bodies of the pars compacta, and the termination of these fibers in the striatum. In the most simplified models, stimulation of the dopaminergic neurons of the substantia nigra induces a specific response in the striatum—namely, an inhibitory effect on the already low firing rate of neostriatal neurons. However, the effects of dopamine have proved more difficult to resolve, in large part because there are now five known types of postsynaptic dopamine receptors (D_1 to D_5), each with its particular anatomic distribution and pharmacologic action. This heterogeneity is reflected in the excitatory effect of dopamine on the small spiny neurons of the putamen and an inhibitory effect on others.

The five types of dopamine receptors are found in differing concentration throughout various parts of the brain, each displaying differing affinities for dopamine itself and for various drugs and other agents (Table 4-2; see Jenner). The D_1 and D_2 receptors are highly represented in the striatum, D_3 in the nucleus accumbens, D_4 in the frontal cortex and certain limbic structures, and D_5 in the hippocampus. In the striatum, the effects of dopamine act as a class of “ D_1 -like” (D_1 and D_5 subtypes) and “ D_2 -like” (D_2 , D_3 , and D_4 subtypes) receptors. Stimulation of the D_1 class stimulates adenyl cyclase, while D_2 receptor binding inhibits this enzyme. Whether dopamine functions in an excitatory or inhibitory manner at a particular synapse is determined by the local receptor. As mentioned earlier, excitatory D_1 receptors predominate on the small spiny putaminal neurons that are the origin of the direct striatopallidal output pathway, while D_2 receptors mediate the inhibitory influence of dopamine on the indirect striatopallidal output, as indicated in Fig. 4-4.

Some of the clinical and pharmacologic effects of dopamine are made clear by considering both the anatomic sites of various receptors and their physiologic effects. For example, it appears that drug-induced parkinsonian syndromes and tardive dyskinesias (described further on) are prone to occur when drugs are administered that competitively bind to the D_2 receptor, but that the newer antipsychotic drugs, which produce fewer of these effects, have a stronger affinity for the D_4 receptor. However, the situation is actually far more complex, in part due to the synergistic activities of D_1 and D_2 receptors, each potentiating the other at some sites of convergence, and the presence on the presynaptic terminals of nigrostriatal neurons of D_2 receptors, which inhibit dopamine synthesis and release.

Even these intricacies do not capture the complexity of neural

transmission in the basal ganglia. In contrast to the almost instantaneous actions of glutamate and its antagonist, GABA, at synapses, the monoamines have more protracted effects lasting for seconds or as long as several hours. And they influence rapid as well as slower synaptic activities. Dopamine and related neurotransmitters have a slower influence through the “second messenger” cyclic adenosine monophosphate (cAMP), which in turn controls the phosphorylation or dephosphorylation of numerous intraneuronal proteins. These intracellular effects are summarized by Greengard.

The effects of certain drugs are better understood on the basis of the manner in which they alter or interfere with neurotransmitter function. Several of these drugs—namely reserpine, the phenothiazines, and the butyrophenones (notably haloperidol)—induce prominent parkinsonian syndromes in humans. Reserpine, for example, depletes the striatum and other parts of the brain of dopamine; haloperidol and the phenothiazines work by a different mechanism, probably by blocking dopamine receptors within the striatum.

The basic validity of the physiologic pharmacologic model outlined is supported by the observation that excess doses of L-dopa or of a direct-acting dopamine receptor agonist lead to excessive motor activity. Furthermore, the therapeutic effects of the main drugs utilized in the treatment of Parkinson disease become understandable in the context of neurotransmitter function. To correct the basic dopamine deficiency from a loss of nigral cells that

underlies Parkinson disease, attempts were at first made to administer dopamine directly. However, dopamine as such cannot pass the blood-brain barrier and therefore has no therapeutic effect. But its immediate dopamine precursor, L-dopa, does cross the blood-brain barrier and is effective in decreasing the symptoms of Parkinson disease as well as of the above-described MPTP-induced parkinsonism. This effect is enhanced by the addition of an inhibitor of dopa-decarboxylase, an important enzyme in the catabolism of dopamine. The addition of an enzyme inhibitor of this type (carbidopa or benserazide) to L-dopa results in an increase of dopamine concentration in the brain while sparing other organs from exposure to high levels of the drug. Similarly, drugs that inhibit catechol O-methyltransferase (COMT), another enzyme that breaks down dopamine, can prolong the effects of administered L-dopa.

Because of the pharmacologic effects of ACh and dopamine, it was originally postulated by Hornykiewicz that a functional equilibrium exists in the striatum between the excitatory activity of ACh and the inhibitory activity of dopamine. In Parkinson disease, the decreased release of dopamine by the substantia nigra onto the striatum disinhibits neurons that synthesize ACh, resulting in a predominance of cholinergic activity—a notion supported by the observation that parkinsonian symptoms are aggravated by centrally acting cholinergic drugs and improved by anticholinergic drugs. According to this theory, administration of anticholinergic drugs restores the ratio between dopamine and acetylcholine, with the new equilibrium being set at a lower-than-normal level because the striatal levels of dopamine are low to begin with. The use of drugs that enhance dopamine synthesis or its release or that directly stimulate dopaminergic receptors in the striatum (e.g., bromocriptine) represents a more physiologic method of treating Parkinson disease, but this approach has limitations, as outlined in Chap. 39.

The Pathology of Basal Ganglionic Disease

The extrapyramidal motor syndrome as we know it today was first delineated on clinical grounds and so named by S. A. K. Wilson in 1912. In the disease that now bears his name and that he called *hepatolenticular degeneration*, the most striking abnormality in the nervous system was a bilaterally symmetrical degeneration of the putamens, sometimes to the point of cavitation. To these lesions Wilson correctly attributed the characteristic symptoms of rigidity and tremor. Shortly thereafter, van Woerkom described a similar clinical syndrome in a patient with acquired liver disease (Wilson's cases were familial); in the acquired form also, the most prominent lesions consisted of foci of neuronal degeneration in the striatum. Clinicopathologic studies of Huntington chorea—beginning with those of Meynert (1871) and followed by those of Jelgersma (1908) and Alzheimer (1911)—related the movement disorder as well as the rigidity to a loss of nerve cells in the striatum. In 1920, Oskar and Cecile Vogt gave a detailed account of the neuropathologic changes in several patients who had been afflicted with choreoathetosis since early infancy; the changes, which they described as a *status fibrosus* or *status dysmyelinatus*, were confined to the caudate and lenticular nuclei. Surprisingly, it was not until 1919 that Tretiakoff demonstrated the underlying cell loss of the substantia nigra in cases of what was then called *paralysis agitans* and is now known as Parkinson disease. A series of observations, culminating with those of J. Purdon Martin and later of Mitchell and colleagues, related hemiballismus to lesions in the subthalamic nucleus of Luys and its immediate connections.

Bhatia and Marsden, relying on published imaging studies, some quite crude, reviewed some 240 cases in which there were lesions in the caudate, putamen, and globus pallidus associated with movement and behavioral abnormalities. Dystonia had occurred in 36 percent, chorea in 8 percent, parkinsonism in only 6 percent, and dystonia-parkinsonism in 3 percent. Bilateral lesions of the lenticular nuclei resulted in parkinsonism in 19 percent and dystonia-parkinsonism in 6 percent. It is also notable that a common persisting behavioral abnormality was abulia (apathy and loss of initiative, spontaneous thought, and emotional responsiveness), occurring in 28 percent of those with caudate lesions. The deficiencies of this type of case analysis, conceded by the authors to be imprecise (e.g., computed tomography studies) and obtained without regard to the temporal aspects of the functional disorder—time of onset, duration, and changes during the course of the illness, are obvious. We find it surprising that choreoathetosis was not more frequent. Needed, of course, are detailed anatomic (postmortem) studies of cases in which the disturbances of function were stable for many months or years. Such an example is the case of generalized dystonia with pallidolusian atrophy reported by Wooten and coworkers.

Table 4-3 summarizes the clinicopathologic correlations of extrapyramidal movement disorders that are accepted by most neurologists; it must be emphasized, however, that there is still some uncertainty as to the finer details.

SYMPTOMS OF BASAL GANGLIA DISEASE

In broad terms, all motor disorders may be considered to consist of certain functional deficits (or *negative symptoms*) and, the opposite, excessive motor activity (*positive symptoms*), the latter being ascribed to the release or disinhibition of the activity of undamaged parts of the motor nervous system. When diseases of the basal ganglia are analyzed along these classic lines, *bradykinesia*, *hypokinesia*, and *loss of normal postural reflexes* stand out as the primary negative symptoms, and *tremor*, *rigidity*, and *involuntary movements* that constitute a category of “*dyskinesias*” that include chorea, athetosis, ballismus, and dystonia as the positive ones. Disorders of phonation, articulation, and locomotion are more difficult to classify. In some instances they are clearly a consequence of rigidity and postural disorders, while in others, where rigidity is slight or negligible, they seem to represent primary deficiencies. Stress and nervous tension characteristically worsen both the motor deficiency and the abnormal movements in all extrapyramidal syndromes, just as relaxation improves them. The specific symptoms of basal ganglia disease are elaborated below.

Hypokinesia and Bradykinesia

The terms *hypokinesia* and *akinesia* (the extreme form) refer to a disinclination on the part of the patient to use an affected part and to engage it freely in all the natural actions of the body. There may, in addition, be slowness in the initiation and execution of a movement. In contrast to what occurs in paralysis (the primary symptom of corticospinal tract lesions), strength is not significantly diminished. Also, hypokinesia is unlike apraxia, in which a lesion erases the memory of the pattern of movements necessary for an intended act, leaving other actions intact. Clinically, the phenomenon of hypokinesia is expressed most clearly in the parkinsonian patient and takes the form of an extreme underactivity (poverty of movement).

Table 4-3
Clinicopathologic correlations of extrapyramidal motor disorders

SYMPTOMS	PRINCIPAL LOCATION OF MORBID ANATOMY
Unilateral plastic rigidity with rest tremor (Parkinson disease)	Contralateral substantia nigra plus (?) other mesencephalic structures
Unilateral hemiballismus and hemichorea	Contralateral subthalamic nucleus of Luys or luisial-pallidal connections
Chronic chorea of Huntington type	Caudate nucleus and putamen
Athetosis and dystonia	Contralateral striatum (pathology of dystonia musculorum deformans unknown)
Cerebellar incoordination, intention tremor, and hypotonia	Ipsilateral cerebellar hemisphere; ipsilateral middle or inferior cerebellar peduncle; brachium conjunctivum (ipsilateral if below decussation, contralateral if above)
Decerebrate rigidity, i.e., extension of arms and legs, opisthotonus	Usually bilateral in tegmentum of upper brainstem, at level of red nucleus or between red and vestibular nuclei
Palatal and facial myoclonus (rhythmic)	Ipsilateral central tegmental tract, with denervation of inferior olfactory nucleus and nucleus ambiguus
Diffuse myoclonus	Neuronal degeneration, usually diffuse or predominating in cerebral or cerebellar cortex and dentate nuclei

The frequent automatic, habitual movements observed in the normal individual—such as putting the hand to the face, folding the arms, or crossing the legs—are absent or greatly reduced. In looking to one side, the eyes move, but not the head. In arising from a chair, there is a failure to make the usual small preliminary adjustments, such as pulling the feet back, putting the hands on the arms of the chair, and so forth. Blinking is infrequent. Saliva is not swallowed as quickly as it is produced, and drooling results. The face lacks expressive mobility (“masked facies,” or hypomimia). Speech is rapid and monotonic and the voice is soft.

Bradykinesia, which connotes slowness rather than lack of movement, is probably another aspect of the same physiologic difficulty. Not only is the parkinsonian patient slightly “slow off the mark” (displaying a longer-than-normal interval between a command and the first contraction of muscle—i.e., increased reaction time), but the velocity of movement, or the time from onset to completion of movement, is slower than normal. Hallett distinguishes between akinesia and bradykinesia, equating akinesia with

a prolonged reaction time and bradykinesia with a prolonged time of execution, but he concedes that if bradykinesia is severe, it may result in akinesia. This is apparently not the result of slowness in formulating the plan of movement; that is to say, there is no “bradypraxia.” For a time, bradykinesia was attributed to the frequently associated rigidity, which could reasonably hamper all movements; but the incorrectness of this explanation became apparent when it was discovered that an appropriately placed stereotactic lesion in a patient with Parkinson disease may abolish rigidity while leaving the akinesia unaltered. Thus it appears that apart from their contribution to the maintenance of posture, the basal ganglia provide an essential element for the performance of the large variety of voluntary and semiautomatic actions required for the full repertoire of natural human motility.

Hallett and Khoshbin, in an analysis of ballistic (rapid) movements in the parkinsonian patient, found that the normal triphasic sequence of agonist-antagonist-agonist activation, as described in the next chapter, is intact but lacks the energy (number of activated motor units) to complete the movement. Several smaller triphasic sequences are then needed, which slows the movement. The patient experiences these phenomena as not only a slowness but also a type of weakness. That cells in the basal ganglia participate in the initiation of movement is also evident from the fact that the firing rates in these neurons increase before movement is detected clinically.

In terms of pathologic anatomy and physiology, bradykinesia may be caused by any process or drug that interrupts some component of the cortico-striato-pallido-thalamic circuit. Clinical examples include reduced dopaminergic input from the substantia nigra to the striatum, as in Parkinson disease; dopamine receptor blockade by neuroleptic drugs; extensive degeneration of striatal neurons, as in striatonigral degeneration and the rigid form of Huntington chorea; and destruction of the medial pallidum, as in Wilson and Hallervorden-Spatz diseases.

As illustrated in Fig. 4-4B, which gives a schematic representation of the hypokinetic state of Parkinson’s disease, changes in the cortico-striato-pallido-thalamic circuit (in this case mainly the direct striatopallidal pathway) can be interpreted in terms of altered neurochemical and resultant physiologic connectivity within the basal ganglia. The reciprocal situation, enhanced motor activity, is summarized in the analogous diagram for Huntington disease (Figure 4-4C), in which a reduction in the activity of the indirect striatopallidal pathway leads to enhanced excitatory motor drive in the thalamo-cortical motor pathway.

A number of other disorders of voluntary movement may also be observed in patients with diseases of the basal ganglia. A persistent voluntary contraction of hand muscles, as in holding a pencil, may fail to be inhibited, so that there is interference with the next willed movement. This has been termed *tonic innervation*, or *blocking* and may be brought out by asking the patient to repetitively open and close a fist. Attempts to perform an alternating sequence of movements may be blocked at one point, or there may be a tendency for the voluntary movement to adopt the frequency of the coexistent tremor. Muscles fatigue more readily on repeated activity. In still other cases, performance of a simple movement (e.g., touching finger to nose, forcefully striking an object with the fisted hand) is rendered impossible by the simultaneous contraction of agonist and antagonist muscles not only of the arm and hand but also of the neck, trunk, and even the legs (“intention spasm”).

Disorders of Postural Fixation, Equilibrium, and Righting

These deficits are also demonstrated most clearly in the parkinsonian patient. The prevailing posture is one of involuntary flexion of the trunk and limbs and of the neck. The inability of the patient to make appropriate postural adjustments to tilting or falling and his inability to move from the reclining to the standing position are closely related phenomena. A gentle push on the patient's sternum or back may cause a fall or start a series of small corrective steps that the patient cannot control (festination). These postural abnormalities are not attributable to weakness or to defects in proprioceptive, labyrinthine, or visual function, the principal forces that control the normal posture of the head and trunk. Anticipatory and compensatory righting reflexes are also manifestly impaired. This occurs early in the course of progressive supranuclear palsy and later in Parkinson disease.

A point of interest is whether akinesia and disorders of postural fixation are invariable negative manifestations of all extrapyramidal diseases and whether, without them, there could be any secondary release effects such as dystonia, choreoathetosis, and rigidity. The question has no clear answer. Akinesia and abnormalities of posture are constant features of both Parkinson and Wilson diseases; they seem to be present also in Huntington chorea and in the athetosis of cerebral palsy, but one cannot be sure of their existence in hemiballismus.

Rigidity and Alterations in Muscle Tone

In the form of altered muscle tone known as *rigidity*, the muscles are continuously or intermittently firm and tense. Although brief periods of electromyographic silence can be obtained in selected muscles by persistent attempts to relax the limb, there is obviously a low threshold for involuntary sustained muscle contraction, and this is present during most of the waking state, even when the patient appears quiet and relaxed. In contrast to spasticity, the increased resistance on passive movement that characterizes rigidity is not preceded by an initial "free interval" and has an even or uniform quality throughout the range of movement of the limb, like that experienced in bending a lead pipe or pulling a strand of toffee. The contrasting terms *clasp-knife* spasticity and *lead-pipe* rigidity have been aptly applied to the examiner's sense on manipulating the patient's limb through an arc of movement. Also, the tendon reflexes are not enhanced in the rigid limb and, when released, the limb does not resume its original position, as happens in spasticity.

Rigidity usually involves all muscle groups, both flexor and extensor, but it tends to be more prominent in muscles that maintain a flexed posture, i.e., in the flexor muscles of trunk and limbs. It appears to be somewhat greater in the large muscle groups, but this may be merely a matter of muscle mass. Certainly the small muscles of the face and tongue and even those of the larynx are often affected. Nevertheless, like spasticity, rigidity represents a lower threshold for synaptic excitation of spinal and cranial motor neurons. It can be abolished by the extradural or subarachnoid injection of a local anesthetic, and, as claimed by Foerster many years ago, by posterior root section, presumably by interrupting the afferent fibers of the gamma loop. Recording from muscle spindles has not confirmed this spindle overdrive, and although the phasic myotatic (tendon) reflexes are not increased, the tonic stretch reflexes are. Concordant with the examiner's experience, in the electromyo-

graphic tracing, motor-unit activity is more continuous in rigidity than in spasticity, persisting even after apparent relaxation.

A special feature that may accompany rigidity, first noted by Negro in 1901, is the *cogwheel phenomenon*. When the hypertonic muscle is passively stretched, e.g., when the hand is dorsiflexed, one encounters a rhythmically interrupted, ratchet-like resistance. Most likely this phenomenon represents an associated tremor that, if not manifestly present, emerges faintly during manipulation. It is therefore not a fundamental property of rigidity and is found in many tremulous states.

Rigidity is a prominent feature of many basal ganglionic diseases, such as Parkinson disease (late stages), Wilson disease, striatonigral degeneration (multiple system atrophy), progressive supranuclear palsy, dystonia musculorum deformans (all discussed in Chap. 39), intoxication with neuroleptic drugs, and calcinosis of the basal ganglia. The rigidity is characteristically variable in degree; in some patients with involuntary movements, particularly in those with chorea or dystonia, the limbs may actually be intermittently or persistently hypotonic.

Another distinctive type of variable resistance to passive movement is that in which the patient seems unable to relax a group of muscles on request. When the limb muscles are passively stretched, the patient appears to actively resist the movement (*gegenhalten*, *paratonia*, or oppositional resistance). Natural relaxation normally requires concentration on the part of the patient. If there is inattentiveness—as happens with diseases of the frontal lobes, dementia, or other confusional states—this type of oppositional resistance may raise a question of parkinsonian rigidity. Actually this is not a manifestation of basal ganglia disorder per se but may indicate that the connections of the basal ganglia to the frontal lobes are impaired. A similar difficulty in relaxation is observed normally in small children. Not to be mistaken for rigidity or paratonia is the "waxy flexibility" displayed by the psychotic patient when a limb placed in a suspended position is maintained for minutes in the identical posture.

As to pathophysiology, it is generally agreed that rigidity and bradykinesia result from lesions of the nigrostriatal system and that such lesions produce their effects through a series of sequential inhibitory and excitatory events involving the components and circuitry of the basal ganglia. The normal activating effects of dopamine on both the direct and indirect striatopallidal systems and their effects on thalamocortical drive have been described earlier. Degeneration of the pigmented cells of the substantia nigra deprives striatal neurons of their dopaminergic innervation, with the ultimate result that the normal thalamocortical drive is inhibited, culminating in rigidity, hypo- or akinesia, and bradykinesia.

Involuntary Movements (Chorea, Athetosis, Ballismus, Dystonia)

In deference to usual practice, these symptoms are described separately, as though each represented a discrete clinical phenomenon readily distinguishable from the others. In reality, they usually occur together or blend imperceptibly into each other and have many points of clinical similarity. There are reasons to believe that they have a common anatomic and physiologic basis. One must be mindful that chorea, athetosis, and dystonia are symptoms and are not to be equated with disease entities that happen to incorporate one of these terms in their names (e.g., Huntington chorea, dystonia musculorum deformans). Here the discussion is limited to the

symptoms. The diseases of which these symptoms are a part are considered elsewhere, mainly in Chap. 39.

Somewhat more ambiguous but in common clinical use is the term *dyskinesia*. It encompasses all the active movement phenomena that are due to disease of the basal ganglia, usually implying an element of dystonia, but it has also been used to refer more specifically to the undifferentiated excessive movements that are induced in Parkinson patients at the peak of L-dopa effect and to numerous dystonic and athetotic movements that may follow the use of neuroleptic drugs ("tardive dyskinesias," Chaps. 6 and 43).

Chorea Derived from the Greek word meaning "dance," *chorea* refers to involuntary arrhythmic movements of a forcible, rapid, jerky type. These movements may be simple or quite elaborate and of variable distribution. Although the movements are purposeless, the patient may incorporate them into a deliberate act, as if to make them less noticeable. When superimposed on voluntary actions, they may assume an exaggerated and bizarre character. Grimacing and peculiar respiratory sounds may be other expressions of the movement disorder. Usually the movements are discrete; but if they are very numerous, they become confluent and then resemble athetosis, as described below. In moments when the involuntary movements are absent or briefly held in abeyance, volitional movements of normal strength are possible, since there is no paralysis; but these movements tend also to be excessively quick and poorly sustained. The limbs are often slack or hypotonic and, because of this, the knee jerks tend to be pendular; with the patient sitting on the edge of the examining table and the foot free of the floor, the leg swings back and forth four or five times in response to a tap on the patellar tendon, rather than once or twice, as it does normally. A choreic movement may be superimposed on the reflex movement, checking it in flight, so to speak, and giving rise to the "hung-up" reflex.

The hypotonia in chorea as well as the pendular reflexes may suggest a disturbance of cerebellar function. Lacking, however, are "intention" tremor and true incoordination or ataxia. In patients with hypernatremia and other metabolic disorders, it may be necessary to distinguish chorea from myoclonus. Chorea differs from myoclonus mainly with respect to the speed of the movements; the myoclonic jerk is much faster and may involve single muscles or part of a muscle as well as groups of muscles. Failure to appreciate this difference between chorea and myoclonus often results in an incorrect diagnosis.

Diseases characterized by chorea are listed in Table 4-4. Chorea is a major feature of Huntington disease (hereditary or chronic chorea), in which the movements tend more typically to be choreoathetotic. Also, there is an inherited form of chorea of childhood onset without dementia that has been referred to as *benign hereditary chorea*. The gene mutation is on chromosome 14, different from the expanded gene on chromosome 4 that characterizes Huntington disease. There may be subtle additional ataxia of gait, as noted by Breedveld and colleagues. Not infrequently, chorea has its onset in late life without the other identifying features of Huntington disease. It is then referred to as *senile chorea*, a term that is hardly helpful in understanding the process. Its relation to Huntington chorea is unsettled. It may be a delayed form of the disease, and a few such patients we have seen have had atypical depressions or mild psychosis; but others remain for a decade with only chorea. Genetic testing settles the issue. A number of far less common degenerative conditions are associated with chorea, among them dentatorubropallidolysian atrophy. These are discussed in Chap. 39.

Table 4-4

Diseases characterized by chorea

Inherited disorders

- Huntington disease
- Benign hereditary chorea
- Neuroacanthocytosis
- Dentatorubropallidolysian atrophy
- Wilson disease

Rheumatic chorea

- Sydenham, chorea gravidarum

Drug-induced chorea

- Neuroleptics (phenothiazines, haloperidol, and others)
- Oral contraceptives
- Phenytoin (occasionally other anticonvulsants)
- Excess dosages of L-dopa and dopamine agonist medications
- Cocaine

Chorea symptomatic of systemic disease

- Lupus erythematosus with antiphospholipid antibodies
- Thyrotoxicosis
- Polycythemia vera
- Hyperosmolar, nonketotic hyperglycemia
- AIDS
- Paraneoplastic, often with other movements

Hemichorea, rarely associated with

- Stroke
- Tumor
- Vascular malformation

Typical choreic movements are the dominant feature of Sydenham chorea and of the variety of that disease associated with pregnancy (chorea gravidarum), disorders that are related in some way to streptococcal infection. Striatal abnormalities have been demonstrated by magnetic resonance imaging (MRI) in some cases; they are usually transient but rarely persistent (Emery and Vieco). It is perhaps not surprising that antibodies directed against cells of the basal ganglia have been detected in both acute and late Sydenham chorea (Church et al). Following from the connection to streptococcal infection and the detection of these antibodies, in recent years it has been suggested that the spectrum of poststreptococcal disorders be extended to tic and obsessive-compulsive behavior in children. In these cases the neurologic problems are said to arise suddenly, subside, and return with future streptococcal infections, as discussed in Chap. 6.

The administration of phenothiazine drugs or haloperidol (or an idiosyncratic reaction to these drugs) is a common cause of extrapyramidal movement disorders of all types, including chorea; these may become manifest during use of the drug or in a delayed "tardive" fashion, as already mentioned. Excess dopamine administration in advanced Parkinson disease is perhaps the most common cause of a choreiform dyskinesia in practice, but the movements tend to be more complex and continuous than those seen in chorea.

The use of oral contraceptives sometimes elicits chorea in an otherwise healthy young woman, but the majority of such patients have underlying systemic lupus erythematosus and antiphospholipid antibodies. Whether the chorea (usually unilateral) is the result of a small infarction (as suggested by the a mild hemiparesis on the affected side) or is an immunologic condition is not settled. The re-emergence of chorea in these circumstances as steroids are with-

drawn or birth control pills are introduced suggests a more complex process than simply a small deep infarction—perhaps something akin to Sydenham chorea. Also, only about one-third of cases involve a stroke, and some have demonstrated hypermetabolism of the basal ganglia, also as in Sydenham chorea. A connection between hemichorea and the antiphospholipid syndrome alone, without lupus, is tenuous in our view.

The use of phenytoin or other anticonvulsant drugs causes chorea in sensitive individuals. A transitory chorea may occur in the course of an acute metabolic derangement such as hyperosmolar hyperglycemia, hypoglycemia, or hyponatremia.

Rarely, chorea complicates hyperthyroidism, polycythemia vera, lupus erythematosus or other forms of cerebral arteritis. AIDS has emerged as a cause of a number of subacutely progressive movement disorders, initially asymmetrical in our experience, and chorea has been one manifestation. The usual associations have been with focal lesions in or near the basal ganglionic structures such as toxoplasmosis, progressive multifocal leukoencephalopathy, and lymphoma, but a number of instances are not explained by any of these. An inherited chorea with acanthocytosis of red blood cells has been well described, but the nature of the lesions of the basal ganglia is unknown (Chap. 39). A paraneoplastic variety may combine several aspects of chorea with athetosis and ballismus or dystonia; inflammatory lesions are found in the striatum (Chap. 31).

Chorea may be limited to one side of the body (*hemichorea*). When the involuntary movements involve proximal limb muscles and are of wide range and flinging in nature, the condition is called *hemiballismus* (see further on). A cerebral infarction is the usual cause. A number of rare *paroxysmal kinesigenic* disorders, discussed later in this chapter, may have a choreic component.

The review by Piccolo and colleagues puts the frequency of the various causes of chorea in perspective. Of a large number of consecutive neurologic admissions to two general hospitals, they identified 23 cases of chorea, of which 5 were drug-induced, 5 were AIDS-related, and 6 were due to stroke. Sydenham chorea and arteritis were each found in 1 case. In 4 cases no cause could be determined, and 1 case proved to have Huntington disease.

The anatomic basis of chorea is uncertain or at least inconsistent. In Huntington chorea, there are obvious lesions in the caudate nucleus and putamen. Yet one often observes vascular lesions in these parts without chorea. The precise localization of lesions in Sydenham chorea and other choreic diseases has not been determined beyond a generalized disturbance in the striatum, which is evident on some imaging studies. It is of interest that in instances of chorea related to acute metabolic disturbances, there are sometimes small infarctions in the basal ganglia or metabolic changes in the lenticular nucleus, as shown by imaging studies. One suspects from their close clinical similarity that chorea and hemiballismus relate to disorders of the same system of neurons; however, the subthalamic nucleus is affected only slightly in Huntington chorea.

Athetosis This term stems from a Greek word meaning “unfixed” or “changeable.” The condition is characterized by an inability to sustain the fingers and toes, tongue, or any other part of the body in one position. The maintained posture is interrupted by relatively slow, sinuous, purposeless movements that have a tendency to flow into one another. As a rule, the abnormal movements are most pronounced in the digits and hands, face, tongue, and throat, but no group of muscles is spared. One can detect as the basic patterns of movement an alternation between extension-pronation and

flexion-supination of the arm and between flexion and extension of the fingers, the flexed and adducted thumb being trapped by the flexed fingers as the hand closes. Other characteristic movements are eversion-inversion of the foot, retraction and pursing of the lips, twisting of the neck and torso, and alternate wrinkling and relaxation of the forehead or forceful opening and closing of the eyelids. The movements appear to be slower than those of chorea, but all gradations between the two are seen; in some cases, it is impossible to distinguish between them, hence the term *choreoathetosis*. Discrete voluntary movements of the hand are executed more slowly than normal, and attempts to perform them may result in a cocontraction of antagonistic muscles and a spread (overflow) of contraction to muscles not normally required in the movement (*intention spasm*). The overflow appears related to a failure of the striatum to suppress the activity of unwanted muscle groups. Like polymyoclonus (see Chap. 6), some forms of athetosis occur only during the performance of projected movement (*intention or action athesis*). In other forms, the spasms appear to occur spontaneously, i.e., they are involuntary and, if persistent, give rise to more or less fixed dystonic postures, as described by Yanagisawa and Goto.

Athetosis may affect all four limbs or may be unilateral, especially in children who have suffered a hemiplegia at some previous date (*posthemiplegic athetosis*). Many athetotic patients exhibit variable degrees of rigidity and motor deficit due to associated corticospinal tract disease; these may account for the slower quality of athetosis compared to chorea. In other patients with generalized choreoathetosis, as pointed out above, the limbs may be intermittently hypotonic.

The combination of athetosis and chorea of all four limbs is a cardinal feature of Huntington disease and of a state known as *double athetosis*, which begins in childhood. Athetosis appearing in the first years of life is usually the result of a congenital or postnatal condition such as hypoxia or rarely kernicterus. Postmortem examinations in some of the cases have disclosed a peculiar pathologic change of probable hypoxic etiology, a *status marmoratus*, in the striatum (Chap. 38); in other cases, of probable kernicteric (hyperbilirubinemic) etiology, there has been a loss of nerve cells and myelinated fibers—a *status dysmyelinatus*—in the same regions. In adults, athetosis may occur as an episodic or persistent disorder in hepatic encephalopathy, as a manifestation of chronic intoxication with phenothiazines or haloperidol, and as a feature of certain degenerative diseases, most notably Huntington chorea but also Wilson disease, Hallervorden-Spatz disease, Leigh disease, and other mitochondrial disease variants; less frequently, athetosis may be seen with Niemann-Pick (type C) disease, Kufs disease, neuroacanthocytosis, and ataxia telangiectasia. It may also occur as an effect of excessive L-dopa in the treatment of Parkinson disease, in which case it appears to be due to a decrease in the activity of the subthalamic nucleus and the medial segment of the globus pallidus (Mitchell et al.). Athetosis, usually in combination with chorea, may occur rarely in patients with AIDS and in those taking anticonvulsants. Localized forms of athetosis may occasionally follow vascular lesions of the lenticular nucleus or thalamus, as in the cases described by Dooling and Adams.

Ballismus This term designates an uncontrollable, poorly patterned flinging movement of an entire limb. As remarked earlier, it is closely related to chorea and athetosis, indicated by the frequent coexistence of these movement abnormalities and the tendency for ballismus to blend into a less obtrusive choreoathetosis

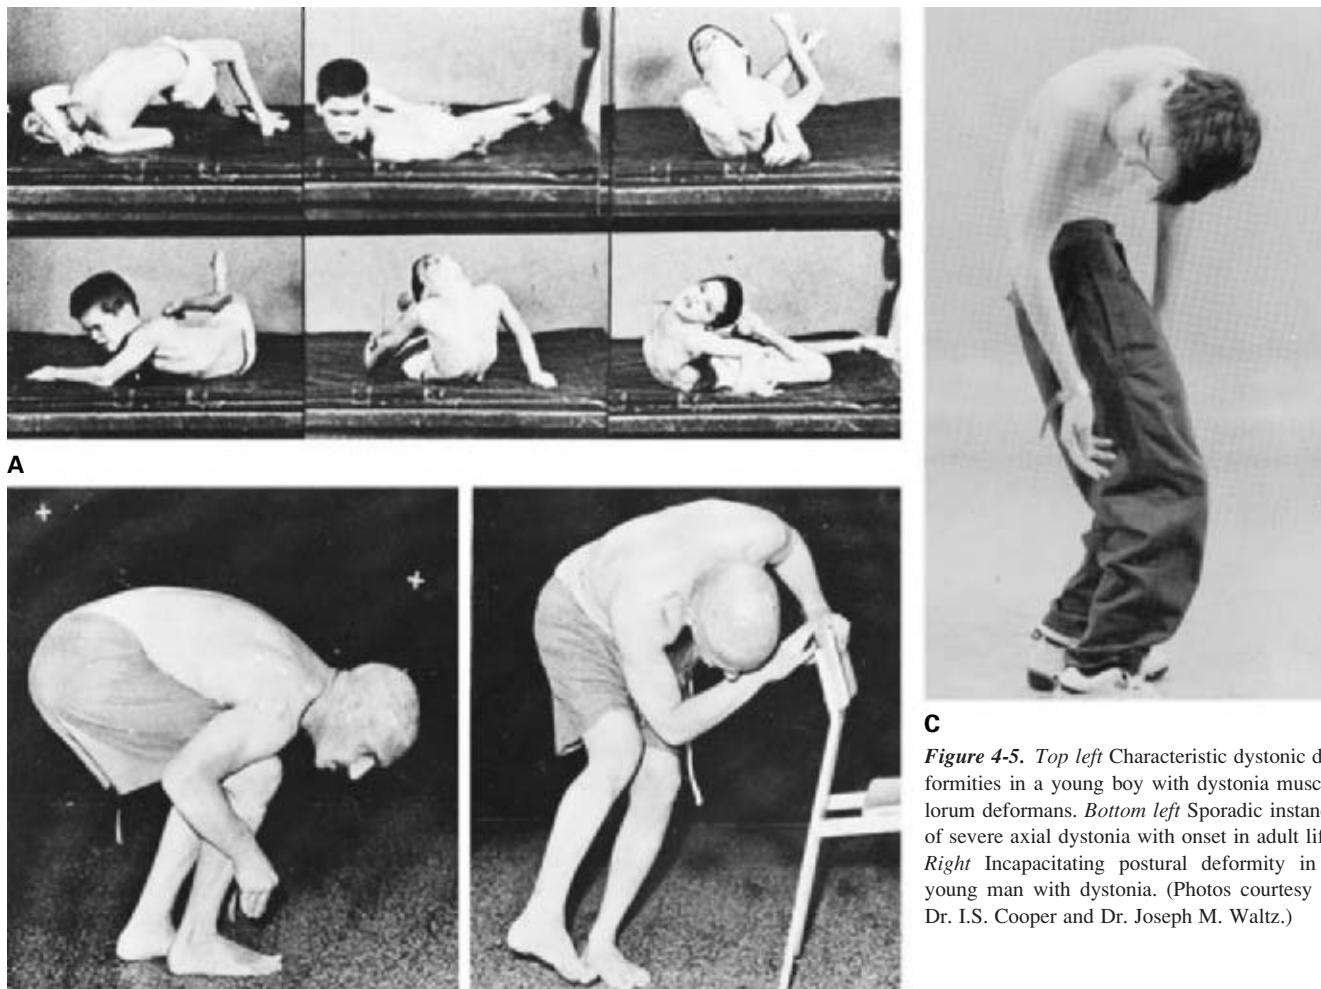

**C**

Figure 4-5. Top left Characteristic dystonic deformities in a young boy with dystonia musculorum deformans. Bottom left Sporadic instance of severe axial dystonia with onset in adult life. Right Incapacitating postural deformity in a young man with dystonia. (Photos courtesy of Dr. I.S. Cooper and Dr. Joseph M. Waltz.)

B

of the distal parts of the affected limb. Ballistic movements are usually unilateral (*hemiballismus*) and the result of an acute lesion of the contralateral subthalamic nucleus or immediately surrounding structures (infarction or hemorrhage, rarely a demyelinative or other lesion). Rarely, a transitory form is linked to a subdural hematoma or thalamic or parietal lesion. The flinging movements may be almost continuous or intermittent, occurring several times a minute, and of such dramatic appearance that it is not unusual for them to be regarded as hysterical in nature.

Bilateral ballismus is very infrequent and usually asymmetrical; here a metabolic disturbance, particularly nonketotic hyperosmolar coma, is the usual cause. When this is found in combination with choreoathetosis, a paraneoplastic process is a rare cause.

When ballismus persists for weeks on end, as it often did before effective treatment became available, the continuous forceful movements can result in exhaustion and even death. In most cases, medication with haloperidol or phenothiazine suppresses the violent movements. In extreme cases, stereotactic lesions placed in the ventrolateral thalamus and zona incerta have proved effective (Krauss and Mundinger).

Dystonia (Torsion Spasm) (See also Chap. 6 for a discussion of focal dystonias.) *Dystonia*, a persistent attitude or posture in one

or the other of the extremes of athetoid movement, is produced by cocontraction of agonist and antagonist muscles that place the limb in an unnatural position. It may take the form of an overextension or overflexion of the hand, inversion of the foot, lateral flexion or retroflexion of the head, torsion of the spine with arching and twisting of the back, forceful closure of the eyes, or a fixed grimace (Fig. 4-5; see also Fig. 6-2, page 92). Defined in this way, dystonia is closely allied to athetosis, differing only in the persistence or fixity of the postural abnormality and the disproportionate involvement of the large axial muscles (those of the trunk and limb girdles). The term *dystonia* is now generally used in this way, but it has been given other meanings as well. Wilson referred to any variability in muscle tone as dystonia. This term has also been applied to fixed abnormalities of posture that may be the end result of certain diseases of the motor system; thus Denny-Brown speaks of "hemiplegic dystonia" and the "flexion dystonia of parkinsonism." If the term is to be used in the latter sense, it would be better to speak of the persistent but reversible athetotic movements of the limbs and trunk as "torsion spasms" or "phasic dystonia," in contrast to "fixed dystonia."

Dystonia, like athetosis, may vary considerably in severity and may show striking fluctuations in individual patients. In its early stages it may be interpreted as an annoying mannerism or hysteria, and only later—in the face of persisting postural abnormality, lack

of the usual psychologic features of hysteria, and the emerging character of the illness—is the correct diagnosis made. Dystonia may be limited to the facial, cervical, or trunk muscles or to those of one limb, and it may cease when the body is in repose. Severe instances result in grotesque movements and distorted positions of the body; sometimes the whole musculature seems to be thrown into spasm by an effort to move an arm or to speak.

Causes of Dystonia Generalized dystonia is seen in its most pronounced form as an uncommon heritable disease, dystonia musculorum deformans, in which case it is associated with a specific mutation in the DYT1 gene on chromosome 9 (page 929). It was in relation to this disease that Oppenheim and Vogt, in 1911, introduced the term *dystonia*. Dystonia also occurs as a manifestation of many other diseases (“symptomatic dystonias”). The latter include double athetosis due to hypoxic damage to the fetal or neonatal brain, kernicterus, Hallervorden-Spatz disease, Huntington disease, Wilson hepatolenticular degeneration, Parkinson disease, lysosomal storage diseases, striatopallidodentatal calcification (due sometimes to hypoparathyroidism), and thyroid disease and exposure to neuroleptic drugs, as discussed below.

Widespread torsion spasm may also be a prominent feature of certain rare heredodegenerative disorders, such as familial striatal necrosis with affection of the optic nerves and other parts of the nervous system (Marsden et al, Novotny et al). A distinct subset of patients with an idiopathic dystonia (described by Nygaard et al) has responded to extremely small doses of L-dopa. The disease is familial, usually autosomal dominant, and the dystonia-athetosis may be combined with elements of parkinsonism. Marked diurnal fluctuation of symptoms is characteristic. In one autopsied case there was hypopigmentation of the substantia nigra. This process, goes by a number of names, including *L-dopa responsive dystonia* and *Segawa disease*. It has been traced to a mutation in the Parkin gene (page 930). Another rare hereditary dystonia that has its onset in adolescence or early adulthood is of interest because of the rapid evolution, at times within an hour but more often over days, of severe dystonic spasms, dysarthria, dysphagia, and postural instability with bradykinesia, which may follow (Dobyns et al). A few cases have followed a febrile episode. The disorder is termed *rapid-onset dystonia-parkinsonism*. It is our understanding that the latter features are mild and not responsive to L-dopa. These hereditary forms of dystonia are discussed in Chap. 39. Restricted or fragmentary forms of dystonia (*dyskinesias*) are the types most commonly encountered in clinical practice. Characteristically the spasms involve only the orbicularis oculi and face or mandibular muscles (blepharospasm-oromandibular dystonia), tongue, cervical muscles (spasmodic torticollis), hand (writer's cramp), or foot. These are described more fully in Chap. 6 as well as in Chap. 39.

Hemidystonia represents an unusual form of acquired movement that, in our experience, is rarely pure. In an analysis of 33 of their own cases and 157 previously published ones, Chuang and colleagues found stroke, mainly in the opposite putamen, to be most often responsible. Traumatic and perinatal damage accounted for several cases and a large proportion had no lesions found by imaging tests. There was a delay of several years between the injury and the start of the movements; these authors also commented on the resistance of this syndrome to drug treatment.

The most frequent cause of *acute generalized dystonic reactions* is exposure to the class of neuroleptic drugs—phenothiazines, butyrophenones, or metoclopramide—and even with the newer agents such as olanzapine, which has the advantage of producing these side effects less frequently than the others. A highly char-

acteristic, almost diagnostic, example of these drug-induced dystonias consists of retrocollis (forced extension of the neck), arching of the back, internal rotation of the arms, and extension of the elbows and wrists—simulating opisthotonus. These reactions respond to some extent to diphenhydramine or benztropine given two or three times in 24 to 48 h. Also, L-dopa, calcium channel blockers, and a number of anticonvulsants and anxiolytics are among a long list of other medications that may on occasion induce dystonia, the various causes of which are listed in Table 4-5. The acute dystonic reactions are idiosyncratic and not as common as the “tardive dyskinesias” that may follow long-standing use or the withdrawal of a medication.

Finally, a peculiar and dramatic spasm of a limb or the entire body may be seen in patients with multiple sclerosis. The movements have aspects of dystonia and spasm and may be provoked by hyperventilation. In our experience, they are most likely to occur in patients with large demyelinating lesions of the cervical spinal cord.

Treatment All manner of drugs have been used in the treatment of chronic generalized dystonia from a number of causes, with a notable lack of success. However, Fahn has reported beneficial ef-

Table 4-5
Diseases characterized by dystonia

Hereditary and degenerative dystonias

- Huntington chorea
- Dystonia musculorum deformans (recessive and autosomal dominant forms)
- Juvenile dystonia—Parkinson syndrome (L-dopa-responsive)
- Dystonia with other heredodegenerative disorders (neural deafness, striatal necrosis with optic nerve affection, paraplegic amyotrophy)
- Focal dystonias and occupational spasms (See Chap. 6), some of which are allied with hereditary torsion dystonia
- Parkinson disease (occasional)
- Progressive supranuclear palsy

Drug-induced dystonia

- Acute and chronic phenothiazine, haloperidol, and other neuroleptic intoxication
- L-Dopa excess in Parkinson disease

Symptomatic (secondary) dystonias

- Wilson disease
- Double athetosis (cerebral palsy) due to cerebral hypoxia
- Kernicterus
- Acquired hepatocerebral degeneration
- AIDS
- Lysosomal storage diseases
- Multiple sclerosis with cord lesion
- Paraneoplastic striatopallidodentatal calcification (Fahr disease)
- Toxic necrosis of lenticular nuclei (e.g., methanol) can be delayed

Idiopathic focal dystonias

- Spasmodic torticollis
- Blepharospasm
- Hemifacial spasm
- Oromandibular dystonia
- Spasmodic dysphonia
- Writer's cramp and other occupational spasms, etc.

fects (more so in children than in adults) with the anticholinergic agents trihexyphenidyl (Artane) and ethopropazine (Parsidol) given in massive doses—which are achieved by increasing the dosage very gradually. The drug-induced tardive dyskinesias require specialized treatment, as described in Chaps. 6 and 42. Reinstitution of the offending drug or anticholinergic agents is often tried. Tetrabenazine, a centrally active monoamine-depleting agent, is effective but not easily available. The acute dystonic drug reactions are treated as noted above.

In the focal dystonias, the most effective treatment has proved to be the periodic injection of botulinum toxin into the affected muscles. Stereotactic surgery on the pallidum and ventrolateral thalamus has given rather unpredictable results, but in recent years there has been a renewed interest in this form of treatment (see page 91).

Paroxysmal Choroathetosis and Dystonia Under the names *paroxysmal kinesigenic dyskinesia*, *familial paroxysmal choroathetosis*, and *periodic dystonia*, among others, there has been described an uncommon sporadic or familial disorder characterized by paroxysmal attacks of choroathetotic movements or dystonic spasms of the limbs and trunk. Both children and young adults are affected.

There are three main forms of familial paroxysmal choroathetosis. One, which has an autosomal dominant (less often recessive) pattern of inheritance and a tendency to affect males, has an onset in adolescence or earlier. It is characterized by numerous brief (less than minutes) attacks of choroathetosis provoked by startle, sudden movement, or hyperventilation—hence the title *paroxysmal kinesigenic choroathetosis*. There may be many dozens of attacks per day or occasional ones. This disorder responds well to anticonvulsant medication, particularly to phenytoin and carbamazepine.

In other families, such as those originally described by Mount and Reback and subsequently by Lance and by Plant et al, the attacks take the form of persistent (5 min to 4 h) dystonic spasms and have reportedly been precipitated by the ingestion of alcohol or coffee or by fatigue but not by movement per se (nonkinesigenic type). The attacks may be predominantly one-sided or bilateral. This form of the disease is inherited as an autosomal dominant trait; a few families have displayed diplopia and spasticity and others have shown a familial tendency to infantile convulsions (each of these types has a different gene locus). Attacks may occur every several days or be separated by years. A favorable response to benzodiazepines (clonazepam) has been reported, even when the drug is given on alternate days (Kurlan and Shoulson).

A third type, formerly thought to be a variant of the Mount-Reback type mentioned above, is precipitated by prolonged exercise and has a separate gene locus. In addition to a response to benzodiazepines, it has the unique characteristic of improving with acetazolamide.

Because of their paroxysmal nature and the response (of the kinesigenic type) to anticonvulsant drugs, these familial disorders had been thought to represent seizures originating in the basal ganglia. Whether the conventional notions of synchronous neuronal activity generating a seizure are even applicable to the basal ganglia seems doubtful to us. Consciousness is not lost and the electroencephalogram is normal, even when recorded during an attack of choroathetosis, arguing against an epileptic discharge in any case.

More common than these familial dyskinesias are sporadic cases and those secondary to focal brain lesions, such as the ones reported by Demirkirian and Jankovic. They classify the paroxys-

mal dyskinesias according to the duration of each attack and the event or activity that precipitates the abnormal movements (kinesigenic, nonkinesigenic, exertional, or hypnagogic). As with the familial cases, the acquired kinesigenically induced movements improve with anticonvulsants; others respond better to clonazepam.

Some cases are an expression of a serious neurologic or metabolic disease, or they may follow injuries such as stroke, trauma, encephalitis, perinatal anoxia, multiple sclerosis, hypoparathyroidism, or thyrotoxicosis. The most severe instances in our experience have been of the kinesigenic variety due to multiple sclerosis and, in a few recent cases, to HIV, as a result of toxoplasmosis, lymphoma, or a presumed encephalitis due to the retrovirus itself. These patients were relatively unresponsive to medications. Also, it should be recalled that oculogyric crises and other nonepileptic spasms have occurred episodically in patients with postencephalitic parkinsonism; these phenomena are now seen with acute and chronic phenothiazine intoxication and with Niemann-Pick disease (type C).

The Identity of Chorea, Athetosis, and Dystonia It must be evident from the foregoing descriptions that the distinctions between chorea and athetosis are probably not fundamental. Even their most prominent differences—the discreteness and rapidity of choreic movements and the slowness and confluence of athetotic ones—may be more apparent than real. As pointed out by Kinnier Wilson, involuntary movements may follow one another in such rapid succession that they become confluent and therefore appear to be slow. In practice, one finds that the patient with relatively slow, confluent movements also shows discrete, rapid ones, and vice versa, and that many patients with chorea and athetosis also exhibit the persistent disorder of movement and posture that is generally designated as dystonia.

In a similar vein, no meaningful distinction except one of degree can be made between choroathetosis and ballismus. Particularly forceful movements of large amplitude (ballismus) are observed in certain patients with Sydenham and Huntington chorea who, according to traditional teaching, exemplify pure forms of chorea and athetosis, respectively. The close relationship between these involuntary movements is illustrated by the patient with hemiballismus who, at the onset of the illness, exhibits wild flinging movements of the arm and, after a period of partial recovery, shows only choroathetotic flexion-extension movements that are limited to the fingers and hand. For this reason, the terms *hemiballismus* and *hemichorea* have sometimes been used interchangeably.

It should be pointed out that all disorders of movement due to lesions of the extrapyramidal system have certain other attributes in common. The abnormalities of movement are superimposed on relatively intact praxic and voluntary movements, implying integrity of the cerebral control of the corticospinal systems. The persistence of the abnormal movements indicates that they are veritable release phenomena; they are abolished by sleep and enhanced by anxiety and excitement; they are caused by a variety of diseases, some of which evoke one type of movement disorder more than another; and they can be altered by certain pharmacologic agents and by stereotactic lesions in certain parts of the motor systems. To the clinician, the most difficult examples are those in which all types of involuntary movement and tremors are combined—a gestalt of dyskinesias.

Finally, while lesions in these parts of the cerebrum are most certainly manifest as disorders of movement, it would be incorrect to assume that other parts of the brain are not as involved; regions

that project to and from the basal ganglia and pass through it on their way to cortical and limbic areas certainly play a role in the creation of abnormal movements. In other words, strict localization of basal ganglionic function is not likely to stand up to critical analysis. Furthermore, a role for the basal ganglia in cognitive function and abnormal behavior is hinted at provocatively in Parkinson disease, progressive supranuclear palsy, Tourette syndrome, and other processes, as summarized by Ring and Serra-Mestres. A certain slowness in thinking has been alluded to earlier, but it is quite

inconsistent. Again, it would be an oversimplification to assign primary importance to the presence of depression, dementia, psychosis, and other disturbances in disease of the basal ganglia or to view changes in these structures as proximate causes of obsessive-compulsive and other behavioral disorders, but some role as part of a larger circuitry is likely. All that can be stated is that such a role is likely in complex behavior, but its precise nature is not known at this time.

CHAPTER 5

INCOORDINATION AND OTHER DISORDERS OF CEREBELLAR FUNCTION

The cerebellum, principally a motor organ, is responsible for the *coordination of movements, especially skilled voluntary ones; the control of posture and gait, and the regulation of muscular tone.* The mechanisms by which these functions are accomplished have been the subject of intense investigation by anatomists and physiologists. Their studies have yielded a mass of data, testimony to the complexity of the organization of the cerebellum and its afferent and efferent connections. A coherent picture of cerebellar function is now emerging, although it is not yet possible, with a few notable exceptions, to relate each of the symptoms of cerebellar disease to a derangement of a discrete anatomic or functional unit of the cerebellum.

Knowledge of cerebellar function has been derived mainly from the study of natural and experimental ablative lesions and to a lesser extent from stimulation of the cerebellum, which produces little in the way of movement or alterations of induced movement. Notably, none of the motor activities of the cerebellum reach conscious kinesthetic perception; its main role is to assist in the initiation and modulation of willed movements that are generated in the cerebral hemispheres. The following outline of cerebellar structure and function has of necessity been simplified; a full account can be found in the writings of Jansen and Brodal, Gilman, and Thach and colleagues, listed at the end of this chapter.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The classic studies of the comparative anatomy and fiber connections of the cerebellum have led to its subdivision into three parts (Fig. 5-1): (1) The *flocculonodular lobe*, located inferiorly, which is phylogenetically the oldest portion of the cerebellum and is much the same in all animals (hence *archicerebellum*). It is separated from the main mass of the cerebellum, or *corpus cerebelli*, by the posterolateral fissure. (2) The *anterior lobe*, or *paleocerebellum*, which is the portion of the *corpus cerebelli* rostral to the primary fissure. In lower animals, the anterior lobe constitutes most of the cerebellum, but in humans it is relatively small, consisting of the anterosuperior vermis and the contiguous paravermian cortex. (3) The *posterior lobe*, or *neocerebellum*, consisting of the middle divisions of the vermis and their large lateral extensions. The major portions of the human cerebellar hemispheres fall into this, the largest, subdivision.

This anatomic subdivision corresponds roughly with the distribution of cerebellar function, based on the arrangement of its af-

ferent fiber connections. The *flocculonodular lobe* receives special proprioceptive impulses from the vestibular nuclei and is therefore also referred to as the *vestibulocerebellum*; it is concerned essentially with equilibrium. The anterior vermis and part of the posterior vermis are referred to as the *spinocerebellum*, since projections to these parts derive to a large extent from the proprioceptors of muscles and tendons in the limbs and are conveyed to the cerebellum in the *dorsal spinocerebellar tract* (from the lower limbs) and the *ventral spinocerebellar tract* (upper limbs). The main influence of the spinocerebellum appears to be on posture and muscle tone. The neocerebellum derives its afferent fibers indirectly from the cerebral cortex via the pontine nuclei and brachium pontis, hence the designation *pontocerebellum*; this portion of the cerebellum is concerned primarily with the coordination of skilled movements that are initiated at a cerebral cortical level. These divisions are necessarily incomplete, because it is now appreciated that certain portions of the cerebellar hemispheres are also involved to some extent in tactual, visual, auditory, and even visceral functions.

On the basis of ablation experiments in animals, three characteristic clinical syndromes corresponding to these major divisions of the cerebellum have been delineated. Lesions of the nodulus and flocculus have been associated with a disturbance of equilibrium and frequently with a positional nystagmus; individual movements of the limbs are not affected. Anterior lobe ablation in primates results in increased shortening and lengthening reactions, somewhat increased tendon reflexes, and an exaggeration of the postural reflexes, particularly the “positive supporting reflex,” which consists of an extension of the limb in response to light

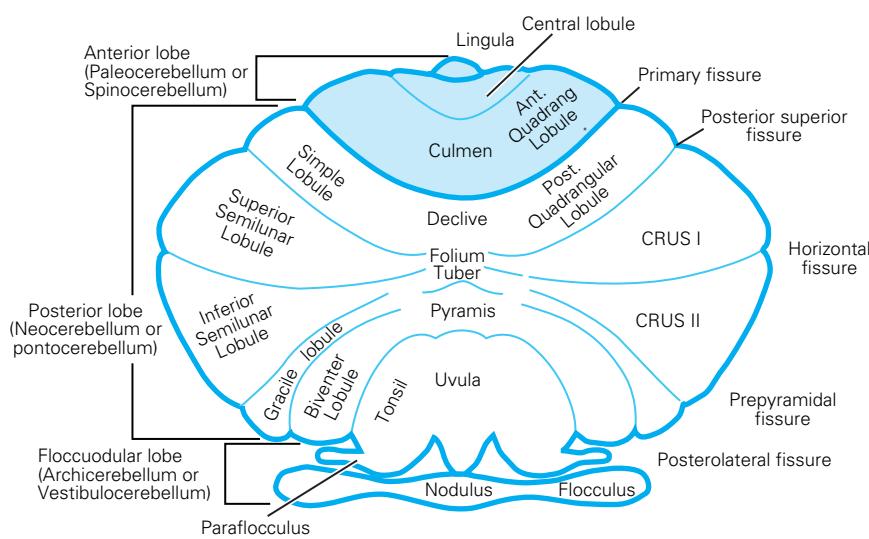

Figure 5-1. Diagram of the cerebellum, illustrating the major fissures, lobes, and lobules and the major phylogenetic divisions (left).

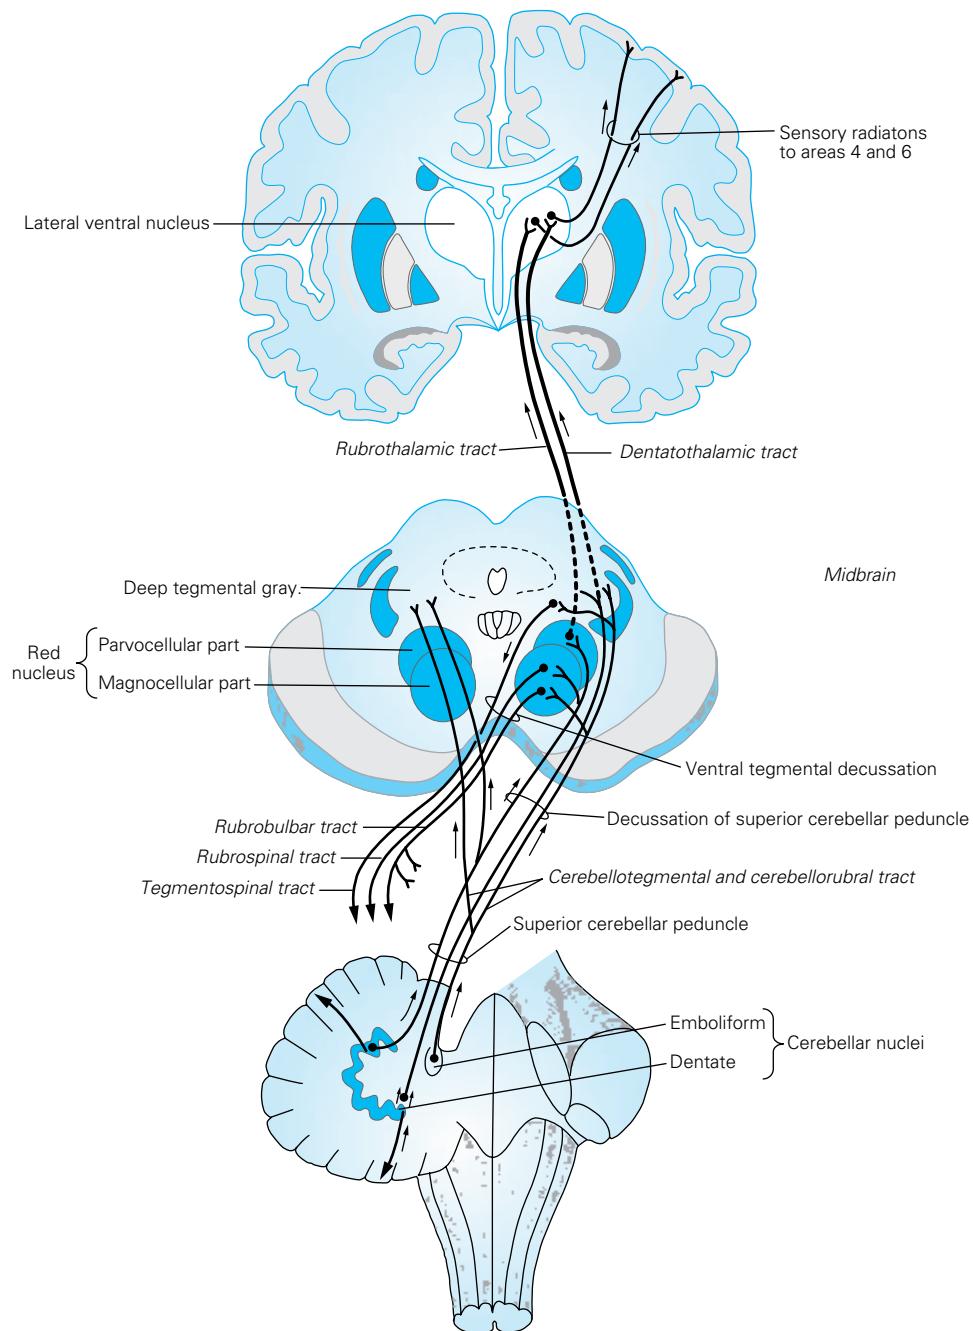

Figure 5-2. Cerebellar projections to the red nucleus, thalamus, and cerebral cortex. (Adapted by permission from House EL et al: *A Systematic Approach to Neuroscience*, 3rd ed. New York, McGraw-Hill, 1979.)

pressure on the foot pad. Ablation of a cerebellar hemisphere in cats and dogs yields inconsistent results, but in monkeys it causes hypotonia and clumsiness of the ipsilateral limbs; if the dentate nucleus is included in the hemispheric ablation, these abnormalities are more enduring and the limbs also show an ataxic or “intention” tremor.

As one might expect, cerebellar function and structure are hardly as simple or precise as the preceding outline suggests. The seminal studies of Chambers and Sprague and of Jansen and Brodal indicate that in respect to both its afferent and efferent projections, the cerebellum is organized into longitudinal (sagittal) rather than

transverse zones. There are three longitudinal zones—the vermic, paravermian or intermediate, and lateral—and there seems to be considerable overlapping from one to another. Chambers and Sprague, on the basis of their investigations in cats, concluded that the vermic zone coordinates movements of the eyes and body with respect to gravity and movement of the head in space. The intermediate zone, which receives both peripheral and central projections (from motor cortex), influences postural tone and also individual movements of the ipsilateral limbs. The lateral zone is concerned mainly with co-ordination of movements of the ipsilateral limbs but is involved in other functions as well.

The efferent fibers of the cerebellar cortex, which consist essentially of the axons of Purkinje cells, project onto the deep cerebellar nuclei (see below). The projections from Purkinje cells are inhibitory; those from the nuclei are excitatory. According to the scheme of Jansen and Brodal, cells of the vermis project mainly to the fastigial nucleus; those of the intermediate zone, to the globule and emboliform nuclei (represented by the interpositus nucleus in animals); and those of the lateral zone, to the dentate nucleus. The deep cerebellar nuclei, in turn, project to the cerebral cortex and certain brainstem nuclei via two main pathways: fibers from the dentate, emboliform, and globose nuclei form the superior cerebellar peduncle, enter the upper pontine tegmentum as the brachium conjunctivum, decussate the level of the inferior colliculus, and ascend to the ventrolateral nucleus of the thalamus and, to a lesser extent, to the intralaminar thalamic nuclei (Fig. 5-2). Some of

the ascending fibers, soon after their decussation, synapse in the red nucleus, but most of them traverse this nucleus without terminating. Ventral thalamic nuclear groups that receive these ascending efferent fibers project to the supplementary motor cortex of that side. Since the pathway from the cerebellar nuclei to the thalamus and then on to the motor cortex is crossed and the connection from the motor cortex through the corticospinal is again crossed, *the effects of a lesion in one cerebellar hemisphere are manifest by signs on the ipsilateral side of the body*.

One pathway forms a loop, called the Mollaret triangle, that is of clinical interest (see also page 85). A small group of fibers

of the superior cerebellar peduncle, following their decussation, descend in the ventromedial tegmentum of the brainstem via the central tegmental fasciculus and terminate in the reticulotegmental and paramedian reticular nuclei of the pons and inferior olivary nuclei of the medulla. These nuclei, in turn, project via the inferior cerebellar peduncle to the cerebellum, mainly the anterior lobe, thus completing a cerebellar-reticular-cerebellar feedback system (Fig. 5-3).

The fastigial nucleus sends fibers to the vestibular nuclei of both sides and, to a lesser extent, to other nuclei of the reticular formation of the pons and medulla. There are also direct fiber connections with the alpha and gamma motor neurons of the spinal cord. The inferior olivary nuclei project via the restiform body (inferior cerebellar peduncle) to the contralateral cerebellar cortex and corresponding parts of the deep cerebellar nuclei. Thus the cerebellum influences motor activity through its connections with the motor cortex and brainstem nuclei and their descending motor pathways. The integration at the thalamic level of basal ganglionic influences with those of the cerebellum is detailed in Chap. 4.

Clinicopathologic observations indicate that the cerebellar cortex, and the anterior lobe in particular, is organized somatotopically. This view has been amply confirmed experimentally by the mapping of evoked potentials from the cerebellar cortex, elicited by a variety of sensory stimuli, and an analysis of the motor effects produced by stimulation of specific parts of the cerebellar cortex. The topographic sensory representation of body parts based on these experimental observations is assumed to be similar to the motor map but is probably not as distinct. The similarity between this scheme and the one derived from the study of human disease becomes apparent when one considers the results of cerebellar lesions discussed further on. Diffuse degenerations of the cerebellum, of course, have widespread effects, including motor, articulatory, gait and eye movements.

Role of the Deep Cerebellar Nuclei The physiologic studies of Allen and Tsukahara and those of Thach and colleagues have greatly increased our knowledge of the role of the deep cerebellar nuclei. These investigators studied the effects of cooling the deep nuclei during a projected movement in the awake macaque monkey. Their observations, coupled with established anatomic data, permit the following conclusions. The *dentate nucleus* receives information from the premotor and supplementary motor cortices via the pontocerebellar system and helps to initiate volitional movements. The latter are accomplished via efferent projections from

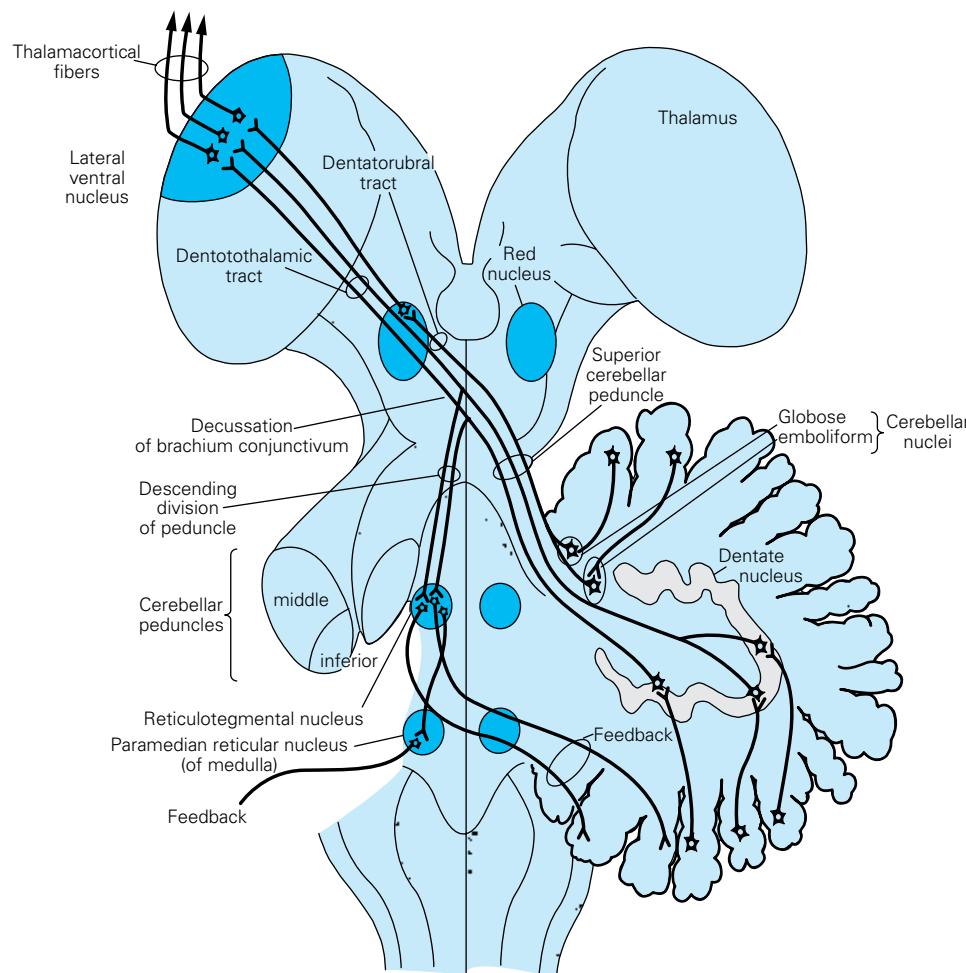

Figure 5-3. Dentatothalamic and dentatorubrothalamic projections via the superior cerebellar peduncle. The “feedback” circuit via the reticular nuclei and reticulocerebellar fibers is also shown (Mollaret triangle).

the dentate nucleus to the ventrolateral thalamus and motor cortex. The dentatal neurons were shown to fire just before the onset of volitional movements, and inactivation of the dentatal neurons delayed the initiation of such movements. The *interpositus nucleus* also receives cerebrocortical projections via the pontocerebellar system; in addition, it receives spinocerebellar projections via the intermediate zone of the cerebellar cortex. The latter projections convey information from Golgi tendon organs, muscle spindles, cutaneous afferents, and spinal cord interneurons involved in movement. The interpositus nucleus fires in relation to a movement once it has started. Also, the *prepositus nucleus* appears to be responsible for making volitional oscillations (alternating movements). Its cells fire in tandem with these actions, and their regularity and amplitude are impaired when these cells are inactivated. In addition, Thach has pointed out that the nucleus interpositus normally damps physiologic tremor; he has suggested that this may play a part in the genesis of so-called intention tremor described further on. The *fastigial nucleus* controls antigravity and other muscle synergies in standing and walking; ablation of this nucleus greatly impairs these motor activities.

Neuronal Organization of the Cerebellar Cortex Coordinated and fluid movements result from a neuronal organization in the cerebellum, which permits a computational comparison between

desired and actual movements while the latter are being carried out. An enormous number of neurons are committed to these tasks, as attested by the fact that the cerebellum contributes only 10 percent to the total weight and volume of the brain but contains half of the brain's neurons. Also, it has been estimated that there are forty times more afferent axons than efferent axons in the various cerebellar pathways—a reflection of the enormous amount of information that is required for the control of motor function.

The cerebellar cortex is configured as a stereotyped three-layered structure containing five types of neurons (Fig. 5-4). In its relatively regular geometry, it is similar to the columnar architecture of the cerebral cortex (pages 388–389), but it differs in

the greater degree of intracortical feedback between neurons and the convergent nature of input fibers. The outermost “molecular” layer of the cerebellum contains two types of inhibitory neurons, the *stellate cells* and the *basket cells*. They are interspersed among the dendrites of the *Purkinje cells*, the cell bodies of which lie in the underlying layer. The Purkinje cell axons constitute the main output of the cerebellum, which is directed at the deep cerebellar and vestibular nuclei described above. Purkinje cells are likewise entirely inhibitory and utilize the neurotransmitter gamma-aminobutyric acid (GABA). The innermost “granular” layer contains an enormous number of densely packed *granule cells* and a few larger *Golgi interneurons*. Axons of the granule cells travel long distances

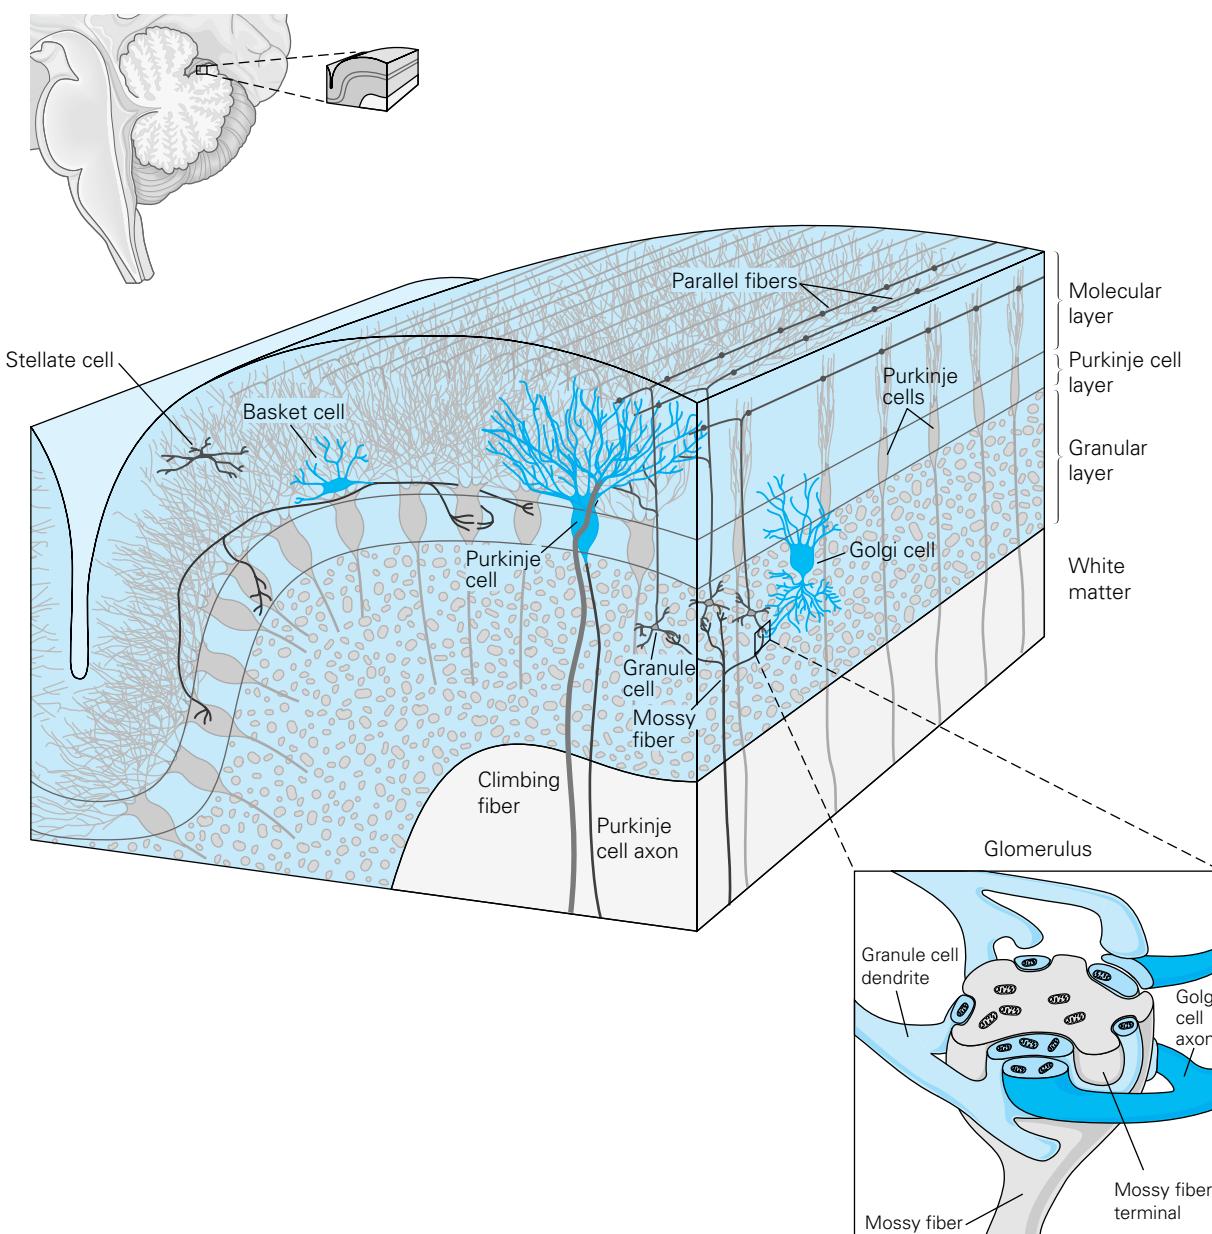

Figure 5-4. Anatomic organization of the cerebellar cortex in a longitudinal and transverse section of a folium.

Shown are the relationships between (a) climbing fibers and Purkinje cells, (b) mossy fibers and both granule cells and Golgi cells, and (c) the parallel fibers that course longitudinally and connect these three main cell types. (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM: *Principles of Neural Science*, 4th ed. New York: McGraw-Hill, 2000.)

as “parallel fibers,” which are oriented along the long axis of the folia and form excitatory synapses with Purkinje cells. Each Purkinje cell is influenced by as many as a million granule cells to produce a single electrical “simple spike.”

The predominant afferent input to the cerebellum is via the *mossy fibers*, which are the axons of the spinocerebellar tracts and the projections from pontine, vestibular and reticular nuclei. They enter through all three cerebellar peduncles, mainly the middle (pontine input) and inferior (vestibulocerebellar) ones. Mossy fibers ramify in the granule layer and excite Golgi and granule neurons through special synapses termed *cerebellar glomeruli*. The other main afferent input is via the *climbing fibers*, which originate in the inferior olives and communicate somatosensory, visual, and cerebral cortical signals (Figs. 5-4 and 5-5). The climbing fibers, so named because of their vine-like configuration around Purkinje cells and their axons, preserve a topographic arrangement from olivary neuronal groups; a similar topographic arrangement is maintained in the Purkinje cell projections. The climbing fibers have specific excitatory effects on Purkinje cells that result in prolonged “complex spike” depolarizations. The firing of stellate and basket cells is facilitated by the same parallel fibers that excite Purkinje cells, and these smaller cells, in turn, inhibit the Purkinje cells. These reciprocal relationships form the feedback loops that permit the exquisitely delicate inhibitory smoothing of limb movements that are lost when the organ is damaged.

The uniform cortical structure of the cerebellum leads the authors to conjecture that the organ has similar effects on all parts of the cerebrum to which it has projections (cortex, basal ganglia, thalamus, etc.). It would follow that the activities of these cerebral structures (motor, cognitive, sensory) would be modulated in a similar way, but this fundamental property of the cerebellum has proved elusive.

Pharmacologic Considerations A number of pharmacologic and biochemical considerations are of interest. Four of the five cell types of the cerebellar cortex (Purkinje, stellate, basket, Golgi) are inhibitory; the granule cells are an exception and are excitatory. Afferent fibers to the cerebellum are of three types, two of which have been mentioned above: (1) *Mossy fibers*, which are the main afferent input to the cerebellum, utilize aspartate. (2) *Climbing fibers*, which are the axons of cells in the inferior olivary nucleus and project to the Purkinje cells of the opposite cerebellar hemisphere. The neurotransmitter of the climbing fibers is unknown. (3) *Aminergic fibers*, which project through the superior cerebellar peduncle and terminate on the Purkinje and granule cells in all parts of the cerebellar cortex. They are of two types: *dopaminergic fibers*, which arise in the ventral mesencephalic tegmentum and project to the interpositus and dentate nuclei and to the granule and Purkinje cells throughout the cortex, and *serotonergic neurons*, which are located in the raphe nuclei of the brainstem and project diffusely to the granule cell and molecular layer. The granule cell axons elaborate the excitatory transmitter glutamate. All the inhibitory cerebellar cortical neurons appear to utilize GABA. The neurotransmitters of the deep nuclei have not been fully elucidated.

CLINICAL FEATURES OF CEREBELLAR DISEASE

The disturbances of movement and posture that result from lesions of the human cerebellum were first cogently analyzed by two eminent neurologists, Joseph Babinski and Gordon Holmes. For Ba-

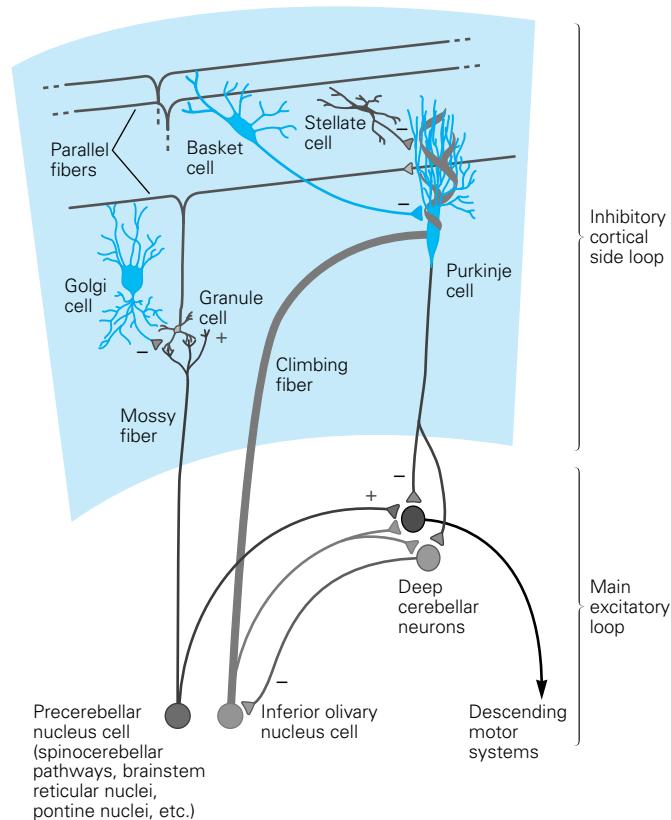

Figure 5-5. The physiologic organization of cerebellar circuitry. The main output of the deep cerebellar nuclei is excitatory and is transmitted through mossy and climbing fibers. This “main loop” is modulated by an inhibitory cortical loop, which is effected by Purkinje cell output but indirectly includes the other main cell types through their connections with Purkinje cells. Recurrent pathways between the deep nuclei and cortical cells via mossy and climbing fibers complete the cerebellar servomechanism for motor control. (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM: *Principles of Neural Science*, 4th ed. New York: McGraw-Hill, 2000.)

binski, the essential function of the cerebellum was the orchestration of muscle synergies in the performance of voluntary movement. A loss or impairment of this function—i.e., *asynergia* or *dyssynergia*—resulted in irregularity or fragmentation of the normal motor sequences involved in any given act. This deficit, most apparent in the execution of rapidly alternating movements, was referred to by Babinski as *dys-* or *adiadochokinesis*, as discussed below in the description of incoordination. He also pointed out that this was accompanied by certain maladjustments of stance and by catalepsy (perseveration of a posture), features that are not as widely appreciated by modern observations.

The abnormalities observed by Holmes were characterized as being in the acceleration and deceleration of movement. He summarized them as defects in the *rate, range, and force* of movement, resulting in an undershooting or overshooting of the target. He used the term *decomposition of movements* to describe the fragmentation of a smooth movement into a series of irregular, jerky components. In Holmes’s view, probably incorrectly, these abnormalities were attributable to an underlying hypotonia. The terminal (“intention”) tremor, for example, and the inability to check the displacement of an outstretched limb were attributed to this latter defect (see further on).

Parts of the hypotheses of both Babinski and Holmes have been sustained by modern physiologic studies. In their analysis of rapid (ballistic) movements, Hallett and colleagues have demonstrated that with cerebellar lesions, there is a prolongation of the interval between the commanded act and the onset of movement. More prominently, there is a derangement of the triphasic agonist-antagonist-agonist motor sequence, referred to in Chaps. 3 and 4; the agonist burst may be too long or too short, or it may continue into the antagonist burst, resulting in excessive agonist-antagonist cocontraction at the onset of movement. These findings explain what has variously been described as asynergia, decomposition of movement, and dysmetria. Diener and Dichgans confirmed these fundamental abnormalities in the timing and amplitude of reciprocal inhibition and of cocontraction of agonist-antagonist muscles and remarked that these were particularly evident in pluriarticular movements.

The symptoms produced in animals by ablation of discrete anatomic or functional zones of the cerebellum bear only an imperfect relationship to the symptoms of cerebellar disease in humans. This is understandable for several reasons. Most of the lesions that occur in humans do not respect the boundaries established by experimental anatomists. Even with lesions that are more or less confined to discrete functional zones (e.g., flocculonodular lobe, anterior lobe), it is difficult to identify the resultant clinical syndromes with those produced by ablation of analogous zones in cats, dogs, and even monkeys, indicating that the functional organization of these parts varies from species to species.

Our own observations affirm what was stated above—that lesions of the cerebellum in humans give rise to the following abnormalities: (1) incoordination (ataxia) of volitional movement; (2) a characteristic tremor (“intention” or ataxic tremor), described in detail in Chap. 6; (3) disorders of equilibrium and gait; and (4) diminished muscle tone, particularly with acute lesions. Dysarthria, a common feature of cerebellar disease, is probably predicated on a similar incoordination of the muscles of articulation. In addition, the stability of eye movements is affected, giving rise to nystagmus.

Extensive lesions of one cerebellar hemisphere, especially of the anterior lobe, cause hypotonia, postural abnormalities, ataxia, and sometimes mild weakness of the ipsilateral arm and leg. Lesions of the deep nuclei and cerebellar peduncles have the same effects as extensive hemispherical lesions. If the lesion involves a limited portion of the cerebellar cortex and subcortical white matter, there may be surprisingly little disturbance of function, or the abnormality may be greatly attenuated with the passage of time. For example, a congenital developmental defect or an early-life sclerotic cortical atrophy of half of the cerebellum may produce no clinical abnormalities. Lesions involving the superior cerebellar peduncle or the dentate nucleus cause the most severe and enduring cerebellar symptoms, manifest mostly as ataxia in the ipsilateral limbs. Disorders of stance and gait depend more on vermicular than on hemispherical or peduncular involvement. Damage in the inferior cerebellum causes vestibulocerebellar symptoms—namely, dizziness, vertigo, vomiting, and nystagmus, in varying proportions. These symptoms often share with disturbances of the vestibular system the feature of worsening with changes in head position.

Incoordination The most prominent manifestations of cerebellar disease, namely, the abnormalities of intended (volitional) movement, are classified under the general heading of *cerebellar incoordination* or *ataxia*. Following Babinski, the terms *dyssynergia*, *dysmetria*, and *dysdiadochokinesis* came into common usage to

describe cerebellar abnormalities of movement. Holmes’s characterization of abnormalities in the *rate*, *range*, and *force* of movement is less confusing, as becomes apparent from an analysis of even simple movements. These abnormalities are brought out by finger-to-nose or toe-to-finger movement, running the heel down the opposite shin, or tracing a square in the air with a hand or foot. In performing these tests, the patient should be asked to move the limb to the target accurately and rapidly.

The *speed of initiating movement* is slowed somewhat in cerebellar disease. In a detailed electrophysiologic analysis of this defect, Hallett and colleagues noted, in both slow and fast movements, that the initial agonist burst was prolonged and the peak force of the agonist contraction was reduced. Also, there is irregularity and slowing of the movement itself, in both acceleration and deceleration. These abnormalities are particularly prominent as the finger or toe approaches its target.

Normally, deceleration of movement is smooth and accurate, even if sharp changes in the direction of a limb are demanded, as in following a moving target. With cerebellar disease, the velocity and force of the movement are not checked in the normal manner. The excursion of the limb may be arrested prematurely, and the target is then reached by a series of jerky movements. Or the limb overshoots the mark (*hypermetria*), due to delayed activation and diminished contraction of antagonist muscles; then the error is corrected by a series of secondary movements in which the finger or toe sways around the target before coming to rest, or moves from side to side a few times on the target itself. This side-to-side movement of the finger as it approaches its mark tends to assume a rhythmic quality; it has traditionally been referred to as *intention tremor*, or *ataxic tremor*, but in reality reflects defective fixation at the shoulder (see Chap. 6). Gilman and colleagues have provided evidence that more than hypotonia is involved in the tremor of cerebellar incoordination. They found that deafferentation of the forelimb of a monkey resulted in dysmetria and kinetic tremor; subsequent cerebellar ablation significantly increased both the dysmetria and tremor, indicating the presence of a mechanism as yet unidentified in addition to depression of the fusimotor efferent-spindle afferent circuit.

All of the foregoing defects in volitional movement are evident in acts that require alternation or rapid change in direction of movement, such as pronation-supination of the forearm or successive touching of each fingertip to the thumb. The normal rhythm of these movements is interrupted by irregularities of force and speed. This is the abnormality that Babinski called *adiadochokinesis*. Even a simple movement may be fragmented (“decomposition” of movement), each component being effected with greater or lesser force than is required. These movement abnormalities together impart a highly characteristic clumsiness to the cerebellar syndromes, an appearance that is not simulated by the weakness of upper or lower motor neuron disorders or by diseases of the basal ganglia.

In addition to intention tremor, there may be a coarse, irregular, wide-range tremor that appears whenever the patient activates limb muscles, either to sustain a posture or to effect a movement. It is elicited by having the patient hold the arms out to the sides with elbows bent (*wing-beating tremor*). Holmes called it *rubral tremor*, and although the lower part of the red nucleus may be the site of the lesion, the nucleus itself is not involved in this type of tremor. Instead, the tremor is due to interruption of the fibers of the superior cerebellar peduncle, which traverse the nucleus. Also, with certain sustained postures (e.g., with arms extended and hands

on knees), the patient with cerebellar disease may develop a rhythmic oscillation of the fingers having much the same tempo as a parkinsonian tremor. A rhythmic tremor of the head or upper trunk (three to four per second) called *titubation*, mainly in the antero-posterior plane, often accompanies midline cerebellar disease.

Cerebellar lesions commonly give rise to a disorder of speech, which may take one of two forms, either a slow, *slurring dysarthria*, like that following interruption of the corticobulbar tracts, or a *scanning dysarthria* with variable intonation, so called because words are broken up into syllables, as when a line of poetry is scanned for meter. The latter disorder is uniquely cerebellar; in addition to its scanning quality, speech is slow, and each syllable, after an involuntary interruption, may be uttered with less force or more force ("explosive speech") than is natural. Urban and associates have deduced from cases of cerebellar infarction that the articulatory muscles are controlled from the rostral paravermian area of the anterior lobe, and this area is affected in most cases with dysarthria.

Ocular movement may be altered as a result of cerebellar disease, specifically if vestibular connections are involved. Patients with cerebellar lesions are unable to hold eccentric positions of gaze, resulting in a special type of nystagmus and the need to make rapid repetitive saccades to look eccentrically. Conjugate voluntary gaze can be accomplished only by a series of jerky movements. Smooth pursuit movements are slower than normal and require that the patient make small "catch-up" saccades in an attempt to keep the moving target near the fovea. On attempted refixation to a target, the eyes overshoot the target and then oscillate through several corrective cycles until precise fixation is attained. It will be recognized that these nystagmoid abnormalities, as well as those of speech, resemble the abnormalities of volitional movements of the limbs. Currently it is believed that nystagmus due to cerebellar disease depends on lesions of the vestibulocerebellum (Thach and Montgomery). Skew deviation (vertical displacement of one eye), ocular flutter, and ocular myoclonus (opsoclonus) may also be to the result of cerebellar disease; these abnormalities and other effects of cerebellar lesions on ocular movement are discussed in Chap. 14.

Disorders of Equilibrium and Gait The patient with cerebellar disease has variable degrees of difficulty in standing and walking, as described more fully in Chap. 7. Standing with feet together may be impossible or maintained only briefly before the patient pitches to one side or backward. Closing the eyes worsens this difficulty slightly, though the Romberg sign (which signifies impaired proprioceptive input) is absent. In walking, the patient's steps are uneven and placement of the foot is misaligned, resulting in unexpected lurching.

Data from patients in whom accurate clinicoanatomic correlations can be made indicate that the disequilibrium syndrome, with normal movements of the limbs, corresponds more closely with lesions of the anterior vermis than with those of the flocculus and nodulus, as had been previously thought. This conclusion is based on the study of a highly stereotyped form of cerebellar degeneration in alcoholics (Chap. 42). In such patients the cerebellar disturbance is often limited to one of stance and gait, in which case the pathologic changes are restricted to the anterior parts of the superior vermis. In more severely affected patients, in whom there is also incoordination of individual movements of the limbs, the changes are found to extend laterally from the vermis, involving the anterior portions of the anterior lobes (in patients with ataxia of the legs)

and the more posterior portions of the anterior lobes (in patients whose arms are affected). In other diseases, involvement of the posterior vermis and its connections with the pontine and mesencephalic reticular formations have caused abnormalities of ocular movement (see Chap. 14). Similar clinicopathologic relationships pertain in patients with familial forms of pure cerebellar cortical degeneration (page 931). In both the alcoholic and familial degenerative cases, despite a serious disturbance of stance and gait, the flocculonodular lobe may be spared completely.

Thus the evidence that flocculonodular lesions in humans cause a disturbance of equilibrium is not conclusive. It rests on the observation that with certain tumors of childhood, namely, medulloblastomas, there may be an unsteadiness of stance and gait but no tremor or incoordination of the limbs. Insofar as these tumors are thought to originate from cell rests in the posterior medullary velum, at the base of the nodulus, it has been inferred that the disturbance of equilibrium results from involvement of this portion of the cerebellum. However, the validity of this deduction remains to be proved. By the time such tumors are inspected at operation or autopsy, they have spread beyond the confines of the nodulus, and strict clinicopathologic correlations are not possible.

Hypotonia This refers to a decrease in the normal resistance that is offered by muscles to passive manipulation (e.g., flexion and extension of a limb); it is the least evident of the cerebellar abnormalities but may explain certain clinical features not otherwise derived from the above deficits. It is related to a depression of gamma and alpha motor neuron activity, as discussed in Chap. 3. Experimentally, in cats and monkeys, acute cerebellar lesions and hypotonia are associated with a depression of fusimotor efferent and spindle afferent activity. With the passage of time, fusimotor activity is restored as hypotonia disappears (Gilman et al). As indicated earlier, Holmes believed, probably incorrectly, that hypotonia was a fundamental defect in cerebellar disease, accounting not only for the defects in postural fixation (see below) but also for certain elements of ataxia and so-called intention tremor.

Hypotonia is much more apparent with acute than with chronic lesions and may be demonstrated in a number of ways. There may be mild flabbiness of the muscles on the affected side. Segments of the limbs may be displaced by the examiner through a wider range than normal. With recent, severe cerebellar lesions, there may be gross asymmetries of posture, so that the shoulder slumps or the body tilts to the ipsilateral side. A conventional test for hypotonia is to tap the wrists of the outstretched arms, in which case the affected limb (or both limbs in diffuse cerebellar disease) will be displaced through a wider range than normal and may oscillate; this is due to a failure of the hypotonic muscles to fixate the arm at the shoulder. When an affected limb is shaken, the flapping movements of the hand are of wider excursion than normal. If the patient places his elbows on the table with the arms flexed and the hands are allowed to hang limply, the hand of the hypotonic limb will sag more than that of the normal one. Forced flexion of a hypotonic arm at the elbow may obliterate the space between the volar aspect of the wrist and the deltoid. Babinski also was impressed with gross alterations of posture, apparently related to hypotonia. These alterations take the form of a passive extension of the neck and an involuntary bending of the knees, apparent when the patient is lifted from a bed or chair or upon first standing.

Failure to check a movement is a closely related phenomenon. Thus, after strongly flexing one arm against a resistance that is suddenly released, the patient may be unable to check the flexion

movement, to the point where the arm may strike the face. This is due to a delay in contraction of the triceps muscle, which ordinarily would arrest overflexion of the arm. This abnormality, incorrectly referred to as *Holmes's rebound phenomenon*, is more appropriately designated as an *impairment of the check reflex*. Stewart and Holmes, who first described this test, made the point that when resistance to flexion is suddenly removed, the normal limb moves only a short distance in flexion and then recoils or rebounds in the opposite direction. In this sense, rebound of the limb is actually deficient in cerebellar disease but is exaggerated in spastic states.

Patients with these various abnormalities of tone may show little or no impairment of motor power, indicating that the maintenance of posture involves more than the voluntary contraction of muscles. It is noteworthy that most of the additional signs of cerebellar hypotonia are absent in the flaccid muscles of peripheral nerve disease—indicating that the cerebellum exerts a unique modulating effect at spinal segmental levels.

Other Symptoms of Cerebellar Disease A slight loss of muscular power and excessive fatigability of muscle may occur with acute cerebellar lesions. Also, in unilateral cerebellar disease, the ipsilateral arm may not swing normally in walking. Insofar as these symptoms cannot be explained by other disturbances of motor function, they may be regarded as primary manifestations of cerebellar disease, but they are never severe or persistent and are of little clinical importance; anything approaching a hemiparesis in distribution or severity should not be attributed to cerebellar disease.

Myoclonic movements—i.e., brief (50- to 100-ms), random contractions of muscles or groups of muscles—are, in some disease processes, combined with cerebellar ataxia. When multiple jerks mar a volitional movement, they may be mistaken for an ataxic tremor. (The same error may be caused by asterixis.) Ramsey Hunt described myoclonus in connection with a rare heredodegenerative disease (see page 937), but it has also been observed in neuronal storage diseases of various kinds. *Action myoclonus* may be the principal residual sign of hypoxic encephalopathy, as described on page 89, and it has been proposed that these conditions have a cerebellar origin. Myoclonus is described more fully in Chap. 6.

More abstruse than the role of the cerebellum in motor control is the proposed participation of this structure in all manner of cognitive function and behavior (see the reviews by Leiner et al and by Schmahmann and Sherman). These authors and others have described a wide range of deficits of memory and cognition, language function, and behavior in patients with disease apparently limited to the cerebellum (as determined by computed tomography and magnetic resonance imaging). It is true that cerebellar lesions interfere with the establishment of conditioned reflexes and perhaps some deterioration in certain learning tasks as detected by specialized tests. To date, however, a uniform clinical pathologic syndrome in which a distinctive cognitive-behavioral deficit or group of deficits is related to a particular cerebellar lesion has not emerged, and the mechanisms by which discrete cerebellar lesions might influence cognitive function remain uncertain.

Differential Diagnosis of Ataxia

In the diagnosis of disorders characterized by *generalized cerebellar ataxia* (affecting limbs, gait, and speech), the mode of onset

(rate of development) and degree of permanence of the ataxia are of particular importance, as summarized in Table 5-1. Each of the major causes is discussed in an appropriate chapter. In adults, paraneoplastic and demyelinating cases account for the largest proportion of cases of subacute onset, and hereditary forms are the usual cause of very slowly progressive and chronic ones, particularly if gait alone is affected. The latter now constitute a large and heterogeneous group for which the genetic basis has been established in most cases; they are reviewed extensively in Chap. 39.

Unilateral ataxia without accompanying signs is most often

Table 5-1
Diagnosis of generalized cerebellar ataxia

MODE OF DEVELOPMENT	CAUSES
Acute-transitory	Intoxication with alcohol, lithium, barbiturate, phenytoin or other anticonvulsants (associated with dysarthria, nystagmus, and sometimes confusion; Chaps. 42, 43). Diamox-responsive episodic ataxia (Chap. 37).
Acute and usually reversible	Childhood hyperammonemias (Chap. 37). Postinfectious, with mild inflammatory changes in CSF (Chap. 36).
Acute-enduring	Viral cerebellar encephalitis (Chap. 33). Hyperthermia with coma at onset (Chap. 17).
Subacute (over weeks)	Intoxication with mercury compounds or toluene (glue sniffing; spray painting; Chap. 43). Postanoxic with intention myoclonus Brain tumors such as medulloblastoma, astrocytoma, hemangioblastoma (usually with headache and papilledema; Chap. 31). Alcoholic-nutritional (Chaps. 41 and 42). Paraneoplastic, often with opsoclonus and specific anticerebellar antibodies (particularly with breast and ovarian carcinoma; Chap. 31.) Creutzfeldt–Jakob disease (Chap. 33). Cerebellar abscess (Chap. 32). Whipple disease (often with myoclonus and oculomasticatory movements) Sprue (gluten enteropathy) Multiple sclerosis
Chronic (months to years)	Friedreich ataxia and other spinocerebellar degenerations; other hereditary cerebellar degenerations [olivopontocerebellar degenerations; cerebellar cortical degenerations (Chap. 39)]. Adult form of fragile-X syndrome Hereditary metabolic diseases, often with myoclonus (Chap. 37). Childhood ataxias, including ataxia telangiectasia, cerebellar agenesis, and dyssynergia cerebellaris myoclonica of Ramsay Hunt (Chap. 39).

caused by infarction or tumor in the ipsilateral cerebellar hemisphere or by demyelinating disease affecting cerebellar connections in the brainstem.

The ataxia of severe sensory neuropathy and of posterior column disease of the spinal (“sensory ataxia”) cord may simulate cerebellar ataxia; presumably this is due to involvement of the large peripheral spinocerebellar afferent fibers. However, there should seldom be difficulty in separating the two if one takes note of the loss of distal joint position sense, absence of associated cerebellar signs such as dysarthria or nystagmus, loss of tendon reflexes, and the corrective effects of vision on sensory ataxia. In peripheral neuropathy of this nature and in spinal cord disease, the Romberg sign is invariably present, reflecting a parallel dysfunction of large afferent fibers in the posterior columns; this sign is not found in lesions of the cerebellar hemispheres except that the patient may initially sway with eyes open and a bit more with eyes closed. This type of tremor reaches an extreme form in the large-fiber polyneuropathy related to antibodies against myelin-associated glycoprotein (MAG) but the features are closer to an exaggerated essential tremor, as discussed in the next chapter and in Chap. 46. In the Miller Fisher syndrome, which is considered to be a variant of Guillain-Barré neuropathy, sensation is intact or affected only slightly and the severe ataxia and intention tremor are presumably

due to a highly selective peripheral disorder of spinocerebellar nerve fibers.

Affection of these same fibers in the spinocerebellar tracts of the cord may produce the same effects; subacute compressive lesions such as thoracic meningioma or demyelinating lesions are the usual causes. Again, there is a prominent Romberg sign. Occasionally, a cerebellar-like tremor in one limb results from a lesion in the dorsolateral cord that interrupts afferent fibers, presumably those directed to the spinocerebellar tracts.

Vertiginous ataxia is primarily an ataxia of gait and is distinguished by the obvious complaint of vertigo and listing to one side, past-pointing, and rotary nystagmus (Chap. 15). The *nonvertiginous ataxia* of gait due to vestibular paresis (e.g., streptomycin toxicity) has special qualities described in Chap. 7. Vertigo and cerebellar ataxia may be concurrent, as in some patients with a paraneoplastic disease and in those with infarction of the lateral medulla and inferior cerebellum. An unusual and transient ataxia of the contralateral limbs occurs acutely after infarction or hemorrhage in the anterior thalamus (*thalamic ataxia*); in addition to neighborhood signs, there is often an accompanying unilateral asterix. Also, a lesion of the superior parietal lobule (areas 5 and 7 of Brodmann) may rarely result in a similar ataxia of the contralateral limbs.

CHAPTER 6

TREMOR, MYOCLONUS, FOCAL DYSTONIAS, AND TICS

The subject of tremor is considered at this point because of its association with diseases of the basal ganglia and cerebellum. In addition, a group of miscellaneous movement disorders—myoclonus, facial and cervical dyskinesias, occupational spasms (focal dystonias), and tics—are described in this chapter. These disorders are largely involuntary in nature and can be quite disabling, but they have an uncertain pathologic basis and an indefinite relationship to the extrapyramidal motor disorders or to other standard categories of neurologic disease. They are brought together here mainly for convenience of exposition.

TREMOR

Tremor may be defined as a more or less involuntary and rhythmic oscillatory movement produced by alternating or irregularly synchronous contractions of reciprocally innervated muscles. Its rhythmic quality distinguishes tremor from other involuntary movements, and the involvement of agonist and antagonistic muscles distinguishes it from clonus. Two general categories are recognized: normal (or physiologic) and abnormal (or pathologic). The former, as the name indicates, is a normal phenomenon; it is present in all contracting muscle groups and persists throughout the waking state and even in certain phases of sleep. The movement is so fine that it can barely be seen by the naked eye, and then only if the fingers are firmly outstretched; in most instances special instruments are required for its detection. It ranges in frequency between 8 and 13 Hz, the dominant rate being 10 Hz in adulthood and somewhat less in childhood and old age. Several hypotheses have been proposed to explain physiologic tremor, a traditional one being that it reflects the passive vibration of body tissues produced by mechanical activity of cardiac origin (ballistocardiogram). Assuredly this is not the whole explanation of physiologic tremor. As Marsden has pointed out, several additional factors—such as spindle input, the unfused grouped firing rates of motor neurons, and the natural resonating frequencies and inertia of the muscles and other structures—are probably of greater significance. Certain abnormal tremors, namely, the metabolic varieties of postural or action tremor and at least one type of familial tremor, are considered by some workers to be variants or exaggerations of physiologic tremor—i.e., “enhanced physiologic tremor” (as discussed further on).

Abnormal or pathologic tremor, which is what one means when the term *tremor* is used clinically, preferentially affects certain muscle groups—the distal parts of the limbs (especially the fingers and hands); less often, the proximal parts; the head, tongue, jaw, or vocal cords; and rarely the trunk—and is present only in the waking state. The rate in most forms is from 4 to 7 Hz, or about half that of physiologic tremor. In any one individual, the rate is fairly constant in all affected parts. With the advent of electromyography (EMG) and mechanical recording devices, abnormal tremors were subdivided according to their rate, their relationship to posture of the limbs and volitional movement, their pattern of EMG activity (synchronous or alternating) in opposing muscle groups, and their response to certain drugs.

The following types of tremor, the features of which are summarized in Table 6-1, are the ones encountered most frequently in clinical practice. In clinical analysis, they are usually distinguishable on the basis of (1) rhythmicity, (2) amplitude, (3) frequency, and (4) relation to movement, postural set, and relaxation. Such analysis also differentiates tremors from a large array of non-tremorous states, such as fasciculations, sensory ataxia, myoclonus, asterixis, epilepsy partialis continua, clonus, and shivering.

Postural and Action Tremors

These terms, which are used interchangeably, refer to a tremor that is present when the limbs and trunk are actively maintained in certain positions (such as holding the arms outstretched) and that may persist throughout active movement. More particularly, the tremor is absent when the limbs are relaxed but becomes evident when the muscles are activated. It is accentuated as greater precision of movement is demanded, but it does not approach the degree of augmentation seen with so-called intention tremor, which is associated with cerebellar disease. In contrast to rest or static (parkinsonian) tremor, which is characterized electromyographically by alternating activity in agonist and antagonist muscles, most cases of action tremor are characterized by relatively rhythmic bursts of grouped motor neuron discharges that occur not quite synchronously and simultaneously in opposing muscle groups. Slight inequalities in the strength and timing of contraction of opposing muscle groups account for the tremor.

Action tremors are of several different types, a feature that makes them more difficult to interpret than other tremors.

Enhanced Physiologic Tremor One type of action tremor seems merely to be an exaggeration of normal or physiologic tremor; it has the same fast frequency as physiologic tremor (about 10 Hz) but a greater amplitude. Such a tremor, best elicited by holding the arms outstretched with fingers spread apart, is characteristic of intense fright and anxiety, certain metabolic disturbances (hyperthyroidism, hypercortisolism, hypoglycemia), pheochromocytoma, intense physical exertion, withdrawal from alcohol and other sedative drugs, and the toxic effects of several drugs—lithium, nicotinic acid, xanthines (coffee, tea, aminophylline, colas), and corticosteroids. It is noteworthy that a transient action tremor of this type can be reproduced by the intravenous injection of epinephrine or beta-adrenergic drugs such as isoproterenol. Young and colleagues have determined that the enhancement of physiologic tremor that occurs in these various metabolic and toxic states is due to stimulation of certain muscular tremorogenic beta-adrenergic receptors by increased levels of circulating catecholamines. Thus it appears that synchronization of motor units in physiologic tremor, though not primarily of neural origin, is nevertheless influenced by central and peripheral nervous activity.

Alcohol Withdrawal Tremor The most prominent feature of the alcohol withdrawal syndrome is a special type of action tremor

Table 6-1
Main types of tremor

TYPE OF TREMOR	FREQUENCY HZ	PREDOMINANT LOCATION(S)	ENHANCING AGENTS	ATTENUATING AGENTS
Physiologic (enhanced)	8–13	Hands	Epinephrine, β -adrenergics	Alcohol, β -adrenergic antagonists
Parkinson (rest)	3–5	Hands and forearms, fingers, feet, lips, tongue	Emotional stress	L-dopa, anticholinergics
Cerebellar (intention, ataxic, “rubral”)	2–4	Limbs, trunk, head	Emotional stress	Alcohol
Postural, or action	5–8	Hands	Anxiety, fright, β -adrenergics, alcohol withdrawal, xanthines, lithium, exercise, fatigue	β -adrenergic antagonists in some cases
Essential (familial, senile)	4–8	Hands, head, vocal cords	Same as above	Alcohol, propanolol, primidone
Alternate beat	3.5–6	Hands, head	Same as above	Clonazepam, alcohol, β -adrenergic antagonists
Orthostatic	4–8, irregular	Legs	Quiet standing	Repose, walking, clonazepam, valproate
Tremor of neuropathy	4–7	Hands	—	—
“Palatal-myoclonus”	60–100/min	Palate, sometimes facial, pharyngeal, proximal limb muscles	—	Clonazepam, valproate

closely related to enhanced physiologic tremor. Withdrawal of other sedative drugs (benzodiazepines, barbiturates) following a sustained period of use may produce much the same effect. Le-Febvre-D'Amour and colleagues have described two somewhat different tremors in the alcohol withdrawal period, one with frequency greater than 8 Hz and continuous activity in antagonistic muscles, thus resembling physiologic tremor but of greater amplitude and responsive to propranolol (Koller et al). The second tremor, of less than 8 Hz, is characterized by discrete bursts of EMG activity occurring synchronously in antagonistic muscles, like that observed in one type of familial tremor (see below). Either of these may occur after a relatively short period of intoxication (“morning shakes”). A number of alcoholics, on recovery from the withdrawal state, exhibit a persistent tremor of essential-familial type, described below. The mechanisms involved in alcohol withdrawal symptoms are discussed in Chap. 42.

Essential (Familial) Tremor This, the commonest type of tremor, is of lower frequency (4 to 8 Hz) than physiologic tremor and is unassociated with other neurologic changes; it is therefore called “essential.” Tremor of this relatively slow type very often occurs as the only neurologic abnormality in several members of a family, in which case it is called *familial* or *hereditary tremor*. Inheritance is as an autosomal dominant trait with virtually complete penetrance. The idiopathic and familial tremors cannot be distinguished on the basis of their physiologic and pharmacologic properties and probably should not, therefore, be considered as separate entities. This condition, sometimes also referred to as “benign tremor,” is hardly so in many patients, in whom it worsens with age and greatly interferes with normal activities. Quite ambiguous is the term *action tremor* when applied to essential tremor, as noted earlier; strictly speaking, it denotes a worsening of trem-

ulousness with activity of the limb, but, as discussed further on, it is the *maintenance of a posture* that truly exaggerates these tremors. Clinically, one type of faster essential tremor is of the same frequency (6 to 8 Hz) as enhanced physiologic tremor, which has led several clinicians to declare their identity. However, there are certain clinical and physiologic differences, as indicated below.

Familial or essential tremor most often makes its appearance late in the second decade, but it may begin in childhood and then persist. A second peak of increased incidence occurs in adults over 35 years of age. Both sexes are affected. It is a relatively common disorder, with an estimated prevalence of 415 per 100,000 persons over the age of 40 years (Haerer et al). The tremor frequency, as remarked earlier, is 4 to 8 Hz, usually at the lower end of this range; it is of variable amplitude. The frequency diminishes slightly with age while its amplitude increases, as described by Elble. Aside from its frequency, *the identifying feature is its appearance or marked enhancement with attempts to maintain a static limb posture*. Like most tremors, essential tremor is worsened by emotion, exercise, and fatigue.

The tremor practically always begins in the arms and is usually symmetrical; in approximately 15 percent of patients, however, it may appear first in the dominant hand. A severe isolated arm or leg tremor should suggest another disease (Parkinson disease or focal dystonia, as described further on). The tremor may be limited to the upper limbs, or a side-to-side or nodding movement of the head may be added or may occur independently. Infrequently, the tremor of the head precedes that of the hands. The head tremor is also postural in nature and disappears when the head is supported. It has also been noted that the limb and head tremors tend to be muted when the patient walks. In some of our patients whose tremor remained isolated to the head for a decade or more, there has been little if any progression to the arms and almost no wors-

ening of the amplitude of movement. In advanced cases, there is involvement of the jaw, lips, tongue, and larynx, the latter imparting a quaver to the voice. The lower limbs are usually spared or only minimally affected. In the large series of familial case studies by Bain and colleagues, solitary jaw or head tremor was not found. Nor was there a clear association with Parkinson disease, cerebellar ataxia, or dystonia. (However, many patients with Parkinson disease have both a resting and an essential tremor). Many patients with essential tremor will have identified the amplifying effects of anxiety and the ameliorating effects of alcohol on their tremor. In a few of our patients, the tremor became greatly exaggerated during emergence from anesthesia.

Electromyographic studies reveal that the tremor is generated by more or less rhythmic and almost simultaneous bursts of activity in pairs of agonist and antagonist muscles (Fig. 6-1B). Less often, especially in the tremors at the lower range of frequency, the activity in agonist and antagonist muscles alternates ("alternate beat tremor"), a feature more characteristic of parkinsonism, which it superficially resembles (see below). Tremor of either pattern may be disabling, but the slower alternate-beat tremor is more of a handicap and, in our experience, is more resistant to treatment. Essential tremor may increase in severity to a point where the patient's handwriting becomes illegible and he cannot bring a spoon or glass to his lips without spilling its contents. Eventually all tasks that require manual dexterity become difficult or impossible. Treatment is discussed further on.

Tremor of Polyneuropathy Adams and coworkers described a disabling action tremor in patients with chronic demyelinating and paraproteinemic polyneuropathies, as discussed in the previous chapter in relation to ataxic tremor. It is a particularly prominent feature of the polyneuropathy caused by IgM antibodies to myelin-associated glycoprotein (MAG) as mentioned in the preceding

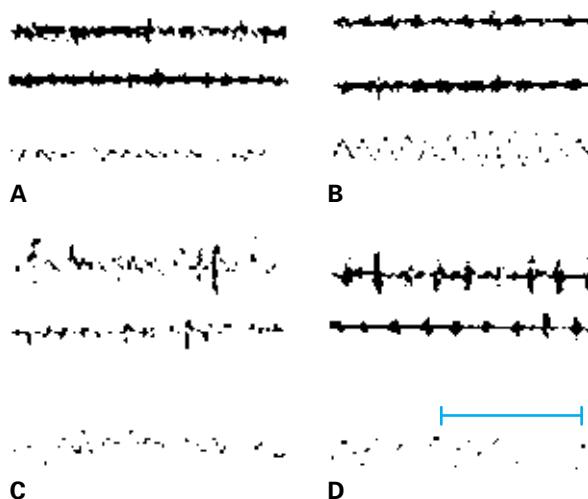

Figure 6-1. Types of tremor. In each, the lowest trace is an accelerometric recording from the outstretched hand; the upper two traces are surface electromyographs from the wrist extensor (upper) and flexor (middle) muscle groups. **A.** A physiologic tremor; there is no evidence of synchronization of electromyographic (EMG) activity. **B.** Essential-familial tremor; the movements are very regular and EMG bursts occur simultaneously in antagonistic muscle groups. **C.** Neuropathic tremor; movements are irregular and EMG bursts vary in timing between the two groups. **D.** Parkinsonian ("rest") tremor; EMG bursts alternate between antagonistic muscle groups. Calibration is 1 s. (Courtesy of Dr. Robert R. Young.)

chapter. It simulates a coarse essential tremor and typically worsens if the patient is asked to hold his finger near a target. The EMG pattern is more irregular than that in the essential-familial tremor. Pedersen and colleagues have found it to vary greatly in amplitude with considerable side-to-side oscillation, which is induced cocontracting muscle activity; they also found little suppression of the tremor with loading of the limb, unlike most other organic tremors. It is hypothesized that there is a disturbance of muscle spindle afferents. Occasionally an inflammatory large-fiber neuropathy, acute or chronic in type, is marked by a prominent ataxic (intention) tremor and a faster action tremor. Also, the inherited disease peripheral muscular atrophy (Charcot-Marie-Tooth disease) may be associated with tremor of the essential-familial type; this combination of symptoms was the basis on which Roussy and Levy incorrectly set it apart as a distinct disease. These polyneuropathies are discussed in Chap. 46.

Other Forms of Action Tremor True action tremors are seen in a number of clinical settings. A coarse action tremor, sometimes combined with myoclonus, accompanies various types of meningoencephalitis (e.g., in the past, it was quite common with syphilitic general paresis) and certain intoxications (methyl bromide and bismuth). Its anatomy and mechanism are obscure. It is important to note again that an action tremor of either the high-frequency or slower (essential) variety may occur in certain diseases of the basal ganglia, including Parkinson disease, in which case both the action and the more typical static tremor are superimposed, with either one predominating.

Treatment of Essential Tremor A curious fact about the familial and essential tremors of the typical (non-alternate-beat) type is that they can be suppressed by a few drinks of alcohol in more than 75 percent of patients; but once the effects of the alcohol have worn off, the tremor returns and may even worsen for a time. This type of tremor can often be inhibited by the beta-adrenergic antagonist propranolol (between 120 and 300 mg per day in divided doses or as a sustained-release preparation) taken orally over a long period of time. However, the benefit is variable and often incomplete; most studies indicate that 50 to 70 percent of patients have some symptomatic relief. Several but not all of the other beta-blocking drugs are somewhat effective; metoprolol and nadolol, which may be better tolerated than propranolol (in terms of bronchospasm, sleepiness, impotence, etc.), are the ones most extensively studied, but they have yielded less consistent results than those for propranolol. The relative merits of different drugs in this class are discussed in review articles by Louis and by Koller et al (2000), which are recommended for further guidance on treatment. Young and associates have shown that neither propranolol nor ethanol, when injected intra-arterially into a limb, decreases the amplitude of essential tremor. These findings suggest that the therapeutic effects of these agents are due less to blockade of the peripheral beta-adrenergic tremorgenic receptors than to the action of these agents on structures within the central nervous system.

The anticonvulsant primidone (Mysoline, in low doses of 25 to 50 mg initially and raised slowly) has also been effective in controlling essential tremor and may be tried in patients who do not respond to or cannot tolerate beta-blocking medications, but many of our patients have not been able to tolerate the side effects of drowsiness, nausea, and slight ataxia. It is recommended that treatment be initiated at a low dosage and increased slowly to 75 mg per day. Gabapentin, topiramate (see Connor) and a large num-

ber of other drugs have been utilized with variable success, but these should be considered second-line therapies; these alternatives are discussed by Louis. Amantadine also has a modest effect on tremor and may be used as an adjunct.

The alternate-beat, kinetic-predominant type of essential tremor is more difficult to suppress but may respond well to clonazepam (Biary and Koller); in our experience, however, this approach has not been as successful. Alcohol and primidone have also been less effective in our experience. Indeed, the tremor has often been resistant to most attempts at suppression by medication.

Injections of botulinum toxin can reduce the severity of essential tremor, but the accompanying weakness of arm and hand muscles often proves unacceptable to the patient. The same medication injected into the vocal cords can suppress severe voice tremor but caution must be exercised to avoid paralyzing the cords.

In desperate cases, a thalamic stimulator of the type used to treat Parkinson disease (page 924) has been quite successful and apparently has produced a durable response over many years; details can be found in the small study reported by Sydow and colleagues.

Parkinsonian (Rest) Tremor

This is a coarse, rhythmic tremor with a frequency of 3 to 5 Hz. Electromyographically, it is characterized by bursts of activity that alternate between opposing muscle groups. The tremor is most often localized in one or both hands and forearms and less frequently in the feet, jaw, lips, or tongue (Fig. 6-1D). It occurs when the limb is in an *attitude of repose* and is suppressed or diminished by willed movement, at least momentarily, only to reassert itself once the limb assumes a new position. For this reason the parkinsonian tremor is often referred to as a *resting tremor*, to distinguish it from postural-action tremor, but these terms must be qualified. Maintaining the arm in an attitude of repose or keeping it still in other positions requires a certain degree of muscular contraction, albeit slight. If the tremulous hand is completely relaxed, as it is when the arm is fully supported at the wrist and elbow, the tremor usually disappears; however, the patient rarely achieves this state. Usually he maintains a state of slight tonic contraction of the trunk and proximal muscles of the limbs. Under conditions of complete rest, i.e., in all except the lightest phases of sleep, the tremor disappears, as do most abnormal tremors except palatal and ocular myoclonus.

Parkinsonian tremor takes the form of flexion-extension or abduction-adduction of the fingers or the hand; pronation-supination of the hand and forearm is also a common presentation. Flexion-extension of the fingers in combination with adduction-abduction of the thumb yields the classic "pill-rolling" tremor. It continues while the patient walks, unlike essential tremor; indeed, it may first become apparent or be exaggerated during walking. When the legs are affected, the tremor takes the form of a flexion-extension movement of the foot, sometimes the knee; in the jaw and lips, it is seen as an up-and-down and pursing movements, respectively. The eyelids, if they are closed lightly, tend to flutter rhythmically (blepharochlonus), and the tongue, when protruded, may move in and out of the mouth at about the same tempo as the tremor elsewhere. The so-called cogwheel effect, which is perceived by the examiner on passive movement of the extremities (Negro's sign), is probably no more than a palpable tremor superimposed on rigidity and as such is not specific for Parkinson disease. The tremor frequency is surprisingly constant over long periods, but the amplitude is variable. Emotional stress augments the

amplitude and may add the effects of an enhanced physiologic or essential tremor; with advance of the disease, increasing rigidity of the limbs obscures or reduces it. Parkinsonian tremor interferes surprisingly little with voluntary movement; for example, it is possible for a tremulous patient to raise a full glass of water to his lips and drain its contents without spilling a drop; ironically, this is not always the case with advanced "benign" essential tremor, as already emphasized.

Resting tremor is most often a manifestation of the Parkinson syndrome, whether the idiopathic variety described by James Parkinson (paralysis agitans) or the drug-induced type. In the former, the tremor is sometimes relatively gentle and more or less limited to the distal muscles; almost always it is asymmetrical; at the outset, it may be unilateral. The tremor of postencephalitic parkinsonism (which is now extinct) often had greater amplitude and involved proximal muscles. In neither disease is there a close correspondence between the degree of tremor and the degree of rigidity or akinesia. A parkinsonian type of tremor may also be seen in elderly persons without akinesia, rigidity, or mask-like facies. In some of these patients, the tremor is followed years later by the other manifestations of Parkinson disease, but in many others it is not, the tremor remaining unchanged for many years or progressing very slowly, unaffected by anti-Parkinson drugs. This probably equates with the earlier mentioned alternate-beat type of essential tremor. Patients with the familial (wilsonian) or acquired form of hepatocerebral degeneration may also show a tremor of parkinsonian type, usually mixed with ataxic tremor and other extrapyramidal motor abnormalities.

Parkinsonian tremor is suppressed to some extent by the phenothiazine derivative ethopropazine (Parsidol), trihexyphenidyl (Artane), and other anticholinergic drugs; it is also suppressed somewhat less consistently but sometimes quite impressively by L-dopa and dopaminergic agonist drugs, which are the mainstays of treatment for Parkinson disease. Stereotactic lesions in the basal ventrolateral nucleus of the thalamus diminish or abolish tremor contralaterally. The situation is made more difficult because a parkinsonian tremor is often associated with an additional tremor of faster frequency (see above and page 916); the latter is of essential type and responds better to beta-blocking drugs than to anti-Parkinson medications. Treatment is discussed in greater detail in Chap. 39.

Intention (Ataxic) Tremor

(See also Chap. 5)

As discussed in Chap. 5, the word *intention* is ambiguous in this context because the tremor itself is not intentional and occurs not when the patient intends to make a movement but only during the most demanding phases of active performance. In this sense it is a *kinetic* or *action tremor*, but the latter term has other connotations to neurologists, as described above. The term *ataxic* is a suitable substitute for *intention*, because this tremor is always combined with cerebellar ataxia and adds to it, as described in Chap. 5. Its salient feature is that it requires for its full expression the performance of an exacting, precise, projected movement. The tremor is absent when the limbs are inactive and during the first part of a voluntary movement, but as the action continues and fine adjustments of the movement are demanded (e.g., in touching the tip of the nose or the examiner's finger), an irregular, more or less rhythmic (2- to 4-Hz) interruption of forward progression with side-to-side oscillation appears and may continue for several beats after

the target has been reached. Unlike familial and parkinsonian tremors, the oscillations occur in more than one plane. The tremor and ataxia may seriously interfere with the patient's performance of skilled acts. In some patients there is a rhythmic oscillation of the head on the trunk (titubation) or of the trunk itself at approximately the same rate. As already indicated, this type of tremor points to disease of the cerebellum or its connections, particularly via the superior cerebellar peduncle, but certain peripheral nerve diseases may occasionally simulate it.

As remarked on page 76, there is another, more violent type of tremor associated with cerebellar ataxia, in which every movement, even lifting the arm slightly or maintaining a static posture with the arms held out to the side, results in a wide-ranging, rhythmic 2- to 5-Hz "wing beating" movement, sometimes of sufficient force to throw the patient off balance. In such cases, the lesion is usually in the midbrain, involving the upward projections of the dentatorubrothalamic fibers and the medial part of the ventral tegmental reticular nucleus. Because of the location of the lesion in the region of the red nucleus, Holmes originally called this a *rubral* tremor. However, experimental evidence in monkeys indicates that the tremor is produced not by a lesion of the red nucleus per se but by interruption of dentothalamic fibers that traverse this nucleus—i.e., the cerebellar efferent fibers that form the superior cerebellar peduncle and brachium conjunctivum (Carpenter). This type of tremor is seen most often in patients with multiple sclerosis and Wilson disease, occasionally with vascular and other lesions of the tegmentum of the midbrain and subthalamus, and rarely as an effect of antipsychotic medications. It is abolished by a lesion in the opposite ventrolateral nucleus of the thalamus. Beta-adrenergic blocking agents, anticholinergic drugs, and L-dopa have little therapeutic effect. Thalamic stimulation may be helpful in severe cases that are the result of multiple sclerosis lesions in the cerebellar peduncles.

The mechanisms involved in the production of intention or ataxic tremor have been discussed in Chap. 5.

Genospasm This is a strongly familial episodic tremor disorder of the chin and lower lip that begins in childhood and may worsen with age. Psychic stress and concentration are known to precipitate the movements, which are described by Danek as "trembling." Rare instances involve other facial muscles. The disorder must be distinguished from essential tremor, facial myokymia, and palatal tremor. The trait is inherited in an autosomal dominant fashion from a locus on chromosome 9.

Primary Orthostatic Tremor This is a rare tremor isolated to the legs that is remarkable by its occurrence only during quiet standing and its cessation almost immediately on walking. It is difficult to classify and more relevant to disorders of gait than it is to tremors of other types. The frequency of this tremor has been recorded as approximately 14 to 16 Hz, making it difficult to observe and more easily palpable. Nonetheless, it may produce considerable disability as the patient attempts to stabilize himself in response to the tremulousness. An important accompanying feature is the sensation of severe imbalance, which causes the patient to assume a widened stance while standing; these patients are unable to walk a straight line (tandem gait). We have observed prominent tonic contraction of the legs during standing, seemingly in an attempt to overcome imbalance (see Heilman, Thompson et al). Falls are surprisingly infrequent; therefore the condition is often attributed to hysteria. The arms are affected little or not at all. Often the

first step or two when the patient begins to walk are halting, but thereafter, the gait is entirely normal. Tremulousness is not present when the patient is seated or reclining, but in the latter positions it can be evoked by strong contraction of the leg muscles against resistance.

Although some authors such as Wee and colleagues have classified the disorder as a type of essential tremor, most of its characteristics suggest otherwise. The suggestion has been made by Sharott and colleagues that it represents an exaggerated physiologic tremor in response to imbalance; others have found an intrinsic rhythm at approximately 16 Hz generated by the damaged spinal cord in patients with myelopathy, suggesting a spinal origin for the tremor.

Many of these cases have responded to the administration of clonazepam, gabapentin, mysoline, or sodium valproate.

Dystonic Tremor Also difficult to classify but not to be overlooked are tremors that are intermixed with dystonia. They tend to be focal in the neck, which is typically rotated slightly to one side, or they may be evident in one dystonic hand. The tremor is not entirely rhythmic, sometimes jerky, and often intermittent. When the underlying dystonic posturing is not overt, the tremor may be ascribed to an obscure origin. These cases are discussed further on, in the section on focal dystonia. In addition, a fair number of patients with dystonia have an essential tremor.

Hysterical Tremor

Tremor is a relatively rare but quite dramatic manifestation of hysteria, but it simulates some types of organic tremor, thereby causing difficulty in diagnosis. Hysterical tremors are usually restricted to a single limb; they are gross in nature, are less regular than the common static or action tremors, and diminish in amplitude or disappear if the patient is distracted, as, for example, when asked to make a complex movement with the opposite hand. If the affected hand and arm are restrained by the examiner, the tremor may move to a more proximal part of the limb or to another part of the body ("chasing the tremor"). Other useful features in identifying hysterical tremor are exaggeration of the tremor by loading the limb—for example, by having the patient hold a book or other heavy object, which reduces almost all other tremors—and the observation of mirror movements in the contralateral hand. Hysterical tremor persists in repose and during movement and is less subject than nonhysterical tremors to the modifying influences of posture and willed movement.

Tremors of Mixed or Complex Type

Not all tremors correspond exactly with those described above. There is frequently a variation in one or more particulars from the classic pattern, or one type of tremor may show a feature ordinarily considered characteristic of another. In some parkinsonian patients, for example, the tremor is accentuated rather than damped by active movement; in others, the tremor may be very mild or absent "at rest" and become obvious only with movement of the limbs. As mentioned above, a patient with classic parkinsonian tremor may, in addition, show a fine tremor of the outstretched hands, i.e., a postural or action tremor, and occasionally even an element of ataxic tremor as well. In a similar vein, essential or familial tremor may, in its advanced stages, assume the aspects of a cerebellar or intention tremor. Gordon Holmes was careful to note that patients

with acute cerebellar lesions sometimes show a parkinsonian tremor in addition to the usual signs of ataxia and ataxic tremor.

The features of one type of tremor may be so mixed with those of another that satisfactory classification is not possible. For example, in certain patients with essential or familial tremor or with cerebellar degeneration, one may observe a rhythmic tremor, characteristically parkinsonian in tempo, which is not apparent in repose but appears with certain sustained postures. It may take the form of an abduction-adduction or flexion-extension of the fingers when the patient's weight is partially supported by the hands, as in the writing position, or it may appear as a tremor of the outstretched fingers or of the thigh when the patient is seated.

Pathophysiology of Tremor

By way of general observation, in patients with tremor of either the parkinsonian, postural, or intention type, Narabayashi has recorded rhythmic burst discharges of unitary cellular activity in the nucleus intermedius ventralis of the thalamus (as well as in the medial pallidum and subthalamic nucleus) synchronous with the beat of the tremor. Neurons that exhibit the synchronous bursts are arranged somatotopically and respond to kinesthetic impulses from the muscles and joints involved in the tremor. A stereotaxic lesion in any of these sites abolishes the tremor. The effectiveness of a thalamic lesion in particular may be due to interruption of pallidothalamic and dentatothalamic projections or, more likely, to interruption of projections from the ventrolateral thalamus to the premotor cortex, since the impulses responsible for cerebellar tremor, like those for choreoathetosis, are ultimately mediated by the lateral corticospinal tract.

Some of what is known about the physiology of specific tremors is noted in the following paragraphs.

Essential Tremor To date, only a few cases of essential tremor have been examined postmortem, and these have disclosed no consistent lesion to which the tremor could indisputably be attributed (Herskovits and Blackwood; Cerosimo and Koller). Action tremors of essential and familial type, like parkinsonian and ataxic (intention) tremors, can be abolished or diminished (contralaterally) by small stereotactic lesions of the basal ventrolateral nucleus of the thalamus, as noted above, by strokes that interrupt the corticospinal system, and by gross unilateral cerebellar lesions; in these respects also they differ from enhanced physiologic tremor. The question of the locus of the generator for essential tremor, if there is such a unitary generator, is unresolved. As indicated by McAuley, various studies that demonstrate rhythmic activity in the cortex corresponding to the tremor activity are more suggestive of a common source elsewhere than of a primary role for the cortex. Based on electrophysiologic recordings in patients, two likely origins of oscillatory activity are the olivocerebellar circuits and the thalamus. Whether a particular structure possesses an intrinsic rhythmicity or, as currently favored, the tremor is released by disease as an expression of reciprocal oscillations in circuits of the dentato-brainstem-cerebellar or thalamic-tegmental systems is not at all clear. Studies of blood flow in patients with essential tremor by Colebatch and coworkers have affirmed that the cerebellum is selectively activated; on this basis they argue that there is a release of an oscillatory mechanism in the olivocerebellar pathway. Dubinsky and Hallett have demonstrated that the inferior olives become hypermetabolic when essential tremor is activated, but this has been questioned by Wills and colleagues, who recorded increased blood flow in the cerebellum and red nuclei but not in the olive. These

proposed mechanisms are reviewed by Elble and serve to emphasize the points made here.

Parkinsonian Tremor The exact anatomic basis of parkinsonian tremor is not known. In Parkinson disease, the visible lesions predominate in the substantia nigra, and this was true also of the postencephalitic form of the disease. In animals, however, experimental lesions confined to the substantia nigra do not result in tremor; neither do lesions in the striatopallidal parts of the basal ganglia. Moreover, not all patients with lesions of the substantia nigra have tremor; in some there are only bradykinesia and rigidity. In a group of 8 patients poisoned with the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analogue that destroys the neurons of the pars compacta of the substantia nigra (see Chaps. 4 and 39), only 4 developed a tremor, which had more the characteristics of a proximal action or postural tremor than of a rest tremor as discussed by Burns and colleagues.

Ward and others have produced a Parkinson-like tremor in monkeys by placing a lesion in the ventromedial tegmentum of the midbrain, just caudal to the red nucleus and dorsal to the substantia nigra. Ward postulated that interruption of the descending fibers at this site liberates an oscillating mechanism in the lower brainstem; this presumably involves the limb innervation via the reticulospinal pathway. Alternative possibilities are that the lesion in the ventromedial tegmentum interrupts the brachium conjunctivum, or a tegmental-thalamic projection, or the descending limb of the superior cerebellar peduncle, which functions as a link in a dentatoreticular-cerebellar feedback mechanism, a hypothesis similar to the one proposed for essential tremor (Fig. 5-3).

Ataxic tremor This has been produced in monkeys by inactivating the deep cerebellar nuclei or by sectioning the superior cerebellar peduncle or the brachium conjunctivum below its decussation. A lesion of the nucleus interpositus or dentate nucleus causes an ipsilateral tremor of ataxic type, as one might expect, associated with other manifestations of cerebellar ataxia. In addition, such a lesion gives rise to a "simple tremor," which is the term that Carpenter applied to a "resting" or parkinsonian tremor. He found that the latter tremor was most prominent during the early postoperative period and was less enduring than ataxic tremor. Nevertheless, the concurrence of the two types of tremor and the fact that both can be abolished by ablation of the contralateral ventrolateral thalamic nucleus suggest that they have closely related neural mechanisms.

Palatal Tremor ("Palatal Myoclonus")

This is a rare and unique disorder consisting of rapid, rhythmic, involuntary movements of the soft palate. For many years it was considered to be a form of uniphasic myoclonus (hence the terms *palatal myoclonus* or *palatal nystagmus*). Because of the persistent rhythmicity, it is now classified as a tremor. There are two forms of this movement, according to Deuschl and colleagues. One is called *essential palatal tremor* and reflects the rhythmic activation of the tensor veli palatini muscles; it has no known pathologic basis. The palatal movement imparts a repetitive audible click, which ceases during sleep. The second, more common form is a *symptomatic palatal tremor*; it involves the levator veli palatini muscles and is due to a diverse group of brainstem lesions that interrupt the central tegmental tract(s), which contain descending fibers from midbrain nuclei to the inferior olive complex. The frequency of the tremor varies greatly and is 26 to 420 cycles per minute in the essential form and 107 to 164 cycles per minute in the symptomatic form.

Symptomatic palatal tremor, in contrast to the essential type and all other tremors, persists during sleep and is sometimes associated with oscillopsia and unilateral or bilateral cerebellar signs. In some cases of the symptomatic type, the pharynx as well as the facial and extraocular muscles (pendular or convergence nystagmus), diaphragm, vocal cords, and even the muscles of the neck and shoulders partake of the persistent rhythmic movements. A similar phenomenon, in which contraction of the masseters occurs concurrently with pendular ocular convergence, has been observed in Whipple disease (*oculomasticatory myorhythmia*).

Magnetic resonance imaging reveals no lesions to account for essential palatal tremor; in the symptomatic form, however, one can see the tegmental brainstem lesions and conspicuous enlargement of the inferior olive nucleus unilaterally or bilaterally. With unilateral palatal tremor, it is the contralateral olive that becomes enlarged. It has been proposed that the lesions in the symptomatic form interrupt the circuit (dentate nucleus–brachium conjunctivum–central tegmental tract–olivary nucleus–dentate nucleus) that Lapresle and Ben Hamida have called the *triangle of Guillain and Mollaret*, (Mollaret triangle, as discussed in Chap. 5) after the persons who first carefully studied the condition (pages 72–73). Our own pathologic material confirms the central tegmental-olivary lesions but contains no examples of the production of palatal myoclonus by lesions of the cerebellum or of the dentate and red nuclei. The lesions have been vascular, neoplastic, demyelinating (multiple sclerosis), or traumatic and have been found in the midbrain or pontine tegmentum. There are no reports on the pathologic anatomy of essential palatal tremor.

The physiologic basis of palatal tremor remains conjectural. Matsuo and Ajax postulated a denervation hypersensitivity of the inferior olive nucleus and its dentate connections, but Kane and Thach have adduced that the critical event is denervation not of the olive but of the nucleus ambiguus and the dorsolateral reticular formation adjacent to it. Dubinsky and colleagues have suggested that palatal tremor may be based on the same mechanism as postural tremor—i.e., presumably a disinhibition of the olive and a rhythmic coupling of neurons in the olive induced by a lesion of the dentato-olivary pathway. We are uncertain whether to designate these rhythmic disorders as uniphasic myoclonus or as tremors.

The use of drugs in treating this movement disorder has met with variable success. Clonazepam (0.25 to 0.5 mg/day, increasing gradually to 3.0 to 6.0 mg/day), sodium valproate (250 mg/day, increasing to 1000 mg/day), and gabapentin have suppressed the movement in some cases, particularly the last of these drugs, which reportedly has had a dramatic effect in some patients. Also, tetrabenazine and haloperidol have been helpful on occasion. Selective injection of the palatal muscles with botulinum toxin affords modest relief; it is particularly helpful in eliminating the annoying ear clicking.

ASTERIXIS

The movement disorder known as *asterixis* was described by Adams and Foley in 1953. It consists essentially of arrhythmic lapses of sustained posture. These sudden interruptions in sustained muscular contraction allow gravity or the inherent elasticity of muscles to produce a movement, which the patient then corrects, sometimes with overshoot. Later Adams and Schwab demonstrated that the initial movement or lapse in posture is associated with EMG silence

for a period of 35 to 200 ms. By interlocking EMG and electroencephalographic (EEG) recordings, Ugawa et al found that a sharp wave, probably generated in the motor cortex, immediately precedes the period of EMG silence. This confirmed that asterixis differs physiologically from both tremor and myoclonus, with which it was formerly confused; it has incorrectly been referred to as a “negative tremor.”

Asterixis is most readily evoked by asking the patient to hold his arms outstretched with hands dorsiflexed or to dorsiflex the hands and extend the fingers while resting the forearms on the bed or the arms of a chair. Flexion movements of the hands may then occur once or several times a minute. The lapses in sustained muscle contraction and the corresponding lapses in EMG activity can be provoked by the persistent contraction of any muscle group—including, for example, the protruded tongue, the closed eyelids, or the trunk muscles. If small finger muscles are affected, an EMG may be required to separate asterixis from tremor and myoclonus.

This sign was first observed in patients with hepatic encephalopathy but was later noted in those with hypercapnia, uremia, and other metabolic and toxic encephalopathies. However, lapses of this type may sometimes appear in the neck and arms of a normal person during a period of drowsiness. They may also be evoked by phenytoin and other anticonvulsants, then indicating that these drugs are present in excessive concentrations.

Unilateral asterixis has been noted in an arm and leg on the side opposite an anterior thalamic infarction or small hemorrhage, stereotaxic thalamotomy, and with an upper midbrain lesion, usually as a transient phenomenon after stroke. A few cases have reportedly followed an infarction in the territory of the anterior cerebral artery, but our experience is limited to those arising from thalamic lesions. Montalban and colleagues observed unilateral asterixis in 45 patients without metabolic or toxic abnormalities. In more than half of these patients, there were lesions in the contralateral thalamus; in the remainder, there was an abnormality in the pons or a cerebral hemisphere. Anticonvulsants exaggerate the sign, which, in one of our patients who had a small hemorrhage in the anterior thalamus, appeared only when the drug was administered.

CLONUS, MYOCLONUS, AND POLYMYOCLONUS

The terms *clonus* (or *clonic*), *myoclonus* (or *myoclonic*), and *polymyoclonus* have been used indiscriminately to designate any rhythmic or arrhythmic series of brief, shock-like muscular contractions associated with disease of the central nervous system. *Clonus* refers to a series of *rhythmic, monophasic* (i.e., *unidirectional contractions and relaxations*) of a group of muscles, differing in this way from tremors, which are always diphasic or bidirectional. *Myoclonus* specifies the shock-like contraction(s) of a group of muscles, irregular in rhythm and amplitude, and, with few exceptions, asynchronous and asymmetrical in distribution; if such contractions occur singly or are repeated in a restricted group of muscles, such as those of an arm or leg, we designate the phenomenon as *segmental myoclonus* or *myoclonus simplex*. Widespread, lightning-like, arrhythmic contractions are referred to as *myoclonus multiplex* or *polymyoclonus*. The discussion that follows makes evident that this is not a matter of mere pedantry but that each of the three phenomena has a distinctive pathophysiology and particular clinical implications.

Clonus

Reference has already been made to the clonus that appears in relation to spasticity and heightened tendon reflexes in diseases affecting the corticospinal tract (page 47). It is most easily elicited by forcefully dorsiflexing the ankle; a series of rhythmic jerks of small to moderate amplitude result. *Epilepsia partialis continua* is a special type of rhythmic epileptic clonus in which one group of muscles—usually of the face, arm, or leg—is continuously (day and night) involved in a series of rhythmic monophasic contractions. These may continue for weeks, months, or years. In most cases there is a corresponding EEG abnormality. The disorder appears to be cerebral in origin, but in most cases its precise anatomic and physiologic basis cannot be determined (see Chap. 16 for further discussion).

Myoclonus Simplex

Patients with idiopathic epilepsy may complain of a localized myoclonic jerk or a short burst of myoclonic jerks, occurring particularly on awakening and on the day or two preceding a major generalized seizure, after which these movements cease. Unlike the complex myoclonus discussed below, very few patients show progressive mental and physical deterioration. One-sided or focal myoclonic jerks are the dominant feature of a particular form of childhood epilepsy—so-called benign epilepsy with rolandic spikes (page 279). Diffuse myoclonic jerks are the main or sometimes only manifestation of a fairly common seizure disorder with distinctive EEG features called juvenile myoclonic epilepsy; this diagnosis is suggested by an onset of myoclonus or single seizures during adolescence and myoclonus or lapses in upright posture that become prominent with sleep deprivation and alcohol consumption. Myoclonus may be associated with atypical petit mal and akinetic seizures in the Lennox-Gastaut syndrome (page 274); the patient often falls during the brief lapse of postural mechanisms that follows a single myoclonic contraction. Similarly, in the West syndrome of infantile spasms, the arms and trunk are suddenly flexed or extended in a single massive myoclonic jerk (“jackknife” or “salaam” seizures); mental regression occurs in fully 80 to 90 percent of cases, even when the seizures are successfully treated with adrenocorticotropic hormone (ACTH). These types of special “myoclonic epilepsies” are discussed further below and in Chap. 16.

Diffuse Myoclonus (Myoclonus Multiplex, or Polymyoclonus)

Under the title *paramyoclonus multiplex*, Friedreich in 1881 described a sporadic instance of widespread muscle jerking in an adult. It was probably in the course of this description that the term *myoclonus* was used for the first time. Muscles were involved diffusely, particularly those of the lower face and proximal segments of the limbs, and the myoclonus persisted for many years, being absent only during sleep. No other neurologic abnormalities accompanied the movement abnormality. The nature and pathologic basis of this disorder were never determined, and its status as a clinical entity has never been secure. Over the years, the term *paramyoclonus multiplex* has been applied to all varieties of myoclonic disorder (and other motor phenomena as well), to the point where it has nearly lost its specific clinical connotation. Myoclonus multiplex of the type described by Friedreich may occur in pure or

“essential” form as a benign, often familial, nonprogressive disease or as part of a more complex progressive syndrome that may prove disabling and fatal. Some have specified the first as primary and the latter as secondary forms, but these designations have little fundamental value, serving only to indicate differences in severity and clinical course. There are also several acquired forms that are associated with various neurologic diseases as discussed below.

Essential (Familial) Myoclonus So-called essential myoclonus may begin at any period of life but usually appears first in childhood and is of unknown etiology. An autosomal dominant mode of inheritance is evident in some families. The myoclonus takes the form of irregular twitches of one or another part of the body, involving groups of muscles, single muscles, or even a portion of a muscle. As a result, an arm may suddenly flex, the head may jerk backward or forward, or the trunk may curve or straighten. The face, neck, jaw, tongue, and ocular muscles may twitch; also the diaphragm. Some muscle contractions cause no visible displacement of a limb. According to Wilson, even fascicles of the platysma may twitch. In this and other forms of myoclonus, the muscle contraction is brief (20 to 50 ms)—i.e., faster than that of chorea, with which it may be confused. The speed of the myoclonic contraction is the same whether it involves a part of a muscle, a whole muscle, or a group of muscles. Many of the patients register little complaint, accepting the constant intrusions of motor activity with stoicism; they generally lead relatively normal, active lives. Seizures, dementia, and other neurologic deficits are notably absent. Occasionally there is hint of a mild cerebellar ataxia and, in one family studied by R. D. Adams, essential tremor was present as well, both in family members with polymyoclonia and in those without. Both the tremor and myoclonus were dramatically suppressed by the ingestion of alcohol. Similar families have been observed by Marsden and colleagues. In a Mayo Clinic series by Aigner and Mulder, 19 of 94 cases of polymyoclonus were of this “essential” type.

Several of the sleep-related syndromes that involve repetitive leg movements include an element of myoclonus. In a few patients, mainly older ones with severe “restless legs syndrome,” the myoclonus and dyskinesias are troublesome in the daytime as well. These patients march in place and rock their bodies during sleep (Walters et al). Opiates may be helpful in suppressing the movements. These disorders are discussed in Chap. 19.

Myoclonic Epilepsy (See also page 274) Myoclonic epilepsy constitutes another important syndrome of multiple etiologies. A relatively benign idiopathic form, juvenile myoclonic epilepsy, has been mentioned and is discussed in Chap 16. A more serious type of myoclonic epilepsy, which in the beginning may be marked by polymyoclonus as an isolated phenomenon, is eventually associated with dementia and other signs of progressive neurologic disease (familial variety of Unverricht and Lundborg, page 285). An outstanding feature of the latter is a remarkable sensitivity of the myoclonus to stimuli of all sorts. If a limb is passively or actively displaced, the resulting myoclonic jerk may lead, through a series of progressively larger and more or less synchronous jerks, to a generalized convulsive seizure. In late childhood this type of stimulus-sensitive myoclonus is usually a manifestation of the juvenile form of lipid storage disease, which, in addition to myoclonus, is characterized by seizures, retinal degeneration, dementia, rigidity, pseudobulbar paralysis, and, in the late stages, by quadriplegia in flexion.

Another form of stimulus-sensitive (reflex) myoclonus, inherited as an autosomal recessive trait, begins in late childhood or adolescence and is associated with neuronal inclusions (Lafora bodies) in the cerebral and cerebellar cortex and in brainstem nuclei (page 274). In yet another familial form (described under the title of *Baltic myoclonus* by Eldridge and associates), necropsy has disclosed a loss of Purkinje cells but no inclusion bodies. Unlike Lafora disease, the Baltic variety of myoclonic epilepsy has a favorable prognosis, particularly if the seizures are treated with valproic acid.

Under the title of *cherry-red-spot myoclonus syndrome*, Rapin and associates have drawn attention to a familial (autosomal recessive) form of diffuse, incapacitating intention myoclonus associated with visual loss and ataxia. This disorder develops insidiously in adolescence. The earliest sign is a cherry-red spot in the macula that may fade in the chronic stages of the illness. The intellect is relatively unimpaired. The specific enzyme defect appears to be a deficiency of lysosomal alpha-neuroaminidase (sialidase), resulting in the excretion of large amounts of sialylated oligosaccharides in the urine. Lowden and O'Brien refer to this disorder as *type I sialidosis* and distinguish it from a second type, in which patients are of short stature (due to chondrodytrophy) and often have a deficiency of beta-galactosidase in tissues and body fluids. In patients with sialidosis, a mucopolysaccharide-like material is stored in liver cells, but neurons show only a nonspecific accumulation of lipofuscin. A similar clinical syndrome of myoclonic epilepsy is seen in a variant form of neuroaxonal dystrophy and in the late childhood–early adult neuronopathic form of Gaucher disease, in which it is associated with supranuclear gaze palsies and cerebellar ataxia (page 821).

Diffuse Myoclonus with Acquired Neurologic Disease (Table 6-2) The clinical settings in which one observes widespread random myoclonic jerks as a transient or persistent phenomenon in adults include structural diseases such as viral encephalitis, Creutzfeldt-Jakob disease, general paresis, advanced Alzheimer and Lewy-body disease, and corticobasalganglionic degeneration (the degenerative types are discussed in Chap. 39), occasionally in Wilson disease, and more often with acquired metabolic disorders (prototypically uremic and anoxic encephalopathy) and certain drug intoxications, notably with haloperidol, lithium, and amphetamines; others are listed in Table 6-2. These account for the majority of instances of myoclonus observed by the neurologist. An acute onset of polymyoclonus with confusion may occur with lithium intoxication; once ingestion is discontinued, there is improvement (slowly over days to weeks) and the myoclonus is replaced by diffuse action tremors, which later subside. Diffuse, severe myoclonus may be a prominent feature of early tetanus and strychnine poisoning.

A polymyoclonus that occurs in acute anoxic encephalopathy should be distinguished from postanoxic action or intention myoclonus that emerges with recovery (it is discussed below). Encephalopathy with diffuse myoclonus may occur in Hashimoto thyroiditis and in Whipple disease with central nervous system involvement (both are discussed in Chap. 40). The factor common to all these disorders is the presence of diffuse neuronal disease.

Myoclonus in association with signs of cerebellar incoordination, including *opsoclonus* (rapid, irregular, but predominantly conjugate movements of the eyes in all planes), is another syndrome that has been described in both children and adults under a

Table 6-2

Causes of generalized and regional myoclonus

Epileptic forms (myoclonic epilepsies)

- Unverricht-Lundborg disease
- Lafora body disease
- Baltic myoclonus
- Benign epilepsy with rolandic spikes
- Juvenile myoclonic epilepsy
- Infantile spasms (West syndrome)
- Cherry-red spot–myoclonus (sialidase deficiency)
- Myoclonus epilepsy with ragged red fibers (MERRF)
- Ceroid lipofuscinosis (Kufs disease)
- Tay-Sachs disease

Essential and heredofamilial forms

Myoclonic dementias

- Creutzfeldt-Jakob disease
- Subacute sclerosing panencephalitis
- Familial progressive poliodystrophy
- Alzheimer, Lewy-body, and Wilson diseases (occasional in late stages)
- Whipple disease of the central nervous system
- Corticobasal ganglionic degeneration
- Dentatorubropallidoluysian atrophy
- AIDS dementia

Myoclonus with cerebellar disease (myoclonic ataxia)

- Opsoclonus-myoclonus syndrome [Paraneoplastic (anti-Ri), neuroblastoma, post- and parainfectious]
- Postanoxic myoclonus (Lance Adams)
- Ramsay-Hunt dysynergia cerebellaris myoclonica

Metabolic and toxic disorders

- Cerebral hypoxia (acute variety)
- Uremia
- Hashimoto thyroiditis
- Lithium intoxication
- Haloperidol and sometimes phenothiazine intoxication
- Hepatic encephalopathy (rare)
- Cyclosporine toxicity
- Nicotinic acid deficiency encephalopathy
- Tetanus
- Other drug toxicities

Focal and spinal forms of myoclonus

- Herpes zoster myelitis
- Other unspecified viral myelitis
- Multiple sclerosis
- Traumatic spinal cord injury
- Arteriovenous malformation of spinal cord
- Subacute myoclonic spinal neuronitis

variety of names. Most cases run a chronic course, waxing and waning in severity. Many of the childhood cases have been associated with occult *neuroblastoma*, and some have responded to the administration of corticosteroids. In adults, a similar syndrome has been described as a remote effect of carcinoma (mainly of lung, breast, and ovary), but it also occurs at all ages as a relatively benign manifestation of a benign postinfectious (possibly viral) illness (Baringer et al). In some cases, myoclonus is associated only with cerebellar ataxia and tremor, opsoclonus being absent; in others, myoclonus, seizures, retinal degeneration, cerebellar tremor,

and ataxia have been combined (e.g., dyssynergia cerebellaris myoclonica of Ramsay Hunt; see page 937).

As mentioned above, diffuse myoclonus is a prominent and often an early feature of a unique transmissible subacute illness in adults commonly referred to as *Creutzfeldt-Jakob* disease and characterized by dementia, disturbances of gait and coordination and all manner of mental and visual aberrations. Originally, the jerks are random in character, but late in the disease they may attain a certain rhythmicity and symmetry. In addition, there is an exaggerated startle response, and violent myoclonus may be elicited by tactile, auditory, or visual stimuli in advanced stages of the disease. In this condition too, there is a progressive destruction of nerve cells, mainly but not exclusively of the cerebral and cerebellar cortices, and a striking degree of gliosis. In addition to parenchymal destruction, the cortical tissue shows a fine-meshed vacuolation; hence the preferable designation *subacute spongiform encephalopathy*. Both the sporadic and rare familial forms of this disease are due to an unconventional transmissible agent, or prion (see also page 653).

In yet another group of “*myoclonic dementias*,” the most prominent associated abnormality is a progressive deterioration of intellect. Like the myoclonic epilepsies, the myoclonic dementias may be sporadic or familial and may affect both children and adults. A rare childhood type is subacute sclerosing panencephalitis (SSPE), which is an acquired subacute or chronic (occasionally remitting) disease related in some way to previous infection with the measles virus (page 650). Another type, familial in nature and affecting infants and young children, has been described by Ford, who called it *progressive poliodystrophy*. On a background of normal birth and development over the first few months or years of life, there occurs a progressive psychomotor deterioration, with spastic quadriplegia, seizures, myoclonus, and blindness. The fundamental pathologic alteration is a destruction of nerve cells in the cerebral and cerebellar cortices with replacement gliosis.

Intention or Action (Postanoxic) Myoclonus This type of myoclonus was described by Lance and Adams in 1963 in a group of patients who were recovering from hypoxic encephalopathy. When the patient is relaxed, the limb and other skeletal muscles are quiet (except in the most severe cases); only seldom does the myoclonus appear during slow, smooth (ramp) movements. Fast (ballistic) movements, however, especially when directed to a target, as in touching the examiner’s finger, elicit a series of irregular myoclonic jerks that differ in speed and rhythmicity from intention tremor. For this reason it was called *intention or action myoclonus*. Only the limb that is moving is involved; hence it is a localized, stimulus-evoked myoclonus. Speech may be affected; it is fragmented by the myoclonic jerks, and a syllable or word may be almost compulsively repeated, as in palilalia.

Action myoclonus is almost always associated with cerebellar ataxia. The pathologic anatomy has not been ascertained. Lance and Adams found the irregular discharges to be transmitted via the corticospinal tracts, preceded in some cases by a discharge from the motor cortex. Chadwick and coworkers postulated a reticular loop reflex mechanism. Hallett and colleagues found that a cortical reflex mechanism was operative in some cases and a reticular reflex mechanism in others. Whether these are two aspects of one mechanism could not be decided.

Barbiturates and valproic acid have been helpful in some cases. Clonazepam in combination with valproate is our preference. Several clinical trials and case reports have suggested that the ex-

perimental drug piracetam, and, more persuasively, the anticonvulsant levetiracetam may be useful (Krauss et al). The use of 5-hydroxytryptophan alone or in combination with tryptophan or other drugs has been recommended in the past (van Woert et al). Usually, a combination of several of these medications is required to make the patient functional.

Spinal or Segmental Myoclonus

(See also page 1066)

The notion that monophasic restricted myoclonus always emanates from the cerebral cortex, cerebellum, or brainstem cannot be sustained, for there are forms that are traceable to a purely spinal lesion. A subacute spinal myoclonus of obscure origin was described many years ago by Campbell and Garland, and similar cases continue to be cited in the literature. We have seen several such cases where myoclonus was isolated to the musculature of the abdominal or thoracic wall on one side or to the legs; only rarely were we able to establish a cause, and the spinal fluid has been normal. It takes the form of an almost continuous arrhythmic jerking of a group of muscles. This form has been referred to as “*propriospinous*,” particularly when it involves repetitive flexion or extension myoclonus of the torso that is aggravated by stretching or action.

A sharply demarcated segmental myoclonus has been induced in animals by the Newcastle disease virus, and examples of myelitis with irregular segmental myoclonic jerks (either rhythmic or arrhythmic) have been reported in humans. Many such cases involve the legs or a few muscles of one leg. In our experience, this type of myelitic myoclonus has occurred following zoster myelitis, postinfectious transverse myelitis, and rarely with multiple sclerosis, epidural compression, or after spinal traumatic injury. A paraneoplastic form has also been described. When highly ionic contrast media were used for myelography, painful spasms and myoclonus sometimes occurred in segments where the dye was concentrated by a block.

Treatment is difficult, and one resorts to a combination of anticonvulsants and diazepines, just as in cerebral myoclonus. The glycine inhibitor levetiracetam has reportedly been successful when other drugs have failed (Keswani et al).

Pathophysiology of Myoclonus Multiplex

It seems logical to assume that myoclonus is caused by abnormal discharges of aggregates of motor neurons or interneurons because of the directly enhanced excitability of these cells or the removal of some inhibitory mechanism.

Sensory relationships are a prominent feature of myoclonus multiplex, particularly those related to metabolic disorders, and will eventually shed some light on the mechanism. Flickering light, a loud sound, or an unexpected tactile stimulus to some part of the body initiates a jerk so quickly and consistently that it must utilize a direct sensorimotor pathway or the mechanism involved in the startle reaction. Repeated stimuli may recruit a series of incremental myoclonic jerks that culminate in a generalized convulsion, as often happens in the familial myoclonic syndrome of Unverricht-Lundborg. Another type of sensory myoclonus is the audiogenic form, characteristic of Tay-Sachs disease. Each auditory stimulus results in blinking, abrupt elevation of the arms, and other movements. This generalized myoclonic jerk does not fatigue with successive stimuli and is modality-specific.

Evidence implicating cortical hyperexcitability in myoclonus is indirect, being based mainly on the finding that the cortical components of the somatosensory evoked potential are exceedingly large. In some such instances, the myoclonic jerks also have a strict time relationship ("time-locked") to preceding spikes in the contralateral rolandic area, indicating that the cerebral cortex may play an active and perhaps primary role in the elaboration of myoclonus (Marsden et al; Brown et al); however, it is just as likely that these cortical potentials are projected from subcortical structures that also project to descending motor pathways. In humans, the indication is that postanoxic action myoclonus has its basis in reflex hyperactivity of the reticular formation and that the only consistent damage is in the cerebellum rather than in the cerebral cortex (see above, under "Intention or Action Myoclonus"). Also as already noted, several types of myoclonus are closely coupled with cerebellar cortical degenerations.

Pathologic examinations have been of little help in determining the essential sites of this unstable neuronal discharge because, in most cases, the neuronal disease is so diffuse. The most restricted lesions associated with myoclonus are seemingly located in the cerebellar cortex, dentate nuclei, and pretectal region. A lack of modulating influence of the cerebellum on the thalamocortical system of neurons has been postulated as a likely mechanism, but it is uncertain whether the disinhibited motor activity is then expressed through corticospinal or rubrospinal pathways. For example, pentylenetetrazole (Metrazol) injections evoke myoclonus in the limbs of animals, and the myoclonus persists after transection of corticospinal and other descending tracts until the lower brainstem (medullary reticular) structures are destroyed.

PATHOLOGIC STARTLE SYNDROMES

To some degree, everyone startles or jumps in reaction to a totally unanticipated, potentially threatening stimulus. This normal startle reflex is probably a protective reaction, being seen also in animals, and its purpose seemingly is to prepare the organism for escape. By *pathologic startle* we refer to a greatly exaggerated startle reflex and to a group of other stimulus-induced disorders of which startle is a predominant part. In most ways, startle cannot be separated from myoclonus (simplex) except for its generalized nature and a striking evocation by various stimuli.

Aside from exaggerated forms of the normal startle reflex, the commonest isolated syndrome is so-called startle disease, also referred to as *hyperexplexia* or *hyperekplexia* (Gastaut and Vileneuve). There is a familial proclivity to this disease (e.g., in the "jumping Frenchmen of Maine," and others, as described further on). The subject has been reviewed by Wilkins and colleagues and by Ryan et al; the latter authors, by linkage analysis, localized the gene to chromosome 5q. The resulting biochemical defect is now known to be in the α_1 -subunit of the inhibitory glycine receptor (Shiang et al).

With the description of an increasing number of cases of startle disease, the special attributes of the condition have become more familiar. Any stimulus—most often an auditory one but also a flash of light, a tap on the neck, back, or nose, or even the presence of someone behind the patient—normally evinces a sudden contraction of the orbicularis, neck, and spinal musculature and even the

legs on occasion. In the abnormal startle response, the contraction is more severe and widespread, with less tendency to habituate. There may be a jump and occasionally an involuntary shout and fall to the ground. As pointed out by Suhren and associates and by Kurczynski, the condition is transmitted in some families as an autosomal dominant trait. In the proband described by the latter author, affected infants were persistently hypertonic and hyperreflexic (up to 2 to 4 years of age) and had nocturnal and sometimes diurnal generalized myoclonic jerks, all of which subsided with maturation of the nervous system.

Later in life, excessive startle must be distinguished from epileptic seizures, which may begin with a startle or massive myoclonic jerk (startle epilepsy) and from the multiplex tic disorder Gilles de la Tourette syndrome, of which startle may be a prominent manifestation (page 95). With idiopathic startle disease, even with a fall, there is no loss of consciousness, and the manifestations of tic and other neurologic abnormalities are absent.

An auditory startle response may be a manifestation of other neurologic diseases. It is a prominent feature of Tay-Sachs disease (page 807), subacute sclerosing panencephalitis (SSPE), and of some cases of the "stiff-man syndrome" (page 1279). Auditory, visual, and somatic startle reactions are also conspicuous features of some of the lipid storage diseases and of Creutzfeldt-Jakob disease.

The mechanism of the startle disorder has been a matter of speculation. In animals, the origin of the phenomenon has been localized in the pontine reticular nuclei, with transmission to the lower brainstem and spinal motor neurons via the rubrospinal tracts. During the startle, the EEG may show a vertex or frontal spike-slow-wave complex, followed by a general desynchronization of the cortical rhythms; between startles the EEG is normal. Some authors have postulated a disinhibition of certain brainstem centers. Others, on the basis of testing by somatosensory evoked potentials, have suggested that hyperactive long-loop reflexes constitute the physiologic basis of startle disease (Markand et al). Wilkins and coworkers consider hyperexplexia to be an independent phenomenon (different from the normal startle reflex) and to fall within the spectrum of stimulus-sensitive myoclonic disorders. Presumably, the altered glycine receptor is the source of some form of hyperexcitability in one or another of the motor or reticular alerting systems.

The relationship of hyperexplexia to the phenomenon displayed by the "jumping Frenchmen of Maine" is not altogether clear. The latter was described originally by James Beard, in 1868, among small pockets of French-speaking lumberjacks in northern Maine. The subjects displayed a greatly exaggerated response to minimal stimuli, to which no adaptation was possible. The reaction consisted of jumping, raising the arms, screaming, and flailing of limbs, sometimes with echolalia, echopraxia, and a forced obedience to commands, even if this entailed a risk of serious injury. A similar syndrome in Malaysia and Indonesia is known as *latah* and in Siberia as *myriachit*. This syndrome has been explained in psychologic terms as conditioned (Saint-Hilaire et al) or as culturally determined behavior (Simons). Possibly some of the complex secondary phenomena can be explained in this way, but the stereotyped onset with an uncontrollable startle and the familial occurrence in our view attest to a biologic basis akin to that of hyperexplexia.

Treatment Clonazepam controls the startle disorders to varying degrees.

SPASMODIC TORTICOLLIS AND OTHER FOCAL DYSTONIAS

These focal or segmental dystonias, in contrast to the generalized dystonic disorders described in Chap. 4, are intermittent, brief or prolonged spasms or contractions of a muscle or adjacent group of muscles that places the body part in a forced and unnatural position. When limited to the neck muscles, the spasms may be more pronounced on one side, with rotation and partial extension of the head (*idiopathic cervical dystonia* or *torticollis*), or the posterior or anterior neck muscles may be involved predominantly and the head hyperextended (*retrocollis* spasm, *retrocollis*) or inclined forward (antero- or procollic spasm, *anterocollic*). Other dystonias restricted to craniocervical muscle groups are spasms of the orbicularis oculi, causing forced closure of the eyelids (*blepharospasm*); contraction of the muscles of the mouth and jaw, which may cause forceful opening or closure of the jaw and retraction or pursing of the lips (*oromandibular dystonia*). With the latter condition, the tongue may undergo forceful involuntary protrusion; the throat and neck muscles may be thrown into violent spasm when the patient attempts to speak or the facial muscles may contract in a grimace; the laryngeal muscles may be involved, imparting a high-pitched, strained quality to the voice (*spasmodic dysphonia*). More often, spasmodic dysphonia occurs as an isolated phenomenon. Of the large number of focal dystonias seen in the movement disorder clinic of Columbia Presbyterian Hospital, 44 percent were classified as torticollis, 26 percent as spasmodic dysphonia, 14 percent as blepharospasm, 10 percent as focal dystonia of the right hand and arm (writer's cramp), and 3 percent as oromandibular dystonia. This reflects the distribution in our own and our colleagues' practices.

These movement disorders are involuntary and cannot be inhibited, thereby differing from habit spasms or tics. At one time torticollis was thought to be a type of neurosis, but psychiatrists and neurologists now agree that it is a localized form of dystonia. As discussed in Chap. 4, it is characteristic of these spasms and of similar focal dystonias that occur in the hands or feet to display a simultaneous activation of agonist and antagonist muscles (cocontraction), a tendency for the spasm to spread to adjacent muscle groups that are not normally activated in the movement (overflow), and sometimes to include an arrhythmic intermixed tremor; but these features tend not to be as prominent in most focal dystonias as in the generalized varieties (described in Chap. 4). The tremor in particular may cause difficulty in diagnosis if the slight degree of dystonia is not appreciated except by careful observation and especially by palpation of the involved muscles.

Any of the typical forms of restricted dystonia may represent a tardive dyskinesia; i.e., they complicate treatment with neuroleptic drugs (see further on and pages 94 and 1327). The most common of these is a more or less constant movement of the tongue and lips, which may include lip smacking, tongue protrusion, and similar unnatural orolingual movements. Also, restricted dystonias of the hand or foot often emerge as components of a number of degenerative diseases—Parkinson disease, corticobasal ganglionic degeneration, and progressive supranuclear palsy (all described in Chap. 39). These dystonias may also occur in metabolic diseases such as Wilson disease and nonwilsonian hepatolenticular degeneration. Rarely, a focal dystonia emerges transiently after a stroke that involves the striatopallidal system, mainly the internal segment of the pallidum, or the thalamus, but the varied locations of these

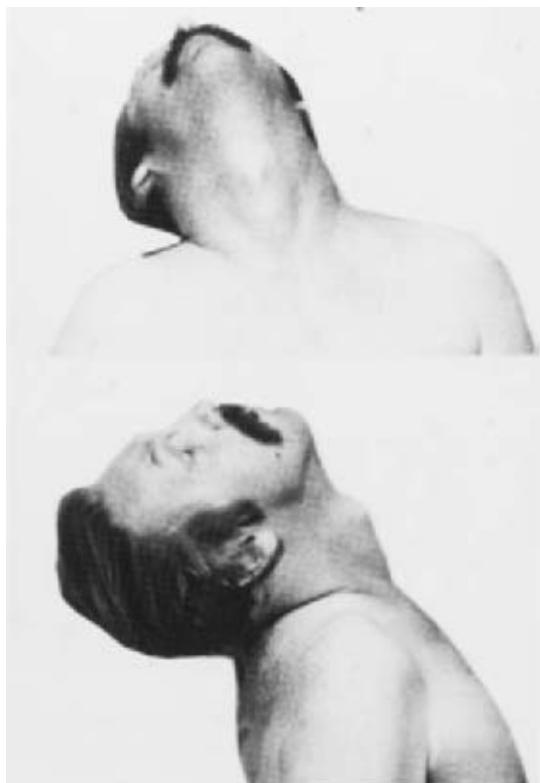

infarctions makes it difficult to draw conclusions about the mechanism of dystonia. Several such cases are described by Krystkowiak and colleagues and by Munchau and colleagues and all fall into the category of *symptomatic or secondary dystonias*. The ones due to acquired systemic disorders are summarized by Janavs and Aminoff.

The pathogenesis of the idiopathic (primary) focal dystonias is uncertain, although there is evidence that a proportion, like the generalized dystonias, is genetically determined. Authoritative commentators, including Marsden, have classed the adult-onset focal dystonias with the broader category of idiopathic torsion dystonia. This view is based on several lines of evidence: the recognition that each of the focal dystonias may appear as an early component of the idiopathic generalized syndrome in children, the occurrence of focal and segmental dystonias in family members of these children, as well as a tendency of the dystonia in some adult patients to spread to other body parts. Perhaps the most compelling observation in this regard has been the finding that there are families in which the only manifestation of the DYT1 mutation (the gene abnormality associated with dystonia musculorum deformans) is a late-onset writer's cramp or other focal dystonia, described further on. Whether this explains most of the cases of adult onset focal dystonia is unclear but it does emphasize the phenotypic variability associated with the DYT1 gene mutation (which codes for a protein called torsin A.) The genetics of primary torsion dystonia is complex and is reviewed in Chap. 39.

It is noteworthy that no consistent pathologic changes have been demonstrated in any of the idiopathic and genetically determined dystonias. Most physiologists cast the disorder in terms of reduced cortical inhibition of unwanted muscle contractions, as summarized in the review by Berardelli and colleagues. Specific physiologic changes in the cortical areas that are pertinent to the dystonias associated with overuse of certain body parts (occupational dystonias) are described below.

Spasmodic Torticollis (Idiopathic Cervical Dystonia)

This, the most frequent form of restricted dystonia, is localized to the neck muscles (see also page 929). It usually begins in early to middle adult life (peak incidence in the fifth decade) as a subtle tilting or turning of the head and tends to worsen slowly (Fig. 6-2A). A condition of unknown cause with the exception of the finding of DYT1 gene abnormality in some patients, it is somewhat more common in women. The quality of the neck and head movements varies; they may be deliberate and smooth or jerky or cause a persistent deviation of the head to one side. Sometimes brief bursts of myoclonic twitching or a slightly irregular, high-frequency tremor accompanies deviation of the head, possibly representing an effort to overcome the contraction of the neck muscles. The tremor tends to beat in the direction of the dystonic movement. The spasms are worse when the patient stands or walks and are characteristically reduced or abolished by a contactual stimulus, such as placing a hand on the chin or neck or exerting mild but steady counterpressure on the side of the deviation or sometimes on the opposite side, or bringing the occiput in contact with the back of a high chair. These maneuvers, termed *gestes*, become less effective as the disease progresses. In many cases, the spasms are reduced when the patient lies down. In chronic cases, as the dystonic position typically becomes increasingly fixed in position, the

(Photographs courtesy of Dr. Joseph M. Waltz.)

affected muscles undergo hypertrophy. Pain in the contracting muscles is a common complaint, especially if there is associated cervical arthropathy.

Although the most prominently affected muscles are the sternomastoid, levator scapulae, and trapezius, EMG studies also show sustained or intermittent activity in the posterior cervical muscles on both sides of the neck. The levator spasm lifts the affected shoulder slightly, and palpable tautness in this muscle is sometimes the earliest feature. As a general observation, we have been impressed with information gained from *palpating the muscles of the neck and shoulder* in order to establish which muscles are the predominant causes of the spasm. In most patients the spasms remain confined to the neck muscles and persist in unmodified form, but in some the spasms spread, involving muscles of the shoulder girdle and back or the face and limbs. The distinction between these two patterns is not fundamental. About 15 percent of patients with torticollis also have oral, mandibular, or hand dystonia, 10 percent have blepharospasm, and a similarly small number have a family history of dystonia or tremor (Chan et al). No neuropathologic changes were found in the single case studies reported by Tarlov and by Zweig and colleagues.

Spasmodic torticollis is resistant to treatment with L-dopa and other antiparkinsonian agents, although occasionally they give slight relief. In a few of our patients (four or five of several dozens), the condition disappeared without therapy, an occurrence observed in 10 to 20 percent in the series of Dauer et al. In their experience, remissions usually occurred during the first few years after onset in patients whose disease began relatively early in life; however, nearly all these patients relapsed within 5 years.

Treatment The periodic (every 3 to 4 months) injection of small amounts of botulinum toxin directly into several sites in the affected muscles is by far the most effective form of treatment. The injections are best guided by palpation of muscles in spasm and by EMG analysis to determine which tonically contracted muscles are most responsible for the aberrant postures. All but 10 percent of patients with torticollis have had some degree of relief from symptoms with this treatment. Adverse effects (excessive weakness of injected muscles, local pain and dysphagia—the latter from a systemic effect of the toxin) are usually mild and transitory. Five to 10 percent of patients eventually become resistant to repeated injections because of the development of neutralizing antibodies to the toxin (see Brin; also Dauer et al).

In the most severe cases and those refractory to treatment with botulinum toxin, a combined sectioning of the spinal accessory nerve (of the more affected sternomastoid) and of the first three cervical motor roots bilaterally has been successful in reducing spasm of the muscles without totally paralyzing them. Considerable relief has been achieved for as long as 6 years in one-third to one-half of cases treated in this way (Krauss et al, Ford et al). Bilateral thalamotomy has also been tried, but since it is less effective and carries a considerable risk, particularly to speech and swallowing, it should be reserved for the most severely affected patients with more widespread dystonia. These surgical procedures are rarely necessary now that botulinum toxin treatment has been refined.

Blepharospasm

From time to time, patients in late adult life, predominantly women, present with the complaint of inability to keep their eyes open. Any attempt to look at a person or object is associated with a persistent

tonic spasm of the eyelids (see Fig. 6-2B). During conversation, the patient struggles to overcome the spasms and is distracted by them. All customary activities are hampered to a varying extent. Reading and watching television are impossible at some times but surprisingly easy at others. Jankovic and Orman, in a survey of 250 such patients, found that the condition of 75 percent progressed in severity over the years to the point, in about 15 percent of cases, where the patients were, in effect, functionally blind. Many instances are a component of Meige syndrome (see next section).

One's first inclination is to think of this disorder as photophobia or a response to an ocular irritation, and indeed the patient may state that bright light is annoying (ocular inflammation, especially of the iris, may produce severe reflex blepharospasm). However, the spasms persist in dim light and even after anesthesia of the corneas. Extraocular movements are quite normal. Blepharospasm may occur as an isolated phenomenon, but just as often it is combined with oromandibular spasms (see below) and sometimes with spasmodic dysphonia, torticollis, and other dystonic fragments. With the exception of a depressive reaction in some patients, psychiatric symptoms are lacking, and the use of psychotherapy, acupuncture, behavior modification therapy, hypnosis, etc., has generally failed to cure the spasms. No neuropathologic lesion or uniform pharmacologic profile has been established in any of these disorders (Marsden et al; see also Hallett).

Treatment In the treatment of blepharospasm, a variety of antiparkinsonian, anticholinergic, and tranquilizing medications may be tried, but one should not be optimistic about the chances of success. A very few of our patients have had temporary and partial relief from L-dopa. Sometimes the blepharospasm disappears spontaneously (in 13 percent of the cases in the series of Jancovic and Orman). The most effective treatment consists of the injection of botulinum toxin into several sites in the orbicularis oculi and adjacent facial muscles. The benefit lasts for 3 to 5 months and repeated cycles of treatment are usually required. There appear to be few adverse systemic effects. Thermolytic destruction of part of the fibers in the branches of the facial nerves that innervate the orbicularis oculi muscles is reserved for the most resistant and disabling cases.

Other Causes of Blepharospasm There are several clinical settings other than the one described above in which blepharospasm may be observed. In the days following cerebral infarction or hemorrhage, the stimulus of lifting the patient's eyelids may lead to strong involuntary closure of the lids. *Reflex blepharospasm*, as Fisher has called this phenomenon, is more commonly associated with a left than a right hemiplegia and is more prominent on the nonparalyzed side. A homolateral blepharospasm has also been observed with a small thalamomesencephalic infarct. In patients with Parkinson disease, progressive supranuclear palsy, or Wilson disease and with other lesions in the rostral brainstem; light closure of the eyelids may induce blepharospasm and an inability to open the eyelids voluntarily.

We have seen an instance of blepharospasm as part of a paraneoplastic midbrain encephalitis, and there have been several reports of it with autoimmune disease such as systemic lupus but the mechanism in these cases is as obscure as for the idiopathic variety. Also among our patients have been two with myasthenia gravis and blepharospasm of the type described by Roberts and colleagues, but we have been unable to ascertain if this represented a functional disturbance or simply an exaggerated response to keeping the lids open. Finally, eye closure with fluttering of the lids in patients with a high degree of suggestibility is usually indicative of a functional disorder.

Lingual, Facial, and Oromandibular Spasms

These special varieties of involuntary movements also appear in later adult life, with a peak age of onset in the sixth decade. Women are affected more frequently than men. The most common type is characterized by forceful opening of the jaw, retraction of the lips, spasm of the platysma, and protrusion of the tongue; or the jaw may be clamped shut and the lips may purse (Fig. 6-2B). Other patterns include lateral jaw deviation and bruxism. Common terms for this condition are the *Meige syndrome*, after the French neurologist who gave an early description of it, and the *Brueghel syndrome*, because of the similarity of the grotesque grimace to that of a subject in a Brueghel painting called *De Gaper*. Difficulty in speaking and swallowing (spastic or spasmodic dysphonia) and blepharospasm are also frequently conjoined, and occasionally patients with these disorders develop torticollis or dystonia of the trunk and limbs. A number have tremor of affected muscles or of the hands as well. All these prolonged, forceful spasms of facial, tongue, and neck muscles have followed the administration of phenothiazine and butyrophenone drugs. More often, however, the disorder induced by neuroleptics is somewhat different, consisting of choreoathetotic chewing, lip smacking, and licking movements (tardive orofacial dyskinesia, rabbit-mouth syndrome; see later on and pages 1025 and 1327).

Very few cases of the Meige syndrome have been studied neuropathologically. In most of them no lesions were found. In one patient there were foci of neuronal loss in the striatum (Altrocchi and Forno); another patient showed a loss of nerve cells and the presence of Lewy bodies in the substantia nigra and related nuclei (Kulisevsky et al).

Treatment Many drugs have been used in the treatment of these craniocervical spasms, but none has effected a cure. Much greater success has been obtained with injections of botulinum toxin into the masseter, temporal, and internal pterygoid muscles. This is true also for spasmodic dysphonia (discussed more fully on page 428), which responds favorably to injections of the toxin into the thyroarytenoid vocalis muscles.

A form of focal dystonia that affects only the jaw muscles has been described (*masticatory spasm* of Romberg); a similar dystonia may be a component of orofacial and generalized dystonias. In the cases described by Thompson and colleagues, the problem began with brief periods of spasm of the pterygoid or masseter muscle on one side. Early on, the differential diagnosis includes bruxism, hemifacial spasm, the odd rhythmic jaw movements associated with Whipple disease, and tetanus. As the illness progresses, forced opening of the mouth and lateral deviation of the jaw may last for days and adventitious lingual movements may be added. A form that occurs with hemifacial atrophy has been described by Kaufman. High doses of benztropine may be helpful, but local botulinum toxin injection is probably the best alternative. An intermittent spasm that is confined to one side of the face (hemifacial spasm) is not, strictly speaking, a dystonia and is considered with disorders of the facial nerve on page 1184.

Writer's Cramp, Musician's Spasm, and Other So-Called Occupational Dystonias

So-called occupational cramps or spasms should be mentioned here, since the prevailing opinion is that they are restricted or focal

"task-specific" dystonias. Men and women are equally affected, most often between the ages of 20 and 50 years. In the commonest form, *writer's cramp*, the patient observes, upon attempting to write, that all the muscles of the thumb and fingers either go into spasm or are inhibited by a feeling of stiffness and pain or hampered in some other inexplicable way (similar to what is shown in Fig. 6-2C). The spasm may be painful and can spread into the forearm or even the upper arm and shoulder. Sometimes the spasm fragments into a tremor that interferes with the execution of fluid, cursive movements. Immediately upon cessation of writing, the spasm disappears. Although the disturbance in writer's cramp is usually limited to the specific act of writing, it may involve other equally demanding manual tasks. At all other times and in the execution of grosser movements, the hand is normal, and there are no other neurologic abnormalities. Many patients learn to write in new ways or to use the other hand, though that, too, may become involved. A few of our younger patients have developed spasmodic torticollis at a later date.

The performance of other highly skilled motor acts, such as playing the piano or fingering the violin, may acquire a similar highly task dependent spasm ("musician's cramp") or in the past, telegrapher's palsy. The "loss of lip" in trombonists and other instrumentalists represents an analogous phenomenon, seen only in experienced musicians. In each case a delicate motor skill, perfected by years of practice and performed almost automatically, suddenly comes to require a conscious and labored effort for its execution. Discrete movements are impaired by a spreading recruitment of unneeded muscles (intention spasm), a feature common to athetotic states.

The nature of these disorders is quite obscure. They had been classed in the past as "occupational neuroses," and a psychiatric causation was suggested repeatedly, but careful clinical analysis has not borne this out. Once developed, the disability persists in varying degrees of severity, even after long periods of inactivity of the affected part.

In monkeys, Byl and colleagues found that sustained, rapid, and repetitive highly stereotypical movements greatly expanded the area of cortical representation of sensory information from the hand. These authors hypothesized that degradation of sensory feedback to the motor cortex was responsible for excessive and persistent motor activity, including dystonia. Such an enlargement of the area of cortical response to magnetic stimulation has also been found by a number of investigators in patients with writer's cramp. Other theories pertaining to the physiology of the focal dystonias have been reviewed by Berardelli et al.

Treatment A high degree of therapeutic success has been obtained by injections of botulinum toxin into specifically involved muscles of the hand and forearm (Cohen et al, Rivest et al) and this is now the most widely used form of therapy. It has been claimed that the patient can be helped by a deconditioning procedure that delivers an electric shock whenever the spasm occurs or by biofeedback, but these forms of treatment have not been rigorously tested.

Drug-Induced Tardive Dyskinesias

(See also Chap. 43)

As already mentioned, dyskinesia is a broadly encompassing term that is applied to all involuntary movements taking the forms of dystonia, chorea, athetosis, and tremor. When modified by the ad-

jective *tardive*, it refers specifically to movements induced by the use of antipsychotic drugs, usually phenothiazines, that persist after the drugs are withdrawn. The movements are intermittent or persistent and not subject to the will of the patient. The facial, lingual, eyelid, and bulbar muscles are most often involved, but neck, shoulder, and spine muscles with arching of the back may be implicated in individual cases. In particular, *tardive dyskinesia* has come to refer to striking repetitive, stereotyped, almost rhythmic mouth and tongue movements that follow exposure to an offending drug and that, once established, persists for months or years. If the drug is discontinued immediately after the movements appear, the problem may not persist. There may be added blepharospasm and truncal, hand, or neck movements and akathisia of the legs, but these are not nearly so prominent as the orofacial and lingual dyskinesias. The problem is easily recognized and familiar to all physicians who treat psychiatric patients. Oromandibular spasm and blepharospasm (Meige syndrome) and Huntington disease may cause difficulty in diagnosis.

In addition to the well-known phenothiazine drugs, less familiar ones such as metoclopramide, pimozide, amoxapine, and clebopride, some of which are used for disorders other than psychosis, and newer agents such as risperidone may also be the cause. Longer exposure is more likely to cause the movements.

There are a number of other drug-induced tardive movement syndromes, mainly varieties of dystonias, some of which have been mentioned earlier, and akathisia (see further on). Often they begin focally in the neck and spread over time to the limbs. One highly characteristic pattern combines retrocollis, backwards arching of the trunk, internal rotation of the arms, extension of the elbows, and flexion of the wrists simulating a decerebrate posture. A few patients have both orofacial and cervical dyskinesias. Many patients report that the dystonia abates during walking and other activities, quite unlike idiopathic torsion dystonia. In current thinking, these drug-induced dyskinesias are viewed as the result of changes in the concentration of dopamine receptors, five of which are currently known, as discussed in Chap 4. Blockade and subsequent unmasking of the D₂ receptor has been specifically linked to the development of the tardive syndromes.

Treatment With reference to therapy, little has been found to be consistently effective. If the movements follow withdrawal of one of the offending drugs, reinstitution of the medication in small doses often reduces the dyskinesias but has the undesired side effects of causing parkinsonism and drowsiness. For this reason most clinicians who are experienced in this field have tended to avoid using these drugs if possible. The movements lessen over a period of months or years and mild cases abate on their own or leave little residual effect; rarely have the symptoms worsened. Some of the newer “atypical” antipsychotic drugs (clozapine, quetiapine, etc.) are reported to be helpful in a few cases and are favored as an initial treatment, particularly if persistent psychosis requires continued drug therapy. Their effect is believed to be the result of slight blocking of D₂ activity.

Dopamine and noradrenergic-depleting drugs such as reserpine and tetrabenazine have also been as successful if used carefully, but the more effective of the two, tetrabenazine, is difficult to obtain in the United States. The dystonias also respond to anticholinergic drugs (trihexyphenidyl 2.5 mg once or twice daily, increased by small increments weekly up to 12.5 mg) if high enough doses can be tolerated.

Further discussion of the side effects of the antipsychosis drugs can be found on page 1327.

TICS AND HABIT SPASMS

Many persons throughout their lives are given to habitual movements. These range from simple, highly personalized, idiosyncratic mannerisms (e.g., of the lips and tongue) to repetitive actions such as sniffing, clearing the throat, protruding the chin, or blinking whenever these individuals become tense. Stereotypy and irresistibility are the main identifying features of these phenomena. The patient admits to making the movements and feels compelled to do so in order to relieve perceived tension. Such movements can be suppressed for a short time by an effort of will, but they reappear as soon as the subject's attention is diverted. In certain cases the tics become so ingrained that the person is unaware of them and seems unable to control them. An interesting feature of many tics is that they correspond to coordinated acts that normally serve some purpose to the organism. It is only their incessant repetition when uncalled for that marks them as habit spasms or tics. The condition varies widely in its expression from a single isolated movement (e.g., blinking, sniffing, throat clearing, or stretching the neck) to a complex of movements.

Children between 5 and 10 years of age are especially likely to develop habit spasms. These consist of blinking, hitching up one shoulder, sniffing, throat clearing, jerking the head or eyes to one side, grimacing, etc. If ignored, such spasms seldom persist for longer than a few weeks or months and tend to diminish if the child is provided rest and a calmer environment. In adults, relief of nervous tension by sedative or tranquilizing drugs may be helpful, but the disposition to tics persists. A putative relationship to streptococcal infection is discussed below.

When idle, adults often display a wide variety of fidgeting types of movement, gestures, and mannerisms that vary in degree from one person to another. They are slower and more complex than tics and spasms. Laypersons refer to them as “bad habits.” Special types of rocking, head bobbing, hand waving (in autism) or hand wringing (typical of Rett syndrome), and other movements, particularly self-stimulating movements, are disorders of motility unique to the mentally retarded. These “rhythmias” have no known pathologic anatomy in the basal ganglia or elsewhere in the brain. Apparently they represent a persistence of some of the rhythmic, repetitive movements (head banging, etc.) of normal infants. In some cases of impaired vision and photic epilepsy, eye rubbing or moving the fingers rhythmically across the field of vision is observed, especially in mentally retarded children.

Gilles de la Tourette Syndrome (Tourette Syndrome)

Multiple tics—sniffing, snorting, involuntary vocalization, and troublesome compulsive and aggressive impulses—constitute the rarest and most severe tic syndrome, Tourette syndrome. The problem begins in childhood, in boys three times more often than girls, usually as a simple tic; as the condition progresses, new tics are added to the repertoire. It is the multiplicity of tics and the combination of motor and vocal tics that distinguish the Tourette syndrome from the more benign, restricted tic disorders.

Vocal tics, usually loud and irritating in pitch, are characteristic. Some patients display repetitive and annoying motor behavior, such as jumping, squatting, or turning in a circle. Other common types of repetitive behavior include the touching of other persons and repeating one's own words (palilalia) and the words or movements of others. Explosive and involuntary cursing and the

compulsive utterance of obscenities (coprolalia) are the most dramatic manifestations. Interestingly, the latter phenomena are uncommon in Japanese patients, whose decorous culture and language contain few obscenities. The full repertoire of tics and compulsions comprised by the Tourette syndrome has been described by Tolosa and Bayes and in the reviews by Jankovic and by Leckman, which are recommended.

Stone and Jankovic have noted the occurrence of persistent blepharospasm, torticollis, and other dystonic fragments in a small number of patients with Tourette syndrome. Isometric contractions of isolated muscle groups (tonic tics) also occur in some patients. As in other tic disorders, there is a premonitory sensation of tightness, discomfort or paresthesias, or a psychic sensation or urge that is relieved by the movement. A fair proportion stutter or display a mild dysfluency of speech. So-called soft neurologic signs are noted in half of the patients. Feinberg and associates have described four patients with arrhythmic myoclonus and vocalization, but it is not clear whether these symptoms represent an unusual variant of Tourette disease or a new syndrome. A degree of cyclicality of symptoms has been noted by several authors; tics tend to happen in groups over minutes or hours and they are clustered over weeks and months. This gives the appearance of a waxing and waning process.

The course of the illness is unpredictable. In half of adolescents the tics subside spontaneously by early adulthood and those that persist become milder with time. Others undergo long remissions only to have tics recur, but in other patients the motor disorder persists throughout life. This variability emphasizes the difficulty in separating transient habit spasms from the Tourette chronic multiple tic syndrome. Isolated and mild but lifelong motor tics probably represent a variant of Tourette syndrome insofar as they display the same predominantly male heredofamilial pattern and similar responses to medication.

As to behavioral disturbances, an attention-deficit hyperactivity disorder (see page 511), obsessive-compulsive traits, or both are said to be evident at some time in the course of the illness, and these interfere to a greater degree than do the tics with progress in school. Poor control of temper, impulsiveness, self-injurious behavior, and certain sociopathic traits are seen in some but by no means all affected children. Evidence of "organic" impairment by psychologic tests was found in 40 to 60 percent of Shapiro's series of patients. Intelligence does not deteriorate. Nonspecific abnormalities of the EEG occur in more than half of the patients but are not consistent enough to be considered a feature of the disease.

In one-third of the cases reported by Shapiro and colleagues, tics were observed in other members of the family. Several other studies have reported a familial clustering of cases in which the pattern of transmission appears to be autosomal dominant with incomplete penetrance (Pauls and Leckman) but this has been disputed and several other potential patterns of transmission that contain predisposing genes have been found by linkage analysis. In any genetic explanation, the marked predominance of males must be accounted for. At the moment, Tourette disease cannot be attributed to a single genetic locus; however, in a given family, the process may arise from simultaneous variants in more than one gene (so called "complex genetics"). Nonetheless, support for the primary genetic nature of Tourette syndrome derives from twin studies, which have revealed higher concordance rates in monozygotic twin pairs than in dizygotic pairs. An ethnic bias (Ashkenazi Jews) has been reported, ranging from 19 to 62 percent in several series, but this has not been borne out in equally large series outside of New York (Lees et al).

As to causation, little is known. The disease is unrelated to social class or to psychiatric illness; there is no consistent association with infection, trauma, or other disease. Hyperactive children who have been treated with stimulants appear to be at increased risk of developing or exacerbating tics (Price et al), but a causal relationship has not been established beyond doubt (see comments regarding treatment below). Reports of a relationship to obsessive-compulsive neurosis have also been inconsistent. Magnetic resonance imaging has shown no uniform abnormalities, and functional imaging has demonstrated numerous but inconsistent abnormalities. Histopathologic changes have not been discerned in the few brains examined by the usual methods. However, Singer and co-workers, who analyzed pre- and postsynaptic dopamine markers in postmortem striatal tissue, found a significant alteration of dopamine uptake mechanisms; more recently, Wolf and colleagues have found that differences in D₂ dopamine receptor binding in the head of the caudate nucleus reflected differences in the phenotypic severity of Tourette syndrome. These observations, coupled with the facts that L-dopa exacerbates the symptoms of Tourette syndrome and that haloperidol, which blocks dopamine (particularly D₂) receptors, is an effective treatment, support the notion of a dopaminergic abnormality in the basal ganglia, more specifically in the caudate nucleus. In this respect, reported instances of compulsive behavior in relation to lesions in the head of the caudate nucleus and its projections from orbitofrontal and cingulate cortices may be pertinent.

Using the model of Sydenham chorea, a recent line of investigation has implicated streptococcal infection in the genesis of abruptly appearing Tourette syndrome and of less generalized tics in children. This association has also been adopted by some authors to explain obsessive-compulsive behavior of sudden and unexplained onset. These putative disorders have been summarized by Swedo and colleagues under the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders with streptococcal infection). In a few cases there has been a relapsing course that is similar to that seen in some Sydenham cases. This information is intriguing but not confirmed.

Treatment Two classes of drugs are used in treatment. The alpha₂-adrenergic agonists clonidine and guanfacine have been useful in several studies, but not in others. These are not as potent as the treatment with neuroleptic drugs, but their side effects are far less severe and they are recommended as the first treatment. The newer drug, guanfacine has the advantage over clonidine of daily dosing and less sedating effect. The initial dose is 0.5 to 1 mg given at bedtime and gradually increased as needed to a total dose of 4 mg. Clonidine is started as a bedtime dose of 0.05 mg and increased every several days by 0.05 mg until a total dose of about 0.1 mg three times daily; guanfacine is given as 1 mg at bedtime and increased by 1 mg monthly, up to 3 mg if needed. The neuroleptics haloperidol, pimozide, sulpiride, and tiapride have proved to be effective therapeutic agents but should be used only in severely affected patients and only after the adrenergic agents have been tried. Haloperidol is instituted in small doses (0.25 mg initially, increasing the dosage gradually to 2 to 10 mg daily). The addition of benztrapine mesylate (0.5 mg daily) at the outset of treatment may help to prevent the adverse motor effects of haloperidol. Pimozide, which has a more specific antidopaminergic action than haloperidol, may be more effective than haloperidol; it should be given in small amounts (0.5 mg daily) to begin with and increased gradually to 8 to 9 mg daily. The so-called atypical neuroleptics, such as risperidone, have also been used with some success. The

potent agent tetrabenazine, a drug that depletes monoamines and blocks dopamine receptors, may be useful if high doses can be tolerated. Further details of the use of these drugs can be found in the review by Leckman.

Simple and isolated motor tics sometimes respond well to clonazepam. Another interesting approach has been to inject botulinum toxin in muscles affected by prominent focal tics, including the vocal ones as described by Scott and colleagues; curiously, this treatment is said to relieve the premonitory sensory urge. Kurlan and associates have noted a lessening of tics after treatment with naltrexone, 50 mg daily. According to a trial conducted by the Tourette's Syndrome Study Group, the hyperactivity component of the Tourette syndrome can be treated safely with methylphenidate or clonidine without fear of worsening the tics.

Akathisia

The term *akathisia* was coined by Haskovec in 1904 to describe an inner feeling of restlessness, an inability to sit still, and a compulsion to move about. When sitting, the patient constantly shifts his body and legs, crosses and uncrosses his legs, and swings the free leg. Running in place and persistent pacing are also characteristic. This abnormality of movement is most prominent in the lower extremities and may not be accompanied, at least in mild forms

of akathisia, by perceptible rigidity or other neurologic abnormalities. In its advanced form, patients complain of difficulty in concentration, distracted, no doubt, by the constant movement.

First noted in patients with Parkinson disease and senile dementia, akathisia is now observed most often in patients receiving neuroleptic drugs (pages 1025 and 1327). However, this disorder may be observed in psychiatric patients who are receiving no medication and in some unmedicated patients with Parkinson disease; it can also be induced in normal individuals by the administration of neuroleptic drugs or L-dopa.

The main diagnostic considerations are an agitated depression, particularly in patients already on neuroleptic medications, and the "restless legs" syndrome of Ekbom—a sleep disorder that may be evident during wakefulness in severe cases (page 339). Patients with the latter affliction describe a crawling sensation in the legs rather than an inner restlessness, although both disorders create an irresistible desire for movement. At times these distinctions are blurred and treatment must be empiric. Many of the medications utilized for the restless legs syndrome, such as propoxyphene or clonazepam, may be tried, or treatment can be directed to the akathisia by selecting a less potent neuroleptic (if it is the suspected cause) or by using an anticholinergic medication, amantadine, or—perhaps the most effective and best tolerated—beta-adrenergic blocking drugs.

CHAPTER 7

DISORDERS OF STANCE AND GAIT

Certain disorders of motor function manifest themselves most clearly as impairments of upright stance and locomotion; their evaluation depends on a knowledge of the neural mechanisms underlying these peculiarly human functions. Analysis of stance, carriage, and gait is a particularly rewarding medical exercise; with some experience, the examiner can sometimes reach a neurologic diagnosis merely by noting the manner in which the patient enters the office. Considering the frequency of falls that result from gait disorders and their consequences, such as hip fractures, and the resultant need for hospital and nursing home care, this is an important subject for all physicians. The substantial dimensions of this latter problem are described by Tinetti and Williams.

NORMAL GAIT

The normal gait seldom attracts attention, but it should be observed with care if slight deviations from normal are to be appreciated. The body is erect, the head is straight, and the arms hang loosely and gracefully at the sides, each moving rhythmically forward with the opposite leg. The feet are slightly everted, the steps are approximately equal, and the internal malleoli almost touch as each foot passes the other. The medial edges of the heels, as they strike the ground with each step, form a straight line. As each leg moves forward, there is coordinated flexion of the hip and knee, dorsiflexion of the foot, and a barely perceptible elevation of the hip, so that the foot clears the ground. Also, with each step, the thorax advances slightly on the side opposite the swinging lower limb. The heel strikes the ground first, and inspection of the shoes will show that this part is most subject to wear. The muscles of greatest importance in maintaining the erect posture are the erector spinae and the extensors of the hips and knees.

The normal *gait cycle*, defined as the period between successive points at which the heel of the same foot strikes the ground, is illustrated in Fig. 7-1; it is based on the studies of Murray and coworkers and of Olsson. In this figure, the cycle is initiated by the heel strike of the right foot. The *stance phase*, during which the foot is in contact with the ground, occupies 60 to 65 percent of the cycle. The *swing phase* begins when the right toes leave the ground. Noteworthy is the fact that for 20 to 25 percent of the walking cycle, both feet are in contact with the ground (*double limb support*). In later life, when the steps shorten and the cadence (the rhythm and number of steps per minute) decreases, the proportion of double limb support increases (see further on). Surface electromyograms show an alternating pattern of activity in the legs, predominating in the flexors during the swing phase and in the extensors during the stance phase.

When analyzed in greater detail, the requirements for locomotion in an upright, bipedal position may be reduced to the following elements: (1) antigravity support of the body, (2) stepping, (3) the maintenance of equilibrium, and (4) a means of propulsion. Locomotion is impaired in the course of neurologic disease when one or more of these mechanical principles are prevented from operating normally.

The upright support of the body is provided by *righting* and *antigravity reflexes*, which allow a person to arise from a lying or sitting position to an upright bipedal stance and to maintain firm extension of the knees, hips, and back, modifiable by the position of the head and neck. These postural reflexes depend on the afferent vestibular, somatosensory (proprioceptive and tactile), and visual impulses, which are integrated in the spinal cord, brainstem, and basal ganglia. Transection of the neuraxis between the red and vestibular nuclei leads to exaggeration of these antigravity reflexes—decerebrate rigidity.

Stepping, the second element, is a basic movement pattern present at birth and integrated at the spinal-midbrain-diencephalic levels. It is elicited by contact of the sole with a flat surface and a shifting of the center of gravity—first laterally onto one foot, allowing the other to be raised, and then forward, allowing the body to move onto the advancing foot. Rhythmic stepping movements can be initiated and sustained in decerebrate or “spinal” cats and dogs. This is accomplished through the activity of interneurons that are organized as rhythmic “locomotor generators,” akin to the pattern generators that permit the rhythmic movement of wings or fins. There is no evidence for a similar system of locomotor control in monkeys or humans, in whom the spinal mechanisms for walking cannot function independently but depend upon higher command centers. The latter are located in the posterior subthalamic region, caudal midbrain tegmentum, and pontine reticular formation; they control the spinal gait mechanisms through the rubrospinal, vestibulospinal, and tectospinal pathways in the ventral cord (see Eidelberg and colleagues and Lawrence and Kuypers). Probably, in the human, the brainstem locomotor regions are also activated by cerebral cortical centers.

Equilibrium involves the maintenance of balance in relation to gravity and to the direction of movement in order to retain a vertical posture. The center of gravity during the continuously unstable equilibrium that prevails in walking must shift within narrow limits from side to side and forward as the weight is borne first on one foot, then on the other. This is accomplished through the activity of highly sensitive postural and righting reflexes, both peripheral (stretch reflexes) and central (vestibulocerebellar reflexes). These reflexes are activated within 100 ms of each shift in the support surface and require reliable afferent information from the visual, vestibular, and proprioceptive systems.

Propulsion is provided by leaning forward and slightly to one side and permitting the body to fall a certain distance before being checked by the support of the leg. Here, both forward and alternating lateral movements must occur. But in running, where at onemoment both feet are off the ground, a forward drive or thrust by the hind leg is also needed.

Obviously, gait varies considerably from one person to another, and it is a commonplace observation that a person may be identified by the sound of his footsteps, notably the pace and the lightness or heaviness of tread. The manner of walking and the carriage of the body may even provide clues to an individual's personality and occupation; Sherlock Holmes expressed great pride

in his talent for reading such clues. Furthermore, the gaits of men and women differ, a woman's steps being quicker and shorter and movement of the trunk and hips more graceful and delicate. Certain female characteristics of gait observed in the male immediately impart an impression of femininity; likewise, male characteristics observed in the female suggest masculinity. The changes in stance and gait that accompany aging—the slightly stooped posture and slow, stiff tread, as described in Chap. 29, on aging—are so familiar that they are not perceived as abnormalities.

ABNORMAL GAITS

Since normal body posture and locomotion require intact vestibular function, proprioception, and vision (we see where we are going and pick our steps), the effects on normal function of deficits in these senses are worth noting.

A blind person—or a normal one who is blindfolded or walks in the dark—moves cautiously, with arms slightly forward to avoid collisions, and shortens his step slightly on a smooth surface; with shortening of the step, there is less rocking of the body and the gait is unnaturally stiff and cautious.

Disorders of vestibular function in relation to gait disorders are most often the result of prolonged administration of aminoglycoside antibiotics or other toxic medications, which destroy the hair cells of the vestibular labyrinth. This also occurs in some patients in the late stages of Ménière disease and, infrequently, for no definable reason. Patients with vestibulopathy show unsteadiness in standing and walking, often without widening their base, and an inability to descend stairs without holding onto the banister. They complain of a particular type of imbalance, usually with movement but at times when standing still—a sensation that may be likened to being on the deck of a rolling ship. Running and turning quickly are even more impaired, with lurching in all directions. The patient has great difficulty in focusing his vision on a fixed target when he is moving or on a moving target when he is either stationary or moving. When the body is in motion or the head is moved suddenly, objects in the environment may appear momentarily blurred or actually jiggle up and down or from side to side (oscillopsia). Driving a car or reading on a train is difficult or impossible; even when walking, the patient may need to stop in order to read a sign. These abnormalities indicate a loss of stabilization of ocular fixation by the vestibular system during body movements. An elderly person, unlike a child or young adult, has difficulty compensating for these abnormalities. Proof that the gait of such persons is dependent on visual clues comes from their performance blindfolded or in the dark, when their unsteadiness and staggering increase to the point of falling. When standing with eyes closed, they sway more than normal but generally do not have a Romberg sign, as described below. The diagnosis is confirmed by testing labyrinthine function (caloric and rotational testing, electronystagmography, and posture platform testing).

A loss of proprioception—as occurs in patients with severe large-fiber polyneuropathy, posterior root lesions (e.g., tabes dorsalis, lumbosacral compression), or interruption of the posterior columns in the cervical spinal cord (multiple sclerosis, vitamin B₁₂

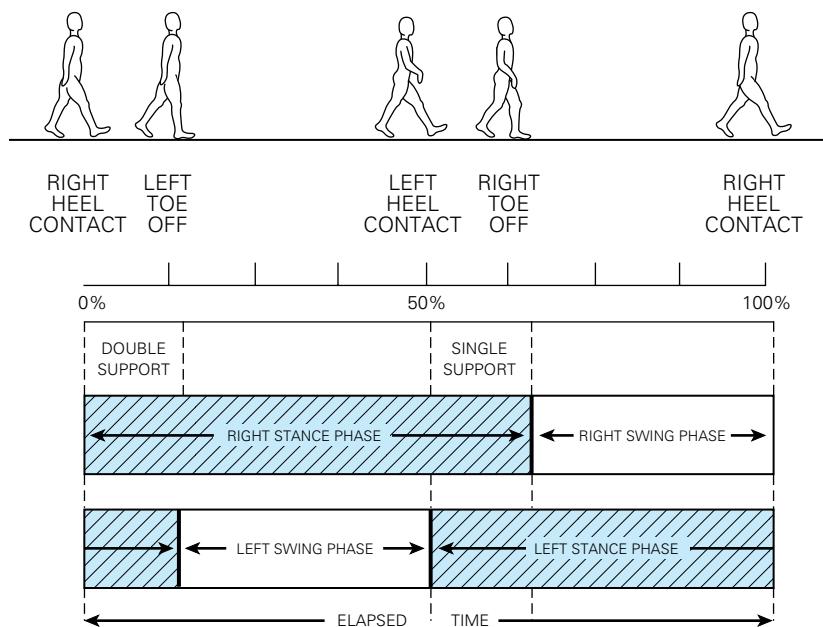

Figure 7-1. The normal gait cycle, based on the studies of Olsson and of Murray et al. See text for details.

deficiency, spondylotic or tumor compression)—abolishes or seriously impairs the capacity for independent locomotion. After years of training, such patients still have difficulty in initiating gait and in forward propulsion. As Purdon Martin illustrated, they hold their hands slightly in front of the body, bend the body and head forward, walk with a wide base and irregular, uneven steps, but still rock the body. If they are tilted to one side, they fail to compensate for their abnormal posture. If they fall, they cannot rise without help; they are unable to crawl or to get into an “all fours” posture. They have difficulty in getting up from a chair. When standing, if instructed to close their eyes, they sway markedly and fall (*Romberg sign*); this sign is the clearest indication that the origin of the problem is a loss of proprioceptive sensibility. This also informs us that static postural reactions are primarily dependent on these proprioceptive sensibilities rather than on visual or labyrinthine information.

With lesions of the basal ganglia, both in monkeys and in humans, the posture of the body and the postural responses to disturbed equilibrium are faulty. There is difficulty in taking the first step; once it is taken, the body pitches forward and a fall can be prevented only by catch-up stepping (propulsion). Similarly, a step backward may induce a series of quickening steps in that direction (retropulsion). Corrective righting reflexes are clearly in abeyance when the patient is pushed off balance (Denny-Brown). These abnormalities are elaborated further on, under “Festinating and Parkinsonian Gait.”

Examination of the Patient with Abnormal Gait

When confronted with a disorder of gait, the examiner must observe the patient's stance and the attitude and dominant positions of the legs, trunk, and arms. It is good practice to watch patients as they walk into the examining room, when they are apt to walk more naturally than during the performance of special tests. They should be asked to stand with feet together and head erect, with

eyes open and then closed. A normal person can stand with feet together and eyes closed while moving the head from side to side, a test that eliminates both visual and vestibular cues and induces certain compensatory trunk and leg movements that depend on proprioceptive afferent mechanisms (Ropper). As already mentioned, the Romberg sign—marked swaying or falling with the eyes closed but not with the eyes open—usually indicates a loss of postural sense, not of cerebellar function, although with vestibular or cerebellar dysfunction there may be a less pronounced exaggeration of swaying with eyes closed and feet together. Swaying due to nervousness may be overcome by asking the patient to touch the tip of his nose alternately with the forefinger of one hand and then the other.

Next, the patient should be asked to walk, noting in particular any hesitation in starting and negotiating turns, width of base, length of stride, foot clearance, arm swing, and cadence. A tendency to veer to one side, as occurs with unilateral cerebellar disease, can be brought out by having the patient walk around a chair. When the affected side is toward the chair, the patient tends to walk into it; when it is away from the chair, there is a veering outward in ever-widening circles. More delicate tests of gait are walking a straight line heel to toe (“tandem walking test”), walking backward, and having the patient arise quickly from a chair, walk briskly, stop and turn suddenly, walk back and then sit down again.

It is instructive to observe the patient’s postural reaction to a sudden push backward and forward or to the side. With postural instability there is a delay or inadequacy of corrective actions. Finally, the patient should be asked to hop on one leg and to jog. If all these tests are successfully executed, it may be assumed that any difficulty in locomotion is not due to impairment of a proprioceptive, labyrinthine-vestibular, basal ganglionic, or cerebellar mechanism. Detailed musculoskeletal and neurologic examination is then necessary to determine which of several other disturbances of function is responsible for the patient’s disorder of gait.

The following types of abnormal gait (Table 7-1) are so distinctive that, with a little practice, they can be recognized at a glance and interpreted correctly.

Cerebellar Gait

The main features of this gait are a wide base (separation of legs), unsteadiness, irregularity of steps, and lateral veering. Steps are uncertain, some are shorter and others longer than intended, and the patient may compensate for these abnormalities by shortening his steps and shuffling, i.e., keeping both feet on the ground simultaneously. Cerebellar gait is often referred to as “reeling” or “drunken,” but these adjectives are not entirely apt, as explained further on.

With cerebellar ataxia, the unsteadiness and irregular swaying of the trunk are more prominent when the patient arises from a chair or turns suddenly while walking and may be most evident when he has to stop walking abruptly and sit down; it may be necessary for him to grasp the chair for support. It is noteworthy that patients with purely cerebellar gait abnormalities may not complain of imbalance or vertigo. Cerebellar ataxia may be so severe that the patient cannot stand without assistance. If it is less severe, standing with feet together and head erect is difficult. In its mildest form, the ataxia is best demonstrated only by having the patient walk a line heel to toe; after a step or two, he loses his balance and finds it necessary to place one foot to the side to avoid falling.

As already emphasized, the patient with cerebellar ataxia who sways perceptibly when standing with feet together and eyes open will sway somewhat more with eyes closed. By contrast, removal of visual clues from a patient with proprioceptive loss causes a marked increase in swaying or falling (Romberg test). Thus, the defect in cerebellar gait is not primarily in antigravity support, step-page, or propulsion but in the coordination of the sensory input from proprioceptive, labyrinthine, and visual information with reflex movements, particularly those that are required to make rapid adjustments to changes in posture and position.

Cerebellar abnormalities of stance and gait are usually accompanied by signs of cerebellar incoordination of the arms and legs, but they need not be. The presence of the latter signs depends on involvement of the cerebellar hemispheres as distinct from the anterosuperior (vermian) midline structures which dominate in the

Table 7-1
Features of gait abnormalities

	CADENCE	STEP LENGTH	BASE	OTHER ASSOCIATED SIGNS
<i>Cerebellar</i>	Irregular	Slightly short	Wide	Erratic shifting of weight
<i>Sensory ataxic</i>	Normal	Short	Slightly wide	Excessive force in step resulting in stamping
<i>Steppage</i>	Normal	Normal	Normal	Overlifting and slapping of feet
<i>Plegic</i>	Slow	Short	Narrow	Circumduction and scraping of affected leg(s)
<i>Dystonic</i>	Slow	Normal	Erratic	Twisting athetoid movements interrupt walking
<i>Parkinsonian-festinating</i>	Slow until festination	Short	Normal	Quicken step, forward leaning, shuffling, may have trouble with gait initiation
<i>Waddling-myopathic</i>	Normal	Normal	Slightly wide	Overlifting of hip(s)
<i>Toppling</i>	Slow until fall	Short	Widened (protective)	Sudden loss of balance
<i>Normal pressure hydrocephalus</i>	Slow	Short	Slightly wide	Numerous problems with handling axial body movement
<i>Frontal lobe</i>	Slow	Greatly shortened	Slightly wide (protective)	Difficulty starting and stopping; tendency for feet to “stick” to floor
<i>Aging and marche à petit pas</i>	Slow	Slightly shortened	Slightly widened	Cautious, slight forward lean

control of gait as described in Chap. 5. If the cerebellar lesions are bilateral, there is often titubation (tremor) of the head and trunk.

Cerebellar gait is seen most commonly in patients with multiple sclerosis, cerebellar tumors (particularly those affecting the vermis disproportionately—e.g., medulloblastoma), stroke (ischemic and hemorrhage), and most dramatically in the cerebellar degenerations. In certain forms of cerebellar degeneration in which the disease process remains stable for many years, e.g., the type associated with chronic alcoholism, the gait disorder becomes altered as compensations are acquired. The base is wide and the steps are still short but more regular, the trunk is inclined slightly forward, the arms are held somewhat away from the body, and the gait assumes a more mechanical, rhythmic quality. In this way the patient can walk for long distances, but he still lacks the capacity to make the necessary postural adjustments in response to sudden changes in position, such as occur in walking on uneven ground.

Many patients with cerebellar disease, particularly of acute type, also show pendularity of the patellar reflexes and other signs of hypotonia of the limbs when they are examined in the sitting or recumbent position, as discussed in Chap. 5. Paradoxically, walking without the support of a cane or the arm of a companion brings out a certain stiffness of the legs and firmness of the muscles. The latter abnormality may be analogous to positive supporting reactions observed in cats and dogs following ablation of the anterior vermis; such animals react to pressure on the foot pad with an extensor thrust of the leg.

Drunken, or Reeling, Gait

This is characteristic of intoxication with alcohol, sedative drugs, and anticonvulsants. The drunken patient totters, reels, tips forward and then backward, appearing each moment to be on the verge of losing his balance and falling. Control over the trunk and legs is greatly impaired. The steps are irregular and uncertain. Such patients appear stupefied and indifferent to the quality of their performance, but under certain circumstances they can momentarily correct the defect. As indicated above, the adjectives *drunken* and *reeling* are used frequently to describe the gait of cerebellar disease, but the similarities between them are only superficial. The severely intoxicated patient reels or sways in many different directions and seemingly makes little or no effort to correct the staggering by watching his legs or the ground, as in cerebellar or sensory ataxia. Also, the variability of the drunken gait is noteworthy. Despite wide excursions of the body and deviation from the line of march, the drunken patient may, for short distances, be able to walk on a narrow base and maintain his balance. In contrast, the patient with cerebellar gait has great difficulty in correcting his balance if he sways or lurches too far to one side. Milder degrees of the drunken gait more closely resemble the gait disorder that follows loss of labyrinthine function (see earlier discussion).

Gait of Sensory Ataxia

This disorder is due to an impairment of joint position or muscular kinesthetic sense resulting from interruption of afferent nerve fibers in the peripheral nerves, posterior roots, sensory ganglia, posterior columns of the spinal cords, or medial lemnisci and occasionally from a lesion of both parietal lobes. Whatever the location of the lesion, its effect is to deprive the patient of knowledge of the po-

sition of his limbs and, more relevant to gait, to interfere with afferent kinesthetic information that does not attain conscious perception. A sense of imbalance is usually present but these patient's do not describe dizziness. These patients are aware that the trouble is in the legs and not in the head, that foot placement is awkward, and that the ability to recover quickly from a misstep is impaired. The resulting disorder is characterized by varying degrees of difficulty in standing and walking; in advanced cases, there is a complete failure of locomotion, although muscular power is retained.

The principal features of the gait disorder are the brusqueness of movement of the legs and stamping of the feet. The feet are placed far apart to correct the instability, and patients carefully watch both the ground and their legs. As they step out, their legs are flung abruptly forward and outward, in irregular steps of variable length and height. Many steps are attended by an audible stamp as the foot is forcibly brought down onto the floor (possibly to enhance joint position sense). The body is held in a slightly flexed position, and some of the weight is supported on the cane that the severely ataxic patient usually carries. To use Ramsay Hunt's characterization, the patient with this gait disorder is recognized by his "stamp and stick." We find similarities in various portrayals of Shelley's Frankenstein. The ataxia is markedly exaggerated when the patient is deprived of his visual cues, as in walking in the dark. Such patients, when asked to stand with feet together and eyes closed, show greatly increased swaying or falling (Romberg sign). It is said that in cases of sensory ataxia, the shoes do not show wear in any one place because the entire sole strikes the ground at once. Examination invariably discloses a loss of position sense in the feet and legs and usually of vibratory sense as well.

Formerly, a disordered gait of this type was observed most frequently with tabes dorsalis, hence the term *tabetic gait*; but it is also seen in Friedreich ataxia and related forms of spinocerebellar degeneration, subacute combined degeneration of the cord (vitamin B₁₂ deficiency), syphilitic meningoencephalitis, a number of chronic sensory polyneuropathies, and those cases of multiple sclerosis or compression of the spinal cord (spondylosis and meningioma are the common causes) in which the posterior columns are predominantly involved.

Steppage or Equine Gait

This is caused by paralysis of the pretibial and peroneal muscles, with resultant inability to dorsiflex and evert the foot (foot drop). The steps are regular and even, but the advancing foot hangs with the toes pointing toward the ground. Walking is accomplished by excessive flexion at the hip, the leg being lifted abnormally high in order for the foot to clear the ground. There is a slapping noise as the foot strikes the floor. Thus there is a superficial similarity to the tabetic gait, especially in cases of severe polyneuropathy, where the features of steppage and sensory ataxia may be combined. However, patients with steppage gait alone are not troubled by a perception of imbalance; they fall mostly from tripping on carpet edges and curbstones.

Foot drop may be unilateral or bilateral and occurs in diseases that affect the peripheral nerves of the legs or motor neurons in the spinal cord, such as chronic acquired neuropathies (diabetic, inflammatory, toxic, nutritional, etc.), Charcot-Marie-Tooth disease (peroneal muscular atrophy), progressive spinal muscular atrophy, and poliomyelitis. It may also be observed in certain types of mus-

cular dystrophy in which the distal musculature of the limbs is involved.

A particular disorder of gait, also of peripheral origin and resembling steppage gait, may be observed in patients with painful dysesthesias of the soles of the feet. Because of the exquisite pain evoked by tactile stimulation of the feet, the patient treads gingerly, as though walking barefoot on hot sand or pavement, with the feet rotated in such a way as to limit contact with their most painful portions. One of the painful peripheral neuropathies (most often of the alcoholic-nutritional type but also toxic and amyloid types), causalgia, or erythromelalgia is the usual cause.

Hemiplegic and Paraplegic (Spastic) Gaits

The patient with hemiplegia or hemiparesis holds the affected leg stiffly and does not flex it freely at the hip, knee, and ankle. The leg tends to rotate outward to describe a semicircle, first away from and then toward the trunk (circumduction). The foot scrapes the floor, and the toe and outer sole of the shoe are worn. One can recognize a spastic gait by the sound of slow, rhythmic scuffing of the foot and wearing of the medial toe of the shoe. The arm on the affected side is weak and stiff to a variable degree; it is carried in a flexed position and does not swing naturally. In the hemiparetic child, the arm tends to abduct as he steps forward. This type of gait disorder is most often a sequela of stroke or trauma but may result from a number of other cerebral conditions that damage the corticospinal pathway on one side.

The spastic paraplegic or paraparetic gait is, in effect, a bilateral hemiplegic gait affecting only the lower limbs. Each leg is advanced slowly and stiffly, with restricted motion at the hips and knees. The legs are extended or slightly bent at the knees and the thighs may be strongly adducted, causing the legs almost to cross as the patient walks (scissors gait). The steps are regular and short, and the patient advances only with great effort, as though wading waist-deep in water. The main features of the hemiplegic and paraplegic gaits can be recalled by the letter S, for *slow*, *stiff*, and *scrapping*. The defect is in the stepping mechanism and in propulsion, not in support or equilibrium.

A spastic paraparetic gait is the major manifestation of cerebral diplegia (cerebral palsy), the result of anoxic or other damage to the brain in the perinatal period. Also, this disorder of gait is seen in a variety of chronic spinal cord diseases involving the dorsolateral and ventral funiculi, including multiple sclerosis, syringomyelia, any type of chronic meningoencephalitis, combined system disease of both the pernicious anemia (PA) and non-PA types, chronic spinal cord compression, adrenomyeloneuropathy, and other familial forms of spastic paraparesis. Frequently, the effects of posterior column disease are added, giving rise to a mixed gait disturbance—a spinal spastic ataxia, as occurs most often in multiple sclerosis and certain spinal cord degenerations.

Festinating and Parkinsonian Gait

The term *festination* derives from the Latin *festinare*, “to hasten,” and appropriately describes the involuntary acceleration or hastening that characterizes the gait of patients with Parkinson disease (page 915). Diminished or absent arm swing, turning en bloc, hesitation in starting to walk, shuffling, or “freezing” briefly when encountering doorways or other obstacles are the other stigmata of the parkinsonian gait. When they are joined to the typical tremor,

unblinking and mask-like facial expression, and general attitude of flexion, immobility, and poverty of movement, there can be little doubt as to the diagnosis. The arms are carried slightly flexed and ahead of the body and do not swing. The legs are stiff and bent at the knees and hips. The steps are short, and the feet barely clear the ground as the patient shuffles along. Once walking has started, the upper part of the body advances ahead of the lower part, and the patient is impelled to take increasingly short and rapid steps as though trying to catch up to his center of gravity. The steps become more and more rapid, and the patient could easily break into a trot and collide with an obstacle or fall if not assisted. Festination may be apparent when the patient is walking forward or backward. The defects are in rocking the body from side to side, so that the feet can clear the floor, and in moving the legs quickly enough to overtake the center of gravity. The problem is compounded by the inadequacy of postural support reflexes, demonstrable, in the standing patient, by a push against the sternum or a tug backward on the shoulder. A normal person readily retains his stability or adjusts to modest displacement of the trunk with a single step backward, but the parkinsonian patient may stagger or fall unless someone stands by to prevent it.

From time to time one encounters a patient with only the freezing component of the parkinsonian gait disorder. This may be an early manifestation of progressive supranuclear palsy, other basal ganglionic degeneration, or Parkinson disease (at least insofar as it is unresponsive to L-dopa), but this also occurs as a virtually isolated phenomenon that progresses independently of other movement disorders or of dementia. Within a few years, as pointed out by Factor and colleagues, the patient is reduced to a chair-bound state.

Other unusual gaits are sometimes observed in Parkinson disease and were particularly prominent in the postencephalitic form, now practically extinct. For example, such a patient may be unable to take a step forward or does so only after he takes a few hops or one or two steps backward. Or walking may be initiated by a series of short steps or a series of steps of increasing size. Occasionally such a patient may run better than he walks or walk backward better than forward. Often, walking so preoccupies the patient that talking simultaneously is impossible for him and he must stop to answer a question.

Choreoathetotic and Dystonic Gaits

Diseases characterized by involuntary movements and dystonic postures seriously affect gait. In fact, a disturbance of gait may be the initial and dominant manifestation of such diseases, and the testing of gait often brings out abnormalities of movement of the limbs and posture that are otherwise not conspicuous.

As the patient with congenital athetosis or Huntington chorea stands or walks, there is a continuous play of irregular movements affecting the face, neck, hands, and, in the advanced stages, the large proximal joints and trunk. The position of the arms and upper parts of the body varies with each step, at times giving the impression of a puppet. There are jerks of the head, grimacing, squirming and twisting movements of the trunk and limbs, and peculiar respiratory noises. One arm may be thrust aloft and the other held behind the body, with wrist and fingers undergoing alternate flexion and extension, supination and pronation. The head may incline in one direction or the other, the lips alternately retract and purse, and the tongue intermittently protrudes from the mouth. The legs advance slowly and awkwardly, the result of superimposed involuntary movements and postures. Sometimes the foot is

plantar-flexed at the ankle and the weight is carried on the toes; or the foot may be dorsiflexed or inverted. An involuntary movement may cause the leg to be suspended in the air momentarily, imparting a lifting or waltzing character to the gait, or it may twist the trunk so violently that the patient may fall.

In dystonia musculorum deformans and focal axial dystonias, the first symptom may be a limp due to inversion or plantar flexion of the foot or a distortion of the pelvis. One leg may be rigidly extended or one shoulder elevated, and the trunk may assume a position of exaggerated flexion, lordosis, or scoliosis. Because of the muscle spasms that deform the body in this manner, the patient may have to walk with knees flexed. The gait may seem normal as the first steps are taken, the abnormal postures asserting themselves as the patient continues to walk. Prominence of the buttocks owing to a lumbar lordosis, combined with flexion of one or both legs at the hip, gives rise to the so-called dromedary gait of Oppenheim. In the more advanced stages, walking becomes impossible owing to torsion of the trunk or the continuous flexion of the legs.

The general features of choreoathetosis and dystonia are described more fully in Chap. 4.

Waddling (Gluteal, or Trendelenburg) Gait

This gait is characteristic of the gluteal muscle weakness that is seen in progressive muscular dystrophy, but it occurs as well in chronic forms of spinal muscular atrophy, in certain inflammatory myopathies, lumbar nerve root compression, and with congenital dislocation of the hips.

In normal walking, as weight is placed alternately on each leg, the hip is fixated by the gluteal muscles, particularly the gluteus medius, allowing for a slight rise of the opposite hip and tilt of the trunk to the weight-bearing side. With weakness of the glutei, there is a failure to stabilize the weight-bearing hip, causing it to bulge outward and the opposite side of the pelvis to drop, with inclination of the trunk to that side. The alternation in lateral trunk movements results in the roll or waddle.

In progressive muscular dystrophy, an accentuation of the lumbar lordosis is often associated. Also, childhood cases may be complicated by muscular contractures, leading to an equinovarus position of the foot, so that the waddle is combined with circumduction of the legs and “walking on the toes.”

With unilateral gluteal weakness, often the result of damage to the first sacral nerve root, tilting and drooping of the pelvis is apparent on only one side as the patient overlifts the leg when walking.

Toppling Gait

Toppling, meaning tottering and falling, occurs with brainstem and cerebellar lesions, especially in the older person following a stroke. It is a frequent feature of the lateral medullary syndrome, in which falling occurs to the side of the infarction. In patients with vestibular neuronitis, falling also occurs to the same side as the lesion. With the Tullio phenomenon (vertigo induced by loud, high-pitched sounds or by yawning, due to a spontaneous or traumatic fenestration of the vestibule of the semicircular canal), the toppling is contraversive; with midbrain strokes, the falls tend to be backward. In patients with *progressive supranuclear palsy* (see page 926), where dystonia of the neck is combined with paralysis of vertical gaze and pseudobulbar features, unexplained falling is of-

ten an early and prominent feature. In addition, the gait is uncertain and hesitant—features that are enhanced, no doubt, by the hazard of falling unpredictably. The cause of the toppling phenomenon is unclear; it does not have its basis in weakness, ataxia, or loss of deep sensation. It appears to be a disorder of balance that is occasioned by precipitant action or the wrong placement of a foot and by a failure of the righting reflexes. Slowness of motor response is another factor. When the defect is due to a central vestibular disorder, the patient may describe a sense of being pushed (pulsion) rather than of imbalance. In midbrain disease, including progressive supranuclear palsy, a remarkable feature is the lack of appreciation of a sense of imbalance. In the advanced stages of Parkinson disease, falling of a similar type may be a serious problem, but it is perhaps surprising how relatively infrequently it occurs.

Primary Orthostatic Tremor (see page 84) This unusual fast tremor of the legs may devastate gait. As discussed in Chap. 6, it is present only when the patient walks or exerts force with the legs while seated. In reaction to a perception of severe imbalance, which is characteristic of the disorder, the patient assumes a widened and often stiff-legged stance.

Gait Disorder in Normal-Pressure Hydrocephalus (See also Chap. 30)

Progressive difficulty in walking is typically the initial and most prominent symptom of normal-pressure hydrocephalus (NPH), a disorder of cerebrospinal fluid (CSF) circulation described on page 535. However, the gait disturbance in NPH has few specific features. Certainly it cannot be categorized as an ataxic or spastic gait or what has been described as an “apraxic” gait; nor does it have more than a superficial resemblance to the parkinsonian gait. Its main features—diminished cadence, widened base, short steps, and shuffling—are the natural compensations observed in patients with all manner of gait disorders. Patients with the gait disorder of NPH may complain of a sense of imbalance or even of dizziness, but most have difficulty in articulating the exact problem. Like patients with other disorders of frontal lobe function, they are able to carry out the motions of stepping while supine or sitting but have difficulty in taking steps when upright or attempting to walk. If these patients are carefully observed as they get on and off an examining table or in and out of bed, they display poor management of the entire axial musculature, moving their bodies without shifting the center of gravity or adjusting their limbs appropriately. Changes in posture, even rolling over in bed, are made en bloc. The erect posture is assumed in a very awkward manner—with hips and knees only slightly flexed and stiff and a delay in swinging the legs over the side of the bed.

Sudarsky and Simon have quantified these defects by means of high-speed cameras and computer analysis. They report a reduction in height of step, an increase in sway, and a decrease in rotation of the pelvis and counterrotation of the torso. Tone in the leg muscles of the NPH patient is increased, with a tendency to cocontraction of flexor and extensor muscle groups. Walking is perceptibly slower than normal, the body is held stiffly and moves en bloc, arm swing is diminished, and there is a tendency to fall backwards—features that are reminiscent of the gait in Parkinson disease. In general, the lack of arm swing and the stooped posture are more prominent in Parkinson disease than in NPH, and, of course, most of the other features of Parkinson disease are lacking, although an apathetic stare and slowness in shifting natural postures

may make the two difficult to distinguish. As with the related “frontal gait,” described below, patients who have difficulty initiating gait or whose steps are so short as to be ineffective are helped by marching to a cadence or in step with the examiner. In patients with untreated NPH, one observes a progressive deterioration of stance and gait—from an inability to walk to an inability to stand, sit, and rise from or turn over in bed. There is no hint of ataxia, but a study of the mechanics of the gait in NPH by Stolze and colleagues described a widened base and slight outward rotation of the feet. Also distinguishing the gait of NPH from that of Parkinson disease in their study was a response in the latter to acoustic and visual cues for cadence. Our own experience is that both types may improve when a cadence is provided.

Frontal Lobe Disorder of Gait

Standing and walking may be severely disturbed by diseases that affect the frontal lobes, particularly their medial parts and their connections with the basal ganglia. This disorder is sometimes spoken of as a frontal lobe ataxia or as an “apraxia of gait” among numerous other labels, since the difficulty in walking cannot be accounted for by weakness, loss of sensation, cerebellar incoordination, or basal ganglionic abnormality. Whether the gait disorder should be designated as an apraxia, in the sense of Liepmann’s concept of arm and hand apraxia, is questionable, since walking is instinctual and not learned. Patients with so-called apraxia of gait do not have apraxia of individual limbs, particularly of the lower limbs; conversely, patients with apraxia of the limbs usually walk normally. More likely, the disorder represents a loss of integration, at the cortical and basal ganglionic levels, of the essential instinctual elements of stance and locomotion that are acquired in infancy and often lost in old age. As a shorthand, they are listed here as “frontal”; in any case, most cases of central gait disorder are accompanied by a degree of frontal lobe dementia.

Patients assume a posture of slight flexion with the feet placed farther apart than normal. They advance slowly, with small, shuffling, hesitant steps. At times they halt, unable to advance without great effort, although they do much better with a little assistance or with exhortation to walk in step with the examiner or to a marching cadence. Turning is accomplished by a series of tiny, uncertain steps that are made with one foot, the other foot being planted on the floor as a pivot. There is a need to seek support from a companion’s arm or nearby furniture. The initiation of walking becomes progressively more difficult; in advanced cases, the patient makes only feeble, abortive stepping movements in place, unable to move his feet and legs forward; in even more advanced cases, the patient can make no stepping movements whatsoever, as though his feet were glued to the floor. These late phenomena have been referred to colloquially as “magnetic feet” or the “slipping clutch” syndrome (Denny-Brown) and as “gait ignition failure” (Atchison et al). In some patients, difficulty in the initiation of gait may be an early and apparently isolated phenomenon; but invariably, with the passage of time, sometimes of years, the other features of the frontal lobe gait disorder become evident. Finally, as in untreated NPH, these patients become unable to stand or even to sit; without support, they fall helplessly backward or to one side. In an attempt to describe these disorders, Liston and colleagues have separated them into three categories: “ignition apraxia,” disequilibrium, and mixed types. They associate trouble starting the gait cycle, shuffling, and freezing with the first type and poor balance with the second. This is a useful restatement of the phenomenology, but

most cases in our experience have been of the combined type, and patients of both types are prone to falling.

Most patients, while seated or supine, are able to make complex movements with their legs, such as drawing imaginary figures or pedaling a bicycle, and quite remarkably, to simulate the motions of walking, all at a time when their gait is seriously impaired. Eventually, however, all movements of the legs become slow and awkward, and the limbs, when passively moved, offer variable resistance (*paratonia, or gegenhalten*). Difficulty in turning over in bed is characteristic, and this maneuver may eventually become impossible. These advanced motor disabilities are usually associated with dementia, but the gait and mental disorders need not evolve in parallel, as emphasized below. Thus, some patients with Alzheimer disease may show a serious degree of dementia for several years before a gait disorder becomes apparent; in other conditions, such as NPH and Binswanger disease, the opposite pertains. Or both the dementia and gait disorder may progress more or less together. Grasping, groping, hyperactive tendon reflexes, and Babinski signs may or may not be present. The end result in some cases is a “cerebral paraplegia in flexion” (Yakovlev), in which the patient lies curled up in bed, immobile and mute, with the limbs fixed by contractures in an attitude of flexion.

In addition to NPH and Alzheimer disease, the causes of this complex frontal lobe gait disorder include widespread neoplasm (meningioma, infiltrating glioma—gliomatosis cerebri), subcortical arteriosclerotic encephalopathy (Binswanger disease; see Thompson and Marsden), Pick disease, progressive supranuclear palsy, and frontal lobe damage from trauma, stroke, or a ruptured anterior communicating aneurysm.

On the basis of success in a small controlled trial conducted by Baezner and colleagues, amantadine 100 mg daily or twice daily may be tried for cases of vascular white matter degeneration with prominent gait difficulty. Selegiline has also been suggested from anecdotal experience.

Gait of the Aged

An alteration of gait unrelated to overt cerebral disease is an almost universal accompaniment of aging (Fig. 7-2). Lost with aging are speed, balance, and many of the quick and graceful adaptive movements that characterize the gait of younger individuals. A slightly stooped posture, varying degrees of slowness and stiffness of walking, shortening of the stride, slight widening of the base, and a tendency to turn en bloc are the main objective characteristics. This has been described as “marche à petit pas”. The shortening of stride and widening of the base provide the support that enables the elderly individual to more confidently maintain his balance, but they result in a somewhat guarded gait, like that of a person walking on a slippery surface or in the dark.

Lacking to a varying degree in the elderly is the ability to make the rapid compensatory postural changes (“rescue responses”) that are necessary to cushion or prevent a fall. A slight misstep, a failure to elevate the foot sufficiently, or tipping of the center of gravity to one side often cannot be corrected—features, no doubt, that account for the frequency of falls and fear of falling among these patients. Most persons with this type of gait disturbance are aware of impaired balance and their need for caution to avoid falls (the “cautious gait”; see Nutt et al). As such, this gait disorder lacks specificity, being a general adaptive or defensive reaction to all forms of defective locomotion.

The nature of this gait disorder is not fully understood. It may

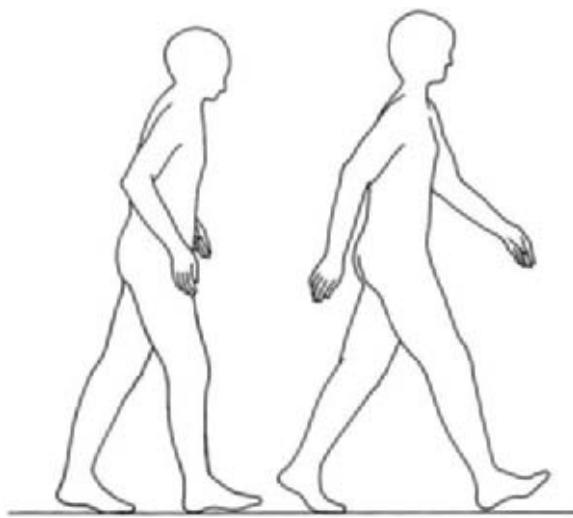

Figure 7-2. Diagram illustrating the changes in posture and gait that accompany aging ("senile gait"). With aging (figure on left), there occurs a decrease in the length of stride, excursion of the hip, elevation of the toes of the forward foot and the heel of the rear foot, shoulder flexion on forward arm swing, and elbow extension on backward swing. (Redrawn by permission from Murray et al.)

simply represent a mild degree of cerebral neuronal loss, attributable to aging itself, which in a severe (pathologic) form is referred to as a "frontal lobe disorder of gait" (as discussed above). Inadequate proprioception, slowness in making corrective postural responses, diminished vestibular function of varying degree, and weakness of pelvic and thigh muscles are probably contributing factors, as are degenerative joint changes of the spine, hips, and knees. However, Baloh and colleagues have found that changes in sensory function do not correlate well with deterioration in gait. Fisher has remarked on the similarity of the senile gait to that of NPH and suggests that hydrocephalus underlies the gait disorder of many elderly but mentally competent persons. We are unable to interpret the many reports of excessive signal changes on magnetic resonance imaging (MRI) in the periventricular white matter that have been said to explain deterioration in gait in older individuals (Benson et al and the above-mentioned study by Baloh and colleagues); in general, the arguments making this association are not persuasive.

We also emphasize here the common and particularly vexing problem encountered almost monthly on our services of *a disproportionate gait disturbance with minimal dementia*. Walking deteriorates over a period of months or years in an elderly individual, sometimes while he is residing in a nursing home, so that the tempo is unclear. The disturbance has most of the features of NPH or of a frontal gait disorder; but frontal atrophy, if present, is not marked, the ventricles are not enlarged, there is no response to drainage of CSF, and cervical spondylosis is not found. Sometimes a functional imaging study such as single-photon emission tomography (SPECT) shows low blood flow in the frontal lobes. Presumably this represents a degenerative process, perhaps of the frontotemporal variety, surprisingly little discussed in the literature. Most authors attribute this disorder to white matter changes in the cerebrum, a notion we have not found entirely persuasive, as noted above. It does appear, as reported by Verghese and colleagues, that there is a likelihood of later so-called vascular dementia in some elderly individuals who have progressive gait deterioration.

They reiterate the valid notion that early gait disorder makes the diagnosis of Alzheimer disease unlikely.

The changes in gait due to aging are discussed further in Chap. 29.

Gaits of the Mentally Retarded

There are, in addition to the disorders described above, peculiarities of gait that defy analysis. One has only to observe the assortment of gait abnormalities among the institutionalized mentally handicapped to appreciate this fact. An ungainly stance with the head too far forward or the neck extended and arms held in odd positions, a wide-based gait with awkward lurches or feet stomping the floor—each patient with his own ungraceful style—these are but a few of the peculiarities that meet the eye. One tries in vain to relate them to a disorder of proprioception, cerebellar deficit, or pyramidal or extrapyramidal disease.

The only plausible explanation that comes to mind is that these pathologic variants of gait are based on a retardation of the natural developmental sequence of the cerebral and spinal mechanisms involved in bipedal locomotion, posture, and righting. The acquisition of the refinements of locomotion—such as running, hopping, jumping, dancing, balancing on one foot, kicking a ball, etc.—are age-linked; i.e., each has its average age of acquisition. There are wide individual variations, but the most striking extremes are found in the mentally handicapped, who may be retarded in these ways as well as in cognitive development. The rhythmic rocking movements and hand clapping, odd mannerisms, waving of the arms, tremors, and other stereotyped patterns mentioned in Chap. 28 make their performances even more eccentric. The Lincoln-Oseretsky scale is an attempt to quantitate maturational delays in the locomotor sphere (Chap. 28).

Hysterical Gait

(See also Chap. 56)

This may take one of several forms, many well described by Keane. There may be a hysterical monoplegia, hemiplegia, or paraplegia. In walking, the patient may hesitate and advance the leg in a grossly ataxic or tremulous manner. Typically, patients with a hysterical paralysis of the leg do not lift the foot from the floor while walking; instead, they tend to drag the leg as a useless member or push it ahead of them as though it were on a skate. In hysterical hemiparesis, the characteristic circumduction of the leg is absent, as are the usual hemiparetic postures, hyperactive tendon reflexes, and Babinski sign. The hysterical paraplegic cannot very well drag both legs and usually depends on canes or crutches or remains helpless in bed or in a wheelchair; the muscles may be flaccid or rigid, with development of contractures. The hysterical gait may take other dramatic forms. Some patients look as though they were walking on stilts, others assume extreme dystonic postures, and still others lurch wildly in all directions without falling, actually demonstrating by their gyrations a normal ability to make rapid and appropriate postural adjustments. The gait disorder may be accompanied by similarly exaggerated movements of the arms, as though to impress the observer with the great effort required to walk and maintain balance. Leg movements in bed may be unimpaired or the patient may display a Hoover sign, which belies genuine leg weakness (page 52). Some of the patients exhibit additional abnormalities of the voice and visual fields, tremors, and asthenic weakness of muscle contraction.

Astasia-abasia—in which patients, though unable to either

stand or walk, display more or less normal use of their legs while in bed and have an otherwise normal neurologic examination and body carriage—is nearly always a hysterical condition. When such patients are placed on their feet, they may take a few steps and then become unable to advance their legs; they lurch in all directions and crumple to the floor if not assisted. On the other hand, one should not assume that a patient who manifests a disorder of gait but no other neurologic abnormality is necessarily suffering from hysteria. Lesions that are restricted to the anterosuperior cerebellar vermis may cause an ataxia that becomes manifest only when the patient attempts to stand and walk; this is true of NPH, frontal lobe disease, and various intoxications such as with phenytoin, as discussed earlier.

Rehabilitative Measures

Once the gait abnormality is stable, i.e., neither progressive nor regressive, one should explore the possibility of rehabilitation by a combination of medical therapy and other corrective measures. The antispasticity agents baclofen and tizanidine are somewhat helpful when stiffness of the limbs exceeds weakness. They may reduce spasticity of the legs, but sometimes at the expense of ex-

posing, to a greater degree than before, a loss of muscle power—the net effect being to the patient's disadvantage. Hypofunction of the labyrinths, as in drug-induced or idiopathic vestibulopathy, has greatly challenged physiatrists. Balance training and the more effective use of postural correction and vision have helped some of these patients to be more steady and better able to function in the activities of daily living and at work (see Baloh and Honrubia). Exercises to strengthen leg muscles can be beneficial, as can weight loss. Likewise, gait ataxia from proprioceptive defects can probably be corrected to some extent by careful attention to visual control and proper placement of the feet. Some success has been reported by Heitmann and colleagues in training elderly persons who fall frequently. Ventricular shunting in idiopathic hydrocephalus has restored locomotion in patients with this syndrome. Once dementia becomes conjoined with any of the gait disorders that occur in advanced age, rehabilitation stands little chance of success, since the ability to attend to small changes in terrain and posture is lost. Progression from the use of a cane, to a pronged cane, and finally to a four-posted walker allows patients with all types of gait disorders to maintain some mobility. The optimal use of these orthoses is best directed by an experienced physical therapist.

SECTION 2

PAIN AND OTHER DISORDERS OF SOMATIC SENSATION, HEADACHE, AND BACKACHE

This page intentionally left blank.

CHAPTER 8

PAIN

Pain, it has been said, is one of “nature’s earliest signs of morbidity,” and it stands pre-eminent among all the sensory experiences by which humans judge the existence of disease within themselves. Indeed, pain is the most common symptom of disease. Relatively few diseases do not have a painful phase, and in many, pain is a characteristic without which diagnosis must be in doubt.

The painful experiences of the sick pose manifold problems in virtually every field of medicine; physicians must therefore learn something of these problems and their management if they are to practice effectively. They must be prepared to recognize disease in patients who have felt only the first rumblings of discomfort, before other symptoms and signs have appeared. Even more problematic are patients who seek treatment for pain that appears to have little or no structural basis; further inquiry may disclose that fear of serious disease, worry, or depression has aggravated some relatively minor ache or that the complaint of pain has become the means of seeking drugs or monetary compensation. They must also cope with the “difficult” pain cases in which no amount of investigation brings to light either medical or psychiatric illness. Finally, the physician must be prepared to manage patients who demand relief from intractable pain caused by established and incurable disease. To deal intelligently with such pain problems requires familiarity with the anatomy of sensory pathways and the sensory supply of body segments as well as insight into the psychologic factors that influence the perception of and reaction to pain.

The dual nature of pain is responsible for some of our difficulty in understanding it. One aspect, the easier to comprehend, is its evocation by particular stimuli and the transmission of pain impulses along certain pathways, i.e., the sensation of pain. Far more abstruse is its quality as a mental state intimately linked to emotion, i.e., the quality of anguish or suffering—“a passion of the soul,” in the words of Aristotle—which defies definition and quantification. This duality is of practical importance, for certain drugs or surgical procedures, such as cingulotomy, may reduce the patient’s reaction to painful stimuli, leaving his awareness of the sensation largely intact. Alternatively, interruption of certain neural pathways may abolish all sensation in an affected part, but the symptom of pain may persist (i.e., denervation dysesthesia or anesthesia dolorosa), even in an amputated limb (“phantom pain”). Unlike most sensory modalities—which are aroused by a specific stimulus such as touch-pressure, heat, or cold—pain can be evoked by any one of these stimuli if it is intense enough.

It is apparent to the authors that in highly specialized medical centers and often even in “pain centers,” few physicians are capable of handling difficult and unusual pain problems in any comprehensive way. In fact, it is to the neurologist that other physicians regularly turn for help with these matters. Although much has been learned about the anatomy of pain pathways, their physiologic mechanisms, and which structures to ablate in order to produce analgesia, relatively little is known about which patients should be subjected to these destructive operations or how to manage their pain by medical means. Here is a subspecialty that should challenge every thoughtful physician, for it demands the highest skill in medicine, neurology, and psychiatry.

ANATOMY AND PHYSIOLOGY OF PAIN

Historical Perspective

For more than a century, views on the nature of pain sensation have been dominated by two major theories. One, known as the *specificity theory*, was from the beginning associated with the name of von Frey. He asserted that the skin consisted of a mosaic of discrete sensory spots and that each spot, when stimulated, gave rise to one sensation—either pain, pressure, warmth, or cold; in his view, each of these sensations had a distinctive end organ in the skin and each stimulus-specific end organ was connected by its own private pathway to the brain. A second theory was that of Goldscheider, who abandoned his own earlier discovery of pain spots to argue that they simply represented pressure spots, a sufficiently intense stimulation of which could produce pain. According to the latter theory, there were no distinctive pain receptors, and the sensation of pain was the result of the summation of impulses excited by pressure or thermal stimuli applied to the skin. Originally called the intensivity theory, it later became known as the *pattern*, or *summation theory*.

In an effort to conciliate the pattern and specificity theories, Head and his colleagues, in 1905, formulated a novel concept of pain sensation, based on observations that followed division of the cutaneous branch of the radial nerve in Head’s own forearm. The zone of impaired sensation contained an innermost area in which superficial sensation was completely abolished. This was surrounded by a narrower (“intermediate”) zone, in which pain sensation was preserved but poorly localized; extreme degrees of temperature were recognized in the intermediate zone, but perception of touch, lesser differences of temperature, and two-point discrimination were abolished. To explain these findings, Head postulated the existence of two systems of cutaneous receptors and conducting fibers: (1) an ancient *protopathic* system, subserving pain and extreme differences in temperature and yielding ungraded, diffuse impressions of an all-or-none type, and (2) a more recently evolved *epicritic* system, which mediated touch, two-point discrimination, and lesser differences in temperature as well as localized pain. The pain and hyperesthesia that follow damage to a peripheral nerve were attributed to a loss of inhibition that was normally exerted by the epicritic upon the protopathic system. This theory was used for many years to explain the sensory alterations that occur with both peripheral and central (thalamic) lesions. It lost credibility for several reasons, but mainly because Head’s original observations (and deductions upon which they were based) could not be corroborated (see Trotter and Davies; also Walshe). Nevertheless, both fast and slow forms of pain conduction were later corroborated (see below).

A later refinement of the pattern and specificity concepts of pain was made in 1965, when Melzack and Wall propounded their “gate-control” theory. They observed, in decerebrate and spinal cats, that peripheral stimulation of large myelinated fibers produced a negative dorsal root potential and that stimulation of small C (pain) fibers caused a positive dorsal root potential. They postulated

that these potentials, which were a reflection of presynaptic inhibition or excitation, modulated the activity of secondary transmitting neurons (T cells) in the dorsal horn, and that this modulation was mediated through inhibitory (I) cells. The essence of this theory is that the large-diameter fibers excite the I cells, which, in turn, cause a presynaptic inhibition of the T cells; conversely, the small pain afferents inhibit the I cells, leaving the T cells in an excitatory state. Melzack and Wall emphasized that pain impulses from the dorsal horn must also be under the control of a descending system of fibers from the brainstem, thalamus, and limbic lobes.

At first the gate-control mechanisms seemed to offer an explanation of the pain of ruptured disc and of certain chronic neuropathies (particularly those with large fiber outfall), and attempts were made to relieve pain by subjecting the peripheral nerves and dorsal columns (presumably their large myelinated fibers) to sustained transcutaneous electrical stimulation. Such selective stimulation would theoretically "close" the gate. In some clinical situations, these procedures have indeed given relief from pain, but not necessarily due to stimulation of large myelinated fibers alone (see Taub and Campbell). But in a number of other instances relating to pain in large- and small-fiber neuropathies, the clinical behavior has been quite out of keeping with what one would expect on the basis of the gate-control mechanism. As with preceding theories, flaws have been exposed in the physiologic observations on which the theory is based. These and other aspects of the gate-control theory of pain have been critically reviewed by P. W. Nathan.

During the last few decades there has been a significant accrual of information on cutaneous sensibility, demanding a modification of earlier anatomic-physiologic and clinical concepts. Interestingly, much of this information is still best described and rationalized in the general framework of the oldest theory, that of specificity, as will be evident from the ensuing discussion on pain and that on other forms of cutaneous sensibility in the chapter that follows.

Pain Receptors and Peripheral Afferent Pathways

In terms of peripheral pain mechanisms, as already implied, there is indeed a high degree, though not an absolute, of specificity in the von Frey sense. In keeping with distinctions between nerve types, the sensory (and motor) fibers have been classified according to their size and function (Table 8-1). It is now well established that two types of afferent fibers in the distal axons of primary sensory neurons respond maximally to nociceptive (i.e., potentially tissue-

damaging) stimuli. One type is the very fine, unmyelinated, slowly conducting C fiber (0.3 to 1.1 μm in diameter); the other is the thinly myelinated, more rapidly conducting A-delta (A- δ) fiber (2 to 5 μm in diameter). The peripheral terminations of both these primary pain afferents or receptors are the free, profusely branched nerve endings in the skin and other organs; these are covered by Schwann cells but contain little or no myelin. There is considerable evidence, based on their response characteristics, that a degree of subspecialization exists within these freely branching, nonencapsulated endings and their small fiber afferents. Three broad categories of free endings or receptors are recognized: mechanoreceptors, thermoreceptors, and polymodal nociceptors. Each ending transduces stimulus energy into an action potential in nerve membranes. The first two types of receptors are activated by innocuous mechanical and thermal stimulation, respectively; the mechanoeffects are transmitted by both A- δ and C fibers and the thermal effects mostly by C fibers. The majority of C fibers are polymodal and are most effectively excited by noxious or tissue-damaging stimuli, but they can respond as well to both mechanical and thermal stimuli and to chemical mediators such as those associated with inflammation. Moreover, certain A- δ fibers respond to light touch, temperature, and pressure as well as to pain stimuli and are capable of discharging in proportion to the intensity of the stimulus. The stimulation of single fibers by intraneuronal electrodes indicates that they can also convey information concerning the nature and location of the stimulus. These observations on the polymodal functions of A- δ and C fibers would explain the earlier observations of Lele and Weddell that modes of sensation other than pain can be evoked from structures such as the cornea, which is innervated solely by free nerve endings.

The manner in which painful stimuli are translated into electrical depolarizations in nerve endings are beginning to be understood. A number of specialized molecules, when activated by noxious stimuli, open cationic channels in membranes of the nerve ending. Opening of these channels, in turn, activates voltage-gated sodium channels and generates an action potential in the sensory axon. The regulation and activation of these receptor molecules is summarized by Mannion and Woolf.

The peripheral afferent pain fibers of both A- δ and C types have their cell bodies in the dorsal root ganglia; central extensions of these nerve cells project, via the dorsal root, to the dorsal horn of the spinal cord (or, in the case of cranial pain afferents, to the nucleus of the trigeminal nerve, the medullary analogue of the dorsal horn). The pain afferents occupy mainly the lateral part of the root entry zone. Within the spinal cord, many of the thinnest fibers

Table 8-1
Classification and function of sensory peripheral nerve fiber types and symptoms associated with intrinsic dysfunction of each type

FIBER TYPE	ALTERNATIVE DESIGNATION	FIBER DIAMETER	CONDUCTION VELOCITY (M/S)	FUNCTION AND SYMPTOMS OF DYSFUNCTION
A-alpha and beta Large, heavily myelinated	II	5–20	30–70	Touch, pressure
A-gamma	Ia	3–6	15–30	Spindle afferents
A-delta Small, thinly myelinated	III	2–5	12–30	Pain and temperature, soma touch (Sharp, lancinating, prickly pain)
B		1–3	3–15	
C Small, unmyelinated; polymodal	IV	0.3–1.1	0.5–2	Slow pain and temperature (Dull, burning, poorly localized pain)

(C fibers) form a discrete bundle, the tract of Lissauer (Fig. 8-1A). That Lissauer's tract is predominantly a pain pathway is shown (in animals) by the ipsilateral segmental analgesia that results from its transection, but it contains deep sensory or propriospinal fibers as well. Although it is customary to speak of a lateral and medial division of the posterior root (the former contains small pain fibers and the latter, large myelinated fibers), the separation into discrete functional bundles is not complete, and in humans the two groups of fibers cannot be differentially interrupted by selective rhizotomy.

Dermatomic Distribution of Pain Fibers

(See Fig. 9-1, page 129)

Each sensory unit (the sensory nerve cell in the dorsal root ganglion, its central and peripheral extensions, and cutaneous and visceral endings) has a unique topography that is maintained throughout the sensory system from the periphery to the sensory cortex. The discrete segmental distribution of the sensory units permits the construction of sensory maps, so useful to clinicians (see Fig. 9-1). This aspect of sensory anatomy is elaborated in the next chapter, which includes maps of the sensory dermatomes and cutaneous nerves. However, as a means of quick orientation to the topography of peripheral pain pathways, it is useful to remember that the facial structures and anterior cranium lie in the fields of the trigeminal nerves; the back of the head, second cervical; the neck, third cervical; the epaulet area, fourth cervical; the deltoid area, fifth cervical; the radial forearm and thumb, sixth cervical; the index and middle fingers, seventh cervical; the little finger and ulnar border of hand and forearm, eighth cervical–first thoracic; the nipple, fifth thoracic; the umbilicus, tenth thoracic; the groin, first lumbar; the medial side of the knee, third lumbar; the great toe, fifth lumbar; the little toe, first sacral; the back of the thigh, second sacral; and the genitoanal zones, third, fourth, and fifth sacrals. The distribution of pain fibers from deep structures, though not fully corresponding to those from the skin, also follows a segmental pattern. The first to fourth thoracic nerve roots are the important sensory pathways for the heart and lungs; the sixth to eighth thoracic, for the upper abdominal organs; and the lower thoracic and upper lumbar, for the lower abdominal viscera.

The Dorsal Horn

The afferent pain fibers, after traversing Lissauer's tract, terminate in the posterior gray matter or dorsal horn, predominantly in the marginal zone. Most of the fibers terminate within the segment of their entry into the cord; some extend ipsilaterally to one or two adjacent rostral and caudal segments; and some project, via the anterior commissure, to the contralateral dorsal horn. The cytoarchitectonic studies of Rexed in the cat (the same organization pertains in primates and probably in humans) have shown that second-order neurons, the sites of synapse of afferent sensory fibers in the dorsal horn, are arranged in a series of six layers or laminae (Fig. 8-1B). Fine, myelinated (A- δ) fibers terminate principally in lamina I of Rexed (marginal cell layer of Waldeyer) and also in the outermost part of lamina II; some A- δ pain fibers penetrate the dorsal gray matter and terminate in the lateral part of lamina V. Unmyelinated (C) fibers terminate in lamina II (substantia gelatinosa). Yet other cells that respond to painful cutaneous stimulation are located in ventral horn laminae VII and VIII. The latter neurons are responsive to descending impulses from brainstem nuclei as well as

segmental sensory impulses. From these cells of termination, second-order axons connect with ventral and lateral horn cells in the same and adjacent spinal segments and subserve both somatic and autonomic reflexes. The main bundle of secondary neurons subserving pain sensation projects contralaterally (and to a lesser extent ipsilaterally) to higher levels; this constitutes the spinothalamic tract, discussed below.

In recent years, a number of important observations have been made concerning the mode of transmission and modulation of pain impulses in the dorsal horn and brainstem. Excitatory amino acids (glutamate, aspartate) and nucleotides such as adenosine triphosphate (ATP) are the putative transmitters at terminals of primary A- δ sensory afferents. Also, A- δ pain afferents, when stimulated, release several neuromodulators that play a role in the transmission of pain sensation. Slower neurotransmission by C neurons involves other substances, of which the most important is the 11-amino acid peptide known as substance P. In animals, substance P has been shown to excite nociceptive dorsal root ganglion and dorsal horn neurons; furthermore, destruction of substance P fibers produces analgesia. In patients with the rare condition of congenital neuropathy and insensitivity to pain, there is a marked depletion of dorsal horn substance P.

A large body of evidence indicates that opiates are important modulators of pain impulses as they are relayed through the dorsal horn and through nuclei in the medulla and midbrain. Thus, opiates have been noted to decrease substance P; at the same time, flexor spinal reflexes, which are evoked by segmental pain, are reduced. Opiate receptors of three types are found on both presynaptic primary afferent terminals and postsynaptic dendrites of small neurons in lamina II. Moreover, lamina II neurons, when activated, release enkephalins, endorphins, and dynorphins—all of which are endogenous, morphine-like peptides that bind specifically to opiate receptors and inhibit pain transmission at the dorsal horn level. The subject of pain modulation by opiates and endogenous morphine-like substances is elaborated further on.

Spinal Afferent Tracts for Pain

Lateral Spinothalamic Tract As indicated above, axons of secondary neurons that subserve pain sensation originate in laminae I, II, V, VII, and VIII of the spinal gray matter. The principal bundle of these axons decussates in the anterior spinal commissure and ascends in the anterolateral fasciculus as the *spinothalamic tract* to terminate in several brainstem and thalamic structures (Fig. 8-2). It is of clinical consequence that the axons carrying pain impulses from each dermatome decussate one to three segments above the level of root entry. For this reason, a discrete lesion of the lateral spinal cord creates a loss of pain and thermal sensation of the contralateral trunk, the dermatomal level of which is *two to three segments below that of the spinal cord lesion*. As the ascending fibers cross the cord, they are added to the inner side of the spinothalamic tract (the principal afferent pathway of the anterolateral fasciculus), so that the longest fibers from the sacral segments come to lie most superficially and fibers from successively more rostral levels occupy progressively deeper positions (Fig. 8-3). This somatotopic arrangement is of importance to the neurosurgeon insofar as the depth to which the funiculus is cut will govern the level of analgesia that is achieved; for the neurologist, it provides an explanation of the special pattern or “sacral sparing” of pain and thermal sensation created by centrally placed lesions of the spinal cord.

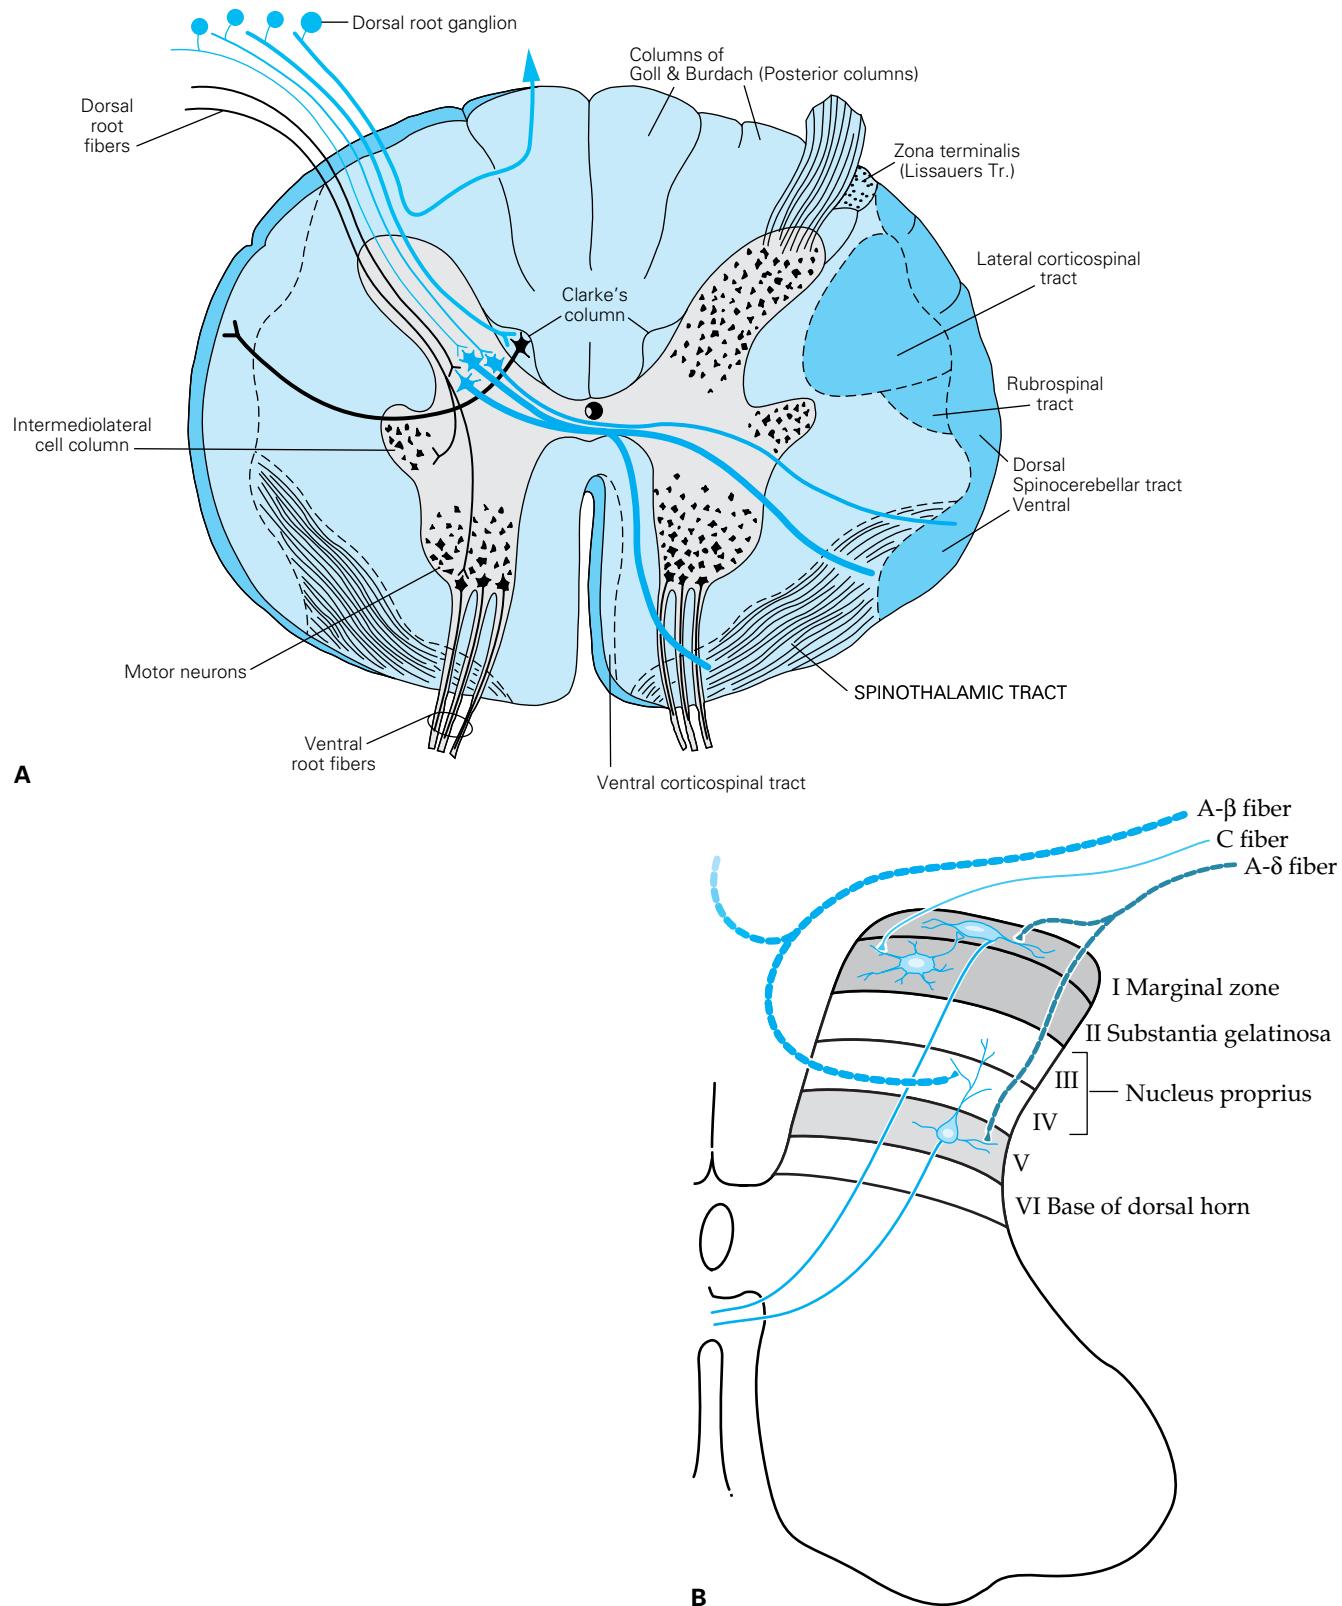

Figure 8-1. A. Spinal cord in transverse section, illustrating the course of the afferent fibers and the major ascending pathways. Fast-conducting pain fibers are not confined to the spinothalamic tract but are scattered diffusely in the anterolateral funiculus (see also Fig. 8-3). B. Transverse section through a cervical segment of the spinal cord, illustrating the subdivision of the gray matter into laminae according to Rexed and the entry and termination of the main sensory fibers. (Adapted from Martin, JH: *Neuroanatomy: Text and Atlas*. New York, McGraw-Hill, 2003, with permission.)

Other Spinocerebral Afferent Tracts In addition to the lateral spinothalamic tract—the above described fast-conducting pathway that projects directly to the thalamus—the anterolateral fasciculus of the cord contains several more slowly conducting, medially placed systems of fibers. One such group of fibers projects directly to the reticular core of the medulla and midbrain and then to the medial and intralaminar nuclei of the thalamus; this group of fibers is referred to as the *spinoreticulothalamic* or *paleospinothalamic* pathway. At the level of the medulla, these fibers synapse in the nucleus gigantocellularis; more rostrally, they connect with nuclei of the parabrachial region, midbrain reticular formation, periaqueductal gray matter, and hypothalamus. A second, more medially placed pathway in the anterolateral cord ascends to the brainstem reticular core via a series of short interneuronal links. It is not clear whether these spinoreticular fibers are collaterals of the spinothalamic tracts, as Cajal originally stated, or whether they represent an independent system, as more recent data seem to indicate. Probably both statements are correct. There is also a third, direct spinohypothalamic pathway in the anterolateral fasciculus.

The conduction of diffuse, poorly localized pain arising from deep and visceral structures (gut, periosteum) has been ascribed to these pathways. Melzack and Casey have proposed that this fiber system (which they refer to as *paramedian*), with its diffuse projection via brainstem and thalamus to the limbic and frontal lobes, subserves the affective aspects of pain, i.e., the unpleasant feelings engendered by pain. It is evident that these spinoreticulothalamic pathways continue to evoke the psychic experience of pain even when the direct spinothalamic pathways have been interrupted. However, it is the direct spinothalamic pathway, which projects to the ventroposterolateral (VPL) nucleus of the thalamus and thence to discrete areas of the sensory cortex, that subserves the *sensory-discriminative* aspects of pain, i.e., the processes that underlie the localization, quality, and possibly the intensity of the noxious stimulus. Also, the pathways for *visceral pain* from the esophagus, stomach, small bowel, and proximal colon are carried largely in the vagus nerve and terminate in the nucleus of the solitary tract (nucleus tractus solitarius, NTS) before projecting to the thalamus, as described below. Other abdominal viscera still activate the NTS when the vagus is severed in animals, probably passing through the splanchnic plexus.

It should be emphasized that the foregoing data concerning the cells of termination of cutaneous nociceptive stimuli and the cells of origin of ascending spinal afferent pathways have all been obtained from studies in animals (including monkeys). In humans, the cells of origin of the long (direct) spinothalamic tract fibers have not been fully identified. Information about this pathway in humans has been derived from the study of postmortem material and from the examination of patients subjected to anterolateral cordotomy for intractable pain. What can be stated of clinical relevance is that unilateral section of the anterolateral funiculus produces a relatively complete loss of pain and thermal sense on the opposite side of the body, extending to a level two or three seg-

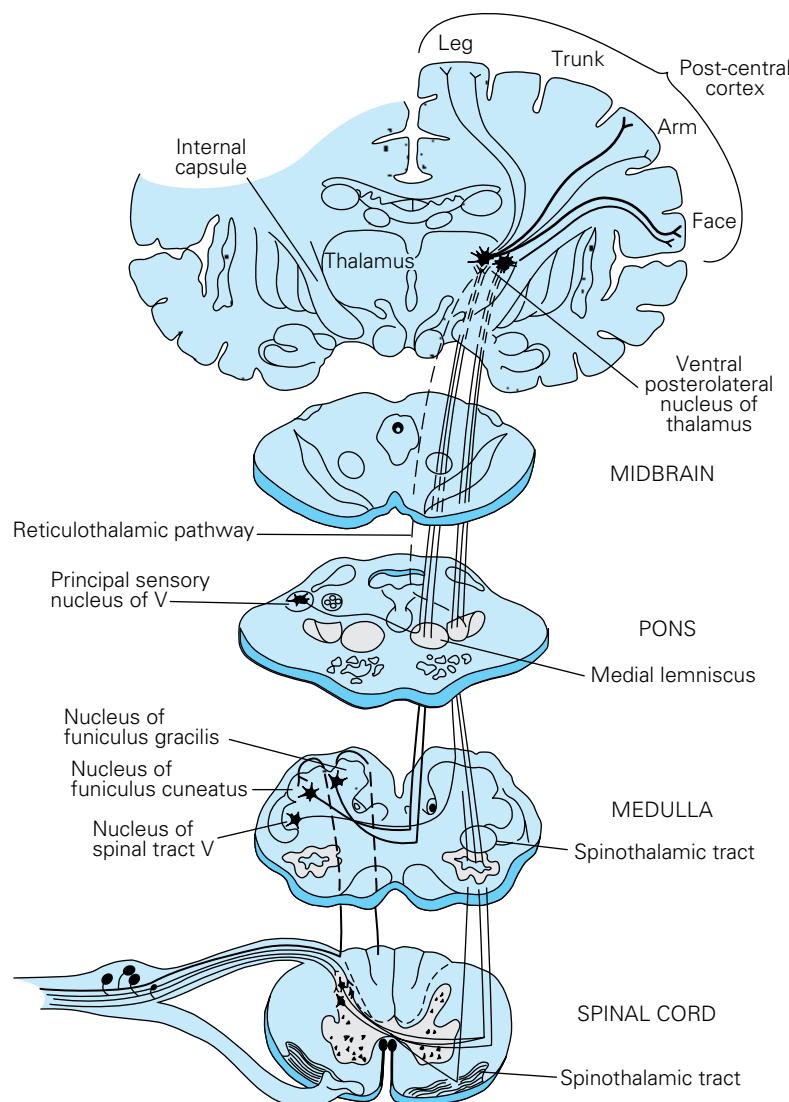

Figure 8-2. The main somatosensory pathways. The spinothalamic tract (pain, thermal sense) and the posterior column–lemniscal system (touch, pressure, joint position) are shown. Offshoots from the ascending anterolateral fasciculus (spinothalamic tract) to nuclei in the medulla, pons, and mesencephalon and nuclear terminations of the tract are indicated. The cortical representation of sensation is shown grossly; it is shown more explicitly in Fig. 9-4 and discussed in Chap. 9.

ments below the lesion as noted earlier. After a variable period of time, pain sensibility usually returns, probably being conducted by pathways that lie outside the anterolateral quadrants of the spinal cord and which gradually increase their capacity to conduct pain impulses. One of these is a longitudinal polysynaptic bundle of small myelinated fibers in the center of the dorsal horn (the dorsal intracornual tract); another consists of axons of lamina I cells that travel in the dorsal part of the lateral funiculus.

Thalamic Terminus of Pain Fibers

The direct spinothalamic fibers separate into two bundles as they approach the thalamus. The lateral division terminates in the ventrobasal and posterior groups of nuclei, the most important of which is the VPL nucleus. The medial contingent terminates mainly in the intralaminar complex of nuclei and in the nucleus submedius.

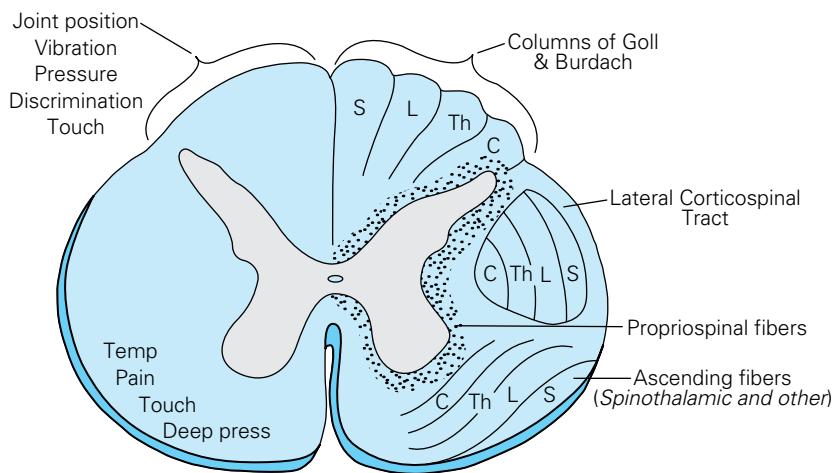

Figure 8-3. Spinal cord showing the segmental arrangement of nerve fibers within major tracts. On the left side are indicated the “sensory modalities” that appear to be mediated by the two main ascending pathways. C, cervical; L, lumbar; S, sacral; Th, thoracic. (Adapted by permission from Brodal A: *Neurological Anatomy*, 3rd ed. New York, Oxford University Press, 1981.)

Spinoreticulothalamic (paleospinothalamic) fibers project onto the medial intralaminar (primarily parafascicular and centrolateral) thalamic nuclei; i.e., they overlap with the terminations of the medially projecting direct spinothalamic pathway. Projections from the dorsal column nuclei, which have a modulating influence on pain transmission, are mainly to the ventrobasal and ventroposterior group of nuclei. Each of the four thalamic nuclear groups that receives nociceptive projections from the spinal cord has a distinct cortical projection, and each is thought to play a different role in pain sensation (see below).

One practical conclusion to be reached from these anatomic and physiologic studies is that at thalamic levels, fibers and cell stations transmitting the nociceptive impulses are not organized into discrete loci. In general, neurophysiologic evidence indicates that as one ascends from peripheral nerve to spinal, medullary, mesencephalic, thalamic, and limbic levels, the predictability of neuron responsiveness to noxious stimuli diminishes. Thus it comes as no surprise that neurosurgical procedures for interrupting afferent pathways become less and less successful at progressively higher levels of the brainstem and thalamus.

Thalamocortical Projections

The ventrobasal thalamic complex and the ventroposterior group of nuclei project to two main cortical areas: the primary sensory (postcentral) cortex (a small number terminate in the precentral cortex) and the upper bank of the sylvian fissure. These cortical areas are described more fully in Chap. 9, but it can be stated here that they are concerned mainly with the reception of tactile and proprioceptive stimuli and with all discriminative sensory functions, including pain. The extent to which either cortical area is activated by thermal and painful stimuli is uncertain. Certainly, stimulation of these (or any other) cortical areas in a normal, alert human being does not produce pain. The intralaminar nuclei, which also project to the hypothalamus, amygdaloid nuclei, and limbic cortex, probably mediate the arousal and affective aspects of pain and the autonomic responses.

The thalamic projections to the primary sensory cortex that is distributed mainly along the postcentral gyrus of the anterior pa-

rietal lobe is shown in Fig. 9-4 (the “sensory homunculus”). The cortical representation allows for accurate localization of the site of origin of a painful stimulus but the notion that thalamic projections terminate solely in this region is an oversimplification.

Thalamic and cerebral cortical localization of *visceral sensation* is not well known. However, cerebral evoked potentials and increased cerebral blood flow (by positron emission tomography studies) have been demonstrated in the thalamus and pre- and postcentral gyri of patients undergoing rectal balloon distention (Silverman et al; Rothstein et al).

Descending Pain-Modulating Systems

Of great importance was the discovery of a system of descending fibers and way stations that modulate activity in nociceptive pathways. The system that has been studied most extensively emanates from the frontal cortex and hypothalamus and projects to cells in the periaqueductal region of the midbrain and then passes to the ventromedial medulla. From there it descends in the dorsal part of the lateral fasciculus of the spinal cord to the posterior horns (laminae I, II, and V; see further discussion under “Endogenous Pain-Control Mechanisms”). Several other descending pathways, noradrenergic and serotonergic, arise in the locus ceruleus, dorsal raphe nucleus, and nucleus reticularis gigantocellularis and are also important modifiers of the nociceptive response. The significance of these pain-modulating pathways is discussed further on.

PHYSIOLOGIC ASPECTS OF PAIN

The stimuli that activate pain receptors vary from one tissue to another. As pointed out above, the adequate stimulus for skin is one that has the potential to injure tissue, i.e., pricking, cutting, crushing, burning, and freezing. These stimuli are ineffective when applied to the stomach and intestine, where pain is produced by an engorged or inflamed mucosa, distention or spasm of smooth muscle, and traction on the mesenteric attachment. In skeletal muscle, pain is caused by ischemia (the basis of intermittent claudication), necrosis, hemorrhage, and injection of irritating solutions as well as by injuries of connective tissue sheaths. Prolonged contraction of skeletal muscle evokes an aching type of pain. Ischemia is also the most important cause of pain in cardiac muscle. Joints are insensitive to pricking, cutting, and cauterization, but pain can be produced in the synovial membrane by inflammation and by exposure to hypertonic saline. The stretching and tearing of ligaments around a joint can evoke severe pain. Injuries to the periosteum give rise to pain but probably not to other sensations. Arteries are a source of pain when pierced by a needle or involved in an inflammatory process. Distention of arteries, as occurs with thrombotic or embolic occlusion, and excessive arterial pulsation, as is postulated in migraine, may be sources of pain; other mechanisms of headache relate to traction on arteries and the meningeal structures by which they are supported (see Chap. 10). Pain due to intraneuronal lesions probably arises from the sheaths of the nerves. Nerve root(s) and sensory ganglia, when compressed (e.g., by a ruptured disc), give rise to pain.

With damage to tissue, there is a release of proteolytic enzymes, which act locally on tissue proteins to liberate substances that excite peripheral nociceptors. These pain-producing substances—which include histamine, prostaglandins, serotonin, and similar polypeptides as well as potassium ions—elicit pain when they are injected intra-arterially or applied to the base of a blister. Other pain-producing substances such as kinins are released from sensory nerve endings or are carried there by the circulation. Also, vascular permeability is increased by these substances.

In addition, direct stimulation of nociceptors releases polypeptide mediators that enhance pain perception. The best-studied of these is substance P, which is released from the nerve endings of C fibers in the skin during peripheral nerve stimulation. It causes erythema by dilating cutaneous vessels and edema by releasing histamine from mast cells; it also acts as a chemoattractant for leukocytes. This reaction, called *neurogenic inflammation* by White and Helme, is mediated by antidromic action potentials from the small nerve cells in the spinal ganglia and is the basis of the axon reflex of Lewis; the reflex is abolished in peripheral nerve diseases and can be studied electrophysiologically as an aid to clinical localization.

Perception of Pain

The *threshold for perception of pain*, i.e., the lowest intensity of a stimulus recognized as pain, is approximately the same in all persons. Inflammation lowers the threshold for perception of pain by a process called *sensitization*. This process allows ordinarily innocuous stimuli to produce pain in sensitized tissues. The pain threshold is, of course, raised by local anesthetics and by certain lesions of the nervous system as well as by centrally acting analgesic drugs. Mechanisms other than lowering or raising the pain threshold are important as well. Placebos reduce pain in about one-third of the groups of patients in which such effects have been recorded. Acupuncture at sites anatomically remote from painful operative fields apparently reduces the pain in some individuals. Distraction and suggestion, by turning attention away from the painful part, reduce the awareness of and response to pain. Strong emotion (fear or rage) suppresses pain, presumably by activation of the above-described descending adrenergic system. The experience of pain appears to be lessened in manic states and enhanced in depression. Neurotic patients in general have the same pain threshold as normal subjects, but their reaction may be excessive or abnormal. The pain thresholds of frontal lobotomized subjects are also unchanged, but they react to painful stimuli only briefly or casually if at all. The degrees of emotional reaction and verbalization also vary with the personality and character of the patient.

The conscious awareness or perception of pain occurs only when pain impulses reach the thalamocortical level. The precise roles of the thalamus and cortical sensory areas in this mental process are not fully understood, however. For many years it was taught that the recognition of a noxious stimulus as such is a function of the thalamus and that the parietal cortex is necessary for appreciation of the intensity, localization, and other discriminatory aspects of sensation. This traditional separation of sensation (in this instance awareness of pain) and perception (awareness of the nature of the painful stimulus) has been abandoned in favor of the view that sensation, perception, and the various conscious and unconscious responses to a pain stimulus comprise an indivisible process. That the cerebral cortex governs the patient's reaction to pain cannot be doubted, however. It is also likely that the cortex can sup-

press or otherwise modify the perception of pain in the same way that corticofugal projections from the sensory cortex modify the rostral transmission of other sensory impulses from thalamic and dorsal column nuclei. It has been shown that central transmission in the spinothalamic tract can be inhibited by stimulation of the sensorimotor areas of the cerebral cortex, and, as indicated above, a number of descending fiber systems have been traced to the dorsal horn laminae from which this tract originates. Other intrinsic mechanisms whereby the perception of pain can be greatly modulated are discussed below.

Endogenous Pain-Control Mechanisms

In recent years, the most important contribution to our understanding of pain has been the discovery of a neuronal analgesia system which can be activated by the administration of opiates or by naturally occurring brain substances that share the properties of opiates. This endogenous system was first demonstrated by Reynolds, who found that stimulation of the ventrolateral periaqueductal gray matter in the rat produced a profound analgesia without altering behavior or motor activity. Subsequently, stimulation of other discrete sites in the medial and caudal regions of the diencephalon and rostral bulbar nuclei (notably raphe magnus and paragigantocellularis) were shown to have the same effect. Under the influence of such electrical stimulation, the animal could be operated upon without anesthesia and move around in an undisturbed manner despite the administration of noxious stimuli. Investigation disclosed that the effect of stimulation-produced analgesia (SPA) is to inhibit the neurons of laminae I, II, and V of the dorsal horn, i.e., the neurons that are activated by noxious stimuli. In human subjects, stimulation of the midbrain periaqueductal gray matter through stereotactically implanted electrodes has also produced a state of analgesia, though not consistently. Other sites in which electrical stimulation is effective in suppressing nociceptive responses are the rostroventral medulla (nucleus raphe magnus and adjacent reticular formation) and the dorsolateral pontine tegmentum. These effects are relayed to the dorsal horn gray matter via a pathway in the dorsolateral funiculus of the spinal cord. Ascending pathways from the dorsal horn, conveying noxious somatic impulses, are also important in activating the modulatory network.

As indicated earlier, opiates also act pre- and postsynaptically on the neurons of laminae I and V of the dorsal horn, suppressing afferent pain impulses from both the A- δ and C fibers. Furthermore, these effects can be reversed by the narcotic antagonist naloxone. Interestingly, naloxone can reduce some forms of stimulation-produced analgesia. Levine and colleagues have demonstrated that not only does naloxone enhance clinical pain but it also interferes with the pain relief produced by placebos. These observations suggest that the heretofore mysterious beneficial effects of placebos (and perhaps of acupuncture) may be due to activation of an endogenous system that shuts off pain through the release of pain-relieving endogenous opioids, or *endorphins* (see below). Prolonged pain and fear are the most powerful activators of this endogenous opioid-mediated modulating system. The same system is probably operative under a variety of other stressful conditions; for example, some soldiers, wounded in battle, require little or no analgesic medication ("stress-induced analgesia"). The opiates also act at several loci in the brainstem, at sites corresponding with those producing analgesia when stimulated electrically and generally conforming to areas in which neurons with endorphin receptors are localized.

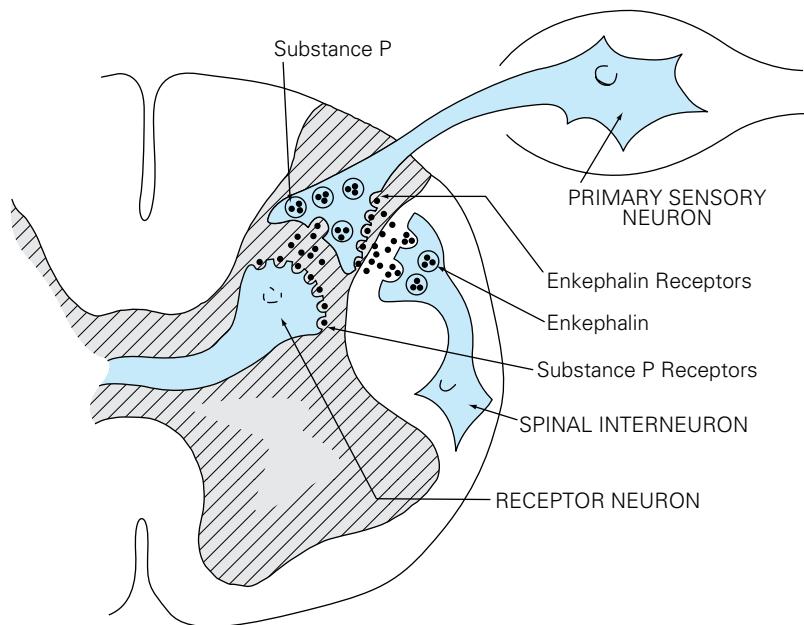

Figure 8-4. Mechanism of action of enkephalin (endorphin) and morphine in the transmission of pain impulses from the periphery to the CNS. Spinal interneurons containing enkephalin synapse with the terminals of pain fibers and inhibit the release of the presumptive transmitter, substance P. As a result, the receptor neuron in the dorsal horn receives less excitatory (pain) impulses and transmits fewer pain impulses to the brain. Morphine binds to unoccupied enkephalin receptors, mimicking the pain-suppressing effects of the endogenous opiate enkephalin.

Soon after the discovery of specific opiate receptors in the central nervous system (CNS), several naturally occurring peptides, which proved to have a potent analgesic effect and to bind specifically to opiate receptors, were identified (see Hughes et al for a summary of these substances). These endogenous, morphine-like compounds are generically referred to as *endorphins*, meaning “the morphines within.” The most widely studied are β -endorphin, a peptide sequence of the pituitary hormone β -lipotropin, and two other peptides, *enkephalin* and *dynorphin*. They are found in greatest concentration in relation to opiate receptors in the midbrain. At the level of the spinal cord, exclusively enkephalin receptors are found. A theoretical construct of the roles of enkephalin (and substance P) at the point of entry of pain fibers into the spinal cord is illustrated in Fig. 8-4. A subgroup of dorsal horn interneurons also contains enkephalin; they are in contact with spinothalamic tract neurons.

Thus it would appear that the central effects of a painful condition are determined by many ascending and descending systems utilizing a variety of transmitters. A deficiency in a particular region would explain persistent or excessive pain. Some aspects of opiate addiction and also the discomfort that follows withdrawal of the drug might conceivably be accounted for in this way. Indeed, it is known that some of these peptides not only relieve pain but suppress withdrawal symptoms.

Finally it should be noted that the descending pain-control systems contain noradrenergic and serotonergic as well as opiate links. A descending norepinephrine-containing pathway, as mentioned, has been traced from the dorsolateral pons to the spinal cord, and its activation blocks spinal nociceptive neurons. The rostroventral medulla contains a large number of serotonergic neurons. Descending fibers from the latter site inhibit dorsal horn cells con-

cerned with pain transmission, perhaps providing a rationale for the use of certain antidepressant medications that are serotonin agonists in patients with chronic pain.

CLINICAL AND PSYCHOLOGIC ASPECTS OF PAIN

Terminology (Table 8-2) Several terms related to the experience of altered sensations and pain are often used interchangeably, but each has specific meaning. *Hyperesthesia* is a general term for heightened cutaneous sensitivity. The term *hyperalgesia* refers to an increased sensitivity and a lowered threshold to painful stimuli. Inflammation and burns of the skin are common causes of hyperalgesia. The term *hypalgesia*, or *hypoalgesia*, refers to the opposite state—i.e., a decreased sensitivity and a raised threshold to painful stimuli. A demonstrable reduction in pain perception (i.e., an elevated threshold, associated with an increased reaction to the stimulus once it is perceived, is sometimes referred to as *hyperpathia* (subtly different from hyperalgesia). In this circumstance there is an excessive reaction to all stimuli, even those (such as light touch) that normally do not evoke pain, a symptom termed *allodynia*. The elicited allodynic pain may have unusual features, outlasting the stimulus and being diffuse, modifiable by fatigue and emotion, and often being mixed with other sensations. The mechanism of these abnormalities is not clear, but both hyperpathia and allodynia are common features of neuropathic or neurogenic pain, i.e., pain generated by peripheral neuropathy. These features are exemplified by causalgia, a special type of burning pain that results from interruption of a peripheral nerve (see page 121).

Table 8-2

Nomenclature in the description of pain and abnormal sensation (see also Table 9-1)

Dysesthesia: Any abnormal sensation described as unpleasant by the patient

Hyperalgesia: Exaggerated pain response from a normally painful stimulus; usually includes aspects of summation with repeated stimulus of constant intensity and aftersensation

Hyperpathia: Abnormally painful and exaggerated reaction to a painful stimulus; related to hyperalgesia

Hyperesthesia (hypesthesia): Exaggerated perception of touch stimulus

Allodynia: Abnormal perception of pain from a normally nonpainful mechanical or thermal stimulus; usually has elements of delay in perception and of aftersensation

Hypoalgesia (hypalgesia): Decreased sensitivity and raised threshold to painful stimuli

Anesthesia: Reduced perception of all sensation, mainly touch

Analgesia: Reduced perception of pain stimulus

Paresthesia: Mainly spontaneous abnormal sensation that is not unpleasant; usually described as “pins and needles”

Causalgia: Burning pain in the distribution of one or more peripheral nerves

Skin Pain and Deep Sensibility As indicated earlier, the nerve endings in each tissue are activated by different mechanisms, and the pain that results is characterized by its quality, locale, and temporal attributes. *Skin pain* is of two types: a pricking pain, evoked immediately on penetration of the skin by a needle point, and a stinging or burning pain, which follows in a second or two. Together they constitute the “double response” of Lewis. Both types of dermal pain can be localized with precision. Compression of nerve by the application of a tourniquet to a limb abolishes pricking pain before burning pain. Like the sensation of a limb “falling asleep,” this is not due to ischemia as commonly thought. The first (fast) pain is thought to be transmitted by the larger (A- δ) fibers and the second (slow) pain, which is somewhat more diffuse and longer-lasting, by the thinner, unmyelinated C fibers.

Deep pain from visceral and skeleto muscular structures is basically aching in quality; if intense, it may be sharp and penetrating (knife-like). Occasionally there is a burning type of pain, as in the “heartburn” of esophageal irritation and rarely in angina pectoris. The pain is felt as being deep to the body surface. It is diffuse and poorly localized, and the margins of the painful zone are not well delineated, presumably because of the relative paucity of nerve endings in viscera. Visceral pain produces two additional sensations. First, there is tenderness at remote superficial sites (“referred hyperalgesia”) and, second, an enhanced pain sensitivity in the same and in nearby organs (“visceral hyperalgesia”). This is a restatement of Head’s early observations, discussed above, and MacKenzie’s mapping of the referred “Head zones,” where somatic and visceral sensibility overlap as discussed below. The concept of visceral hyperalgesia has received considerable attention in a number of pain syndromes in reference to the transition from acute to chronic pain, particularly in headache. It has been speculated that the central mechanism of these syndromes involves glutamate.

Referred Pain The localization of deep pain of visceral origin raises a number of problems. Deep pain has indefinite boundaries and its location is distant from the visceral structure involved. It tends to be referred not to the skin overlying the viscera of origin but to other areas of skin innervated by the same spinal segment (or segments). This pain, projected to some fixed site at a distance from the source, is called *referred pain*. This ostensible explanation for the site of referral is that small-caliber pain afferents from deep structures project to a wide range of lamina V neurons in the dorsal horn, as do cutaneous afferents. The convergence of deep and cutaneous afferents on the same dorsal horn cells, coupled with the fact that cutaneous afferents are far more numerous than visceral afferents and have direct connections with the thalamus, is probably responsible for the phenomenon.

Since the nociceptive receptors and nerves of any given visceral or skeletal structure may project upon the dorsal horns of several adjacent spinal or brainstem segments, the pain from these structures may be fairly widely distributed. For example, afferent pain fibers from cardiac structures, distributed through segments T1 to T4, may be projected superficially to the inner side of the arm and the ulnar border of the hand and arm (T1 and T2) as well as the precordium (T3 and T4). Once this pool of sensory neurons in the dorsal horns of the spinal cord is activated, additional noxious stimuli may heighten the activity in the whole sensory field ipsilaterally and, to a lesser extent, contralaterally.

Another peculiarity of localization is *aberrant reference*, explained by an alteration of the physiologic status of the pools of neurons in adjacent segments of the spinal cord. For example, cer-

vical arthritis or gallbladder disease, causing low-grade discomfort by constantly activating their particular segmental neurons, may induce a shift of cardiac pain cephalad or caudad from its usual locale. Once it becomes chronic, any pain may spread quite widely in a vertical direction on one side of the body. On the other hand, painful stimuli arising from a distant site exert an inhibitory effect on segmental nociceptive flexion reflexes in the leg, as demonstrated by DeBroucker and colleagues. Yet another clinical peculiarity of segmental pain is the reduction in power of muscle contraction that it may cause (reflex paralysis or algesic weakness).

Chronic Pain One of the most perplexing issues in the study of pain is the manner in which chronic pain syndromes arise. Several theories have been offered, none of which satisfactorily account for all the clinically observed phenomena. One hypothesis proposes that in an injured nerve, the unmyelinated sprouts of A- δ and C fibers become capable of spontaneous ectopic excitation and after-discharge and susceptible to ephaptic activation (see summary by Rasminsky). A second proposal derives from the observation that these injured nerves are also sensitive to locally applied or intravenously administered catecholamines because of an overabundance of adrenergic receptors on the regenerating fibers. Either this mechanism or ephapsis (nerve-to-nerve cross-activation) is thought to be the basis of causalgia (persistent burning and aching pain in the territory of a partially injured nerve and beyond) and its associated reflex sympathetic dystrophy; either would explain the relief afforded in these conditions by sympathetic block. This subject is discussed in greater detail in relation to peripheral nerve injuries (see pages 121 and 189).

Central sensory structures, e.g., sensory neurons in the dorsal horns of the spinal cord or thalamus, if chronically bombarded with pain impulses, may become autonomously overactive (being maintained in this state perhaps by excitatory amino acids) and may remain so even after the peripheral pathways have been interrupted. Peripheral nerve lesions have been shown to induce enduring rearrangements of central (spinal cord) processing (Fruhstorfer and Lindblom). For example, avulsion of nerves or nerve roots may cause chronic pain even in analgesic zones (anesthesia dolorosa or “deafferentation pain”). In experimentally deafferented animals, neurons of lamina V begin to discharge irregularly in the absence of stimulation. Later the abnormal discharge subsides in the spinal cord but can still be recorded in the thalamus. Hence, painful states such as causalgia, spinal cord pain, and phantom pain are not abolished simply by cutting spinal nerves or spinal tracts.

Certainly none of these phenomena can adequately explain the entire story of chronic pain. One suspects that structural changes in the cord, of the type alluded to above, are able to produce persistent stimulation of pain pathways. Newer insights into the molecular changes in the spinal cord that may give rise to persistence of the pain after the cessation of an injurious episode are reviewed by Indo and colleagues. It is an open question whether the early treatment of pain may prevent the cascade of biochemical events that allows for both spread and persistence of pain in conditions such as causalgia.

Pain has several other singular attributes. It does not appear to be subject to negative adaptation—i.e., pain may persist as long as the stimulus is operative—whereas other somatic stimuli, if applied continuously, soon cease to be perceived. Furthermore, prolonged stimulation of pain receptors sensitizes them, so that they become responsive to even low grades of stimulation, even to touch (allodynia).

The Emotional Reaction to Pain Another remarkable characteristic of pain is the strong feeling or affect with which it is endowed, nearly always unpleasant. Since pain embodies this element, psychologic conditions assume great importance in all persistent painful states. It is of interest that despite this strong affective aspect of pain, it is difficult to recall precisely, or to re-experience from memory, a previously experienced acute pain. Also, the patient's tolerance of pain and capacity to experience it without verbalization are influenced by race, culture, and personality. Some individuals—by virtue of training, habit, and phlegmatic temperament—remain stoic in the face of pain, and others react in an opposite fashion. In other words, there are inherent variations among individuals that determine the limbic system's response to pain. In this regard it is important to emphasize that pain may be the presenting or predominant symptom in a depressive illness (Chap. 57). This subject of the affective dimension of pain is reviewed in detail by Price, but it must be acknowledged that the models offered are largely theoretical.

Finally, a comment should be made about the devastating behavioral effects of chronic pain. To quote from Ambroise Paré, a sixteenth-century French surgeon, "There is nothing that abateth so much the strength as paine." Continuous pain increases irritability and fatigue, disturbs sleep, and impairs appetite. Ordinarily strong persons can be reduced to a whimpering, pitiable state that may arouse the scorn of healthy observers. Patients in pain may seem irrational about their illness and make unreasonable demands on family and physician. Characteristic is an unwillingness to engage in or continue any activity that might enhance their pain. They withdraw from the main current of daily affairs as their thoughts and speech come to be dominated by the pain. Once a person is subjected to the tyranny of chronic pain, depressive symptoms are practically always added. The demand for and dependence on narcotics often complicate the clinical problem.

APPROACH TO THE PATIENT WITH PAIN AS THE PREDOMINANT SYMPTOM

One learns quickly in dealing with such patients that not all pain is the consequence of serious disease. Every day, healthy persons of all ages have pains that must be taken as part of normal sensory experience. To mention a few, there are the "growing pains" of presumed bone and joint origin of children; the momentary hard pain over an eye or in the temporal or occipital regions, which strikes with such suddenness as to raise the suspicion of a ruptured intracranial aneurysm; inexplicable split-second jabs of pain elsewhere; the more persistent ache in the fleshy part of the shoulder, hip, or extremity that subsides spontaneously or in response to a change in position; the fluctuant precordial discomfort of gastrointestinal origin, which conjures up fear of cardiac disease; and the breathtaking "stitch in the side," due to intercostal or diaphragmatic cramp during exercise. These "normal pains," as they may be called, tend to be brief and to depart as obscurely as they came. Such pains come to notice only when elicited by an inquiring physician or when experienced by a patient given to worry and introspection. They must always be distinguished from the pain of disease.

Whenever pain—by its intensity, duration, and the circumstances of its occurrence—appears to be abnormal or when it constitutes the chief complaint or one of the principal symptoms, the physician must attempt to reach a tentative decision as to its mech-

anism and cause. This is accomplished by a thorough interrogation of the patient, with the physician carefully seeking out the main characteristics of the pain in terms of the following:

1. Location
2. Mode of onset
3. Provoking and relieving factors
4. Quality and time-intensity attributes
5. Duration
6. Severity

Knowledge of these factors in every common disease is the lore of medicine. The severity of pain is often difficult to assess. Extreme degrees of pain are betrayed by the patient's demeanor, but lesser degrees can be roughly estimated by the extent to which the pain has interfered with the patient's sleep, work, and other activities or by the patient's need for bed rest. Some physicians find it helpful, particularly in gauging the effects of analgesic agents, to use a "pain scale," i.e., to have the patient rate the intensity of his pain on a scale of zero (no pain) to ten (worst pain) or to mark it on a line. Needless to say, this general approach is put to use every day in the practice of general medicine. Together with the physical examination, including maneuvers designed to reproduce and relieve the pain and ancillary diagnostic procedures, it enables the physician to identify the source of most pains and the diseases of which they are a part.

Once the pains due to the more common and readily recognized diseases of each organ system are eliminated, there remain a significant number of chronic pains that fall into one of four categories: (1) pain from an obscure medical disease, the nature of which has not yet been disclosed by diagnostic procedures; (2) pain associated with disease of the central or peripheral nervous system (i.e., neurogenic or neuropathic pain); (3) pain associated with psychiatric disease; and (4) pain of unknown cause.

Pain Due to Undiagnosed Medical Disease

Here the source of the pain is usually in a bodily organ and is caused by a lesion that irritates and destroys nerve endings. Hence the term *nociceptive pain* is often used, but it is ambiguous. It usually means an involvement of structures bearing the termination of pain fibers. Carcinomatosis is the most frequent example. Osseous metastases, tumors of the kidney, pancreas, or liver, peritoneal implants, invasion of retroperitoneal tissues or the hilum of the lung, and infiltration of nerves of the brachial or lumbosacral plexuses can be extremely painful, and the origin of the pain may remain obscure for a long time. Sometimes it is necessary to repeat all diagnostic procedures after an interval of a few months, even though at first they were negative. From experience one learns to be cautious about reaching a diagnosis from insufficient data. Treatment in the meantime is directed to the relief of pain, at the same time instilling in the patient a need to cooperate with a program of expectant observation.

Neurogenic or Neuropathic Pain

These terms are generally used interchangeably to designate pain that arises from direct stimulation of nervous tissue itself, central or peripheral, exclusive of pain due to stimulation of sensitized C fibers by lesions of other bodily structures (i.e., the nociceptive pain

described above). This category comprises a variety of disorders involving single and multiple nerves, notably trigeminal neuralgia and those due to herpes zoster, diabetes, and trauma (including causalgia, discussed further on); a number of polyneuropathies of diverse type; root irritation, e.g., from a prolapsed disc; spinal arachnoiditis and spinal cord injuries; the thalamic pain syndrome of Déjerine-Roussy; and rarely parietal lobe infarction such as the ones described by Schmahmann and Leifer. As a rule, lesions of the cerebral cortex and white matter are associated not with pain but with hypalgesia. The clinical features that characterize central pain have been reviewed by Schott (1995). Particular diseases giving rise to neuropathic pain are considered in their appropriate chapters but the following remarks are of a general nature, applicable to all of the painful states that compose this group.

The sensations that characterize neuropathic pain vary and are often multiple; burning, gnawing, aching, and shooting or lancinating qualities are described. There is an almost invariable association with one or more of the symptoms of hyperesthesia, hyperalgesia, allodynia, and hyperpathia (see above). The abnormal sensations coexist in many cases with a sensory deficit and local autonomic dysfunction. Furthermore, the pain may persist in the absence of a stimulus and generally responds poorly to treatment, including the administration of opioid medications. These pains are classified in clinical work by the mechanism that incited them or the anatomic distribution of the pain.

Peripheral Nerve Pain Painful states that fall into this category are in most cases related to disease of the peripheral nerves, and it is to pain from this source that the term *neuropathic* is more strictly applicable. Pain states of peripheral nerve origin far outnumber those due to spinal cord, brainstem, thalamic, and cerebral disease. Although the pain is localized to a sensory territory supplied by a nerve plexus or nerve root, it often radiates to adjacent areas. Sometimes the onset of pain is immediate on receipt of injury; more often it appears at some point during the evolution or recession of the disorder. The disease of the nerve may be obvious, expressed by the usual sensory, motor, reflex, and autonomic changes, or these changes may be undetectable by standard tests. In the latter case, the term *neuralgia* is preferred.

The postulated mechanisms of peripheral nerve pain are diverse and differ from those of central diseases. Some of the current ideas have been mentioned in the earlier section on chronic pain. One mechanism is denervation hypersensitivity, first described by Walter Cannon. He noted that when a group of neurons is deprived of its natural innervation, they become hyperactive. Others point to a reduced density of certain types of fibers in nerves supplying a causalgic zone as the basis of the burning pain, but the comparison of the density of nerves from painful and nonpainful neuropathies has not proved to be consistently different. For example, Dyck and colleagues, in a study of painful versus nonpainful axonal neuropathies, concluded that there was no difference between them in terms of the type of fiber degeneration. Also, the occurrence of ectopic impulse generation all along the surface of injured axons and the possibility of ephaptic activation of unsheathed axons seems applicable particularly to some causalgic states. Stimulation of the nervi nervorum of larger nerves by an expanding intraneuronal lesion or a vascular change was postulated by Asbury and Fields as the mechanism of nerve trunk pain. The sprouting of adrenergic sympathetic axons in response to nerve injury has already been mentioned and is an ostensible explanation for the abolition of causalgic pain by sympathetic blockade. This has given rise to the

term *sympathetically sustained pain* for some cases of causalgia, as discussed below.

Regenerating axonal sprouts, as in a neuroma, are also hypersensitive to mechanical stimuli. On a molecular level, it has been shown that sodium channels accumulate at the site of a neuroma and all along the axon after nerve injury, and that this gives rise to ectopic and spontaneous activity of the sensory nerve cell and its axon. Such firing has been demonstrated in humans after nerve injury. This mechanism is concordant with the relief of neurogenic pain by sodium channel-blocking anticonvulsants. Spontaneous activity in nociceptive C fibers is thought to give rise to burning pain; firing of large myelinated A fibers is believed to produce dysesthetic pain induced by tactile stimuli. The abnormal response to stimulation is also influenced by sensitization of central pain pathways, probably in the dorsal horns of the spinal cord, as outlined in the review by Woolf and Manion. Hyperalgesia is thought to result from such a spinal cord mechanism. Several observations have been made regarding the neurochemical mechanisms that might underlie these changes, but none provides a consistent explanation. Possibly more than one of these mechanisms is operative in a given peripheral nerve disease.

Causalgia and Reflex Sympathetic Dystrophy (Complex Regional Pain Syndrome)

Causalgia (see also pages 119 and 189) is the name that Weir Mitchell applied to a rare (except in time of war) type of peripheral neuralgia consequent upon trauma, with partial interruption of the median or ulnar nerve and, less often, the sciatic or peroneal nerve. It is characterized by persistent, severe pain in the hand or foot, most pronounced in the digits, palm of the hand, or sole. The pain has a burning quality and frequently radiates beyond the territory of the injured nerve. The painful parts are exquisitely sensitive to contactual stimuli, so the patient cannot bear the pressure of clothing or drafts of air; even ambient heat, cold, noise, or emotional stimuli intensify the causalgic symptoms. The affected extremity is kept protected and immobile, often wrapped in a cloth moistened with cool water. Sudomotor, vasomotor, and, later, trophic abnormalities are usual accompaniments of the pain. The skin of the affected part is moist and warm or cool and soon becomes shiny and smooth, at times scaly and discolored.

A number of theories have been proposed to explain the causalgic syndrome. For many years it was attributed to a short-circuiting of impulses, the result of an artificial connection between efferent sympathetic and somatic afferent pain fibers at the point of the nerve injury. The demonstration that the causalgic pain could be abolished by depletion of neurotransmitters at sympathetic adrenergic endings shifted the presumed site of sympathetic-afferent interaction to the nerve terminals and suggested that the abnormal cross-excitation is chemical rather than electrical in nature. An explanation favored in recent years is that an abnormal adrenergic sensitivity develops in injured nociceptors and that circulating or locally secreted sympathetic neurotransmitters trigger the painful afferent activity. Another theory holds that a sustained period of bombardment by sensory pain impulses from one region results in the sensitization of central sensory structures. "True causalgia" of this type can be counted on to respond favorably, if only temporarily, to procaine block of the appropriate sympathetic ganglia and, over the longer time, to regional sympathectomy. Prolonged cooling and the intravenous injection of the sympathetic blocking drug,

guanethidine into the affected limb (with the venous return blocked for several minutes) may alleviate the pain for days or longer. Epidural infusions, particularly of analgesics or ketamine; intravenous infusion of bisphosphonates; and spinal cord stimulators are other forms of treatment (see Kemler). The roles of the central and sympathetic nervous systems in causalgic pain have been critically reviewed by Schott and by Schwartzman and McLellan.

Recent investigations have begun to define the molecular changes that occur in sensory neurons and the spinal cord in cases of chronic pain of this type. Alterations in N-methyl-D-aspartate (NMDA) receptors, induction of cyclooxygenase and prostaglandin synthesis, and changes in GABA-ergic inhibition in the dorsal horns are all implicated (Woolf).

The term *causalgia* is best reserved for the syndrome described above—i.e., persistent burning pain and abnormalities of sympathetic innervation consequent upon trauma to a major nerve in an extremity. Others have applied the term to a wide range of conditions that are characterized by persistent burning pain but have only an inconstant association with sudomotor, vasomotor, and trophic changes and an unpredictable response to sympathetic blockade. These latter states, which have been described under a plethora of terms (e.g., Sudeck atrophy of bone, minor causalgia, shoulder-hand syndrome, algoneurodystrophy), may follow non-traumatic lesions of the peripheral nerves or even lesions of the CNS (“mimocausalgia”).

We have no explanation for the so-called causalgia-dystonia syndrome (Bhatia et al) in which a fixed dystonic posture is engrafted on a site of causalgic pain. The clinical features of both the causalgic and dystonic elements of the syndrome were somewhat unusual in the cases reported. The degree of injury was often trivial or nonexistent and no signs of a neuropathic lesion were evident. Remarkably, both the causalgia and dystonia spread from their initial sites to widely disparate parts of the limbs and body. The syndrome did not respond to any form of treatment, although some patients recovered spontaneously. Its origin is not explained.

The treatment of reflex sympathetic dystrophy is largely unsatisfactory, although a certain degree of improvement can be expected if treatment is started early and the limb is mobilized. The alternatives for treatment are discussed further on.

Central Neurogenic Pain In central lesions, deafferentation of secondary neurons in the posterior horns or of sensory ganglion cells that terminate on them may cause the deafferented cells to become continuously active and, if stimulated by a microelectrode, to reproduce pain. In the patient whose spinal cord has been transected, there may be intolerable pain in regions below the level of the lesion. It may be exacerbated or provoked by movement, fatigue, or emotion and projected to areas disconnected from supraspinal structures (akin to the phantom pain in the missing part of an amputated limb). Here, and in the rare cases of intractable pain with lateral medullary or pontine lesions, loss of the descending inhibitory systems seems a likely explanation. This may also explain the pain of the Déjerine-Roussy thalamic syndrome described on page 141. Altered sensitivity and hyperactivity of central neurons is an alternative possibility.

Further details concerning the subject of neuropathic pain can be found in the writings of Scadding and of Woolf and Mannion (see References).

Pain in Association with Psychiatric Diseases

It is not unusual for patients with endogenous depression to have pain as the predominant symptom. And, as emphasized previously, most patients with chronic pain of all types are depressed. Wells and colleagues, in a survey of a large number of depressed and chronic pain patients, have corroborated this clinical impression. Fields has elaborated a theoretical explanation of the overlap of pain and depression. In such cases one is faced with an extremely difficult clinical problem—that of determining whether a depressive state is primary or secondary. Complaints of weakness and fatigue, depression, anxiety, insomnia, nervousness, irritability, palpitations, etc., are woven into the clinical syndrome, attesting to the prominence of psychiatric disorder. In some instances the diagnostic criteria cited in Chap. 57 provide the answer, but in others it is impossible to make this determination. Empiric treatment with antidepressant medication or, failing this, with electroconvulsive therapy is one way out of the dilemma.

Intractable pain may be the leading symptom of both hysteria and compensation neurosis. Every experienced physician is familiar with the “battle-scarred abdomen” of the woman with hysteria (so-called Briquet disease) who has demanded and yielded to one surgical procedure after another, losing appendix, ovaries, fallopian tubes, uterus, gallbladder, etc., in the process (“diagnosis by evisceration”). The recognition and management of hysteria are discussed in Chap. 56.

Compensation neurosis is often colored by persistent complaints of headaches, neck pain (whiplash injuries), low back pain, etc. The question of ruptured disc is often raised, and laminectomy and spinal fusion may be performed (sometimes more than once) on the basis of dubious radiologic findings. Long delay in the settlement of litigation, allegedly to determine the seriousness of the injury, only enhances the symptoms and prolongs the disability. The medical and legal professions have no certain approach to such problems and often work at cross purposes. We have found that a frank, objective appraisal of the injury, an assessment of the psychiatric problem, and encouragement to settle the legal claims as quickly as possible work in the best interests of all concerned. While hypersuggestibility and relief of pain by placebos may reinforce the physician’s belief that there is a prominent factor of hysteria or malingering (see Chap. 56), such data are difficult to interpret.

Chronic Pain of Indeterminate Cause

This is the most difficult group of all—pain in the thorax, abdomen, flank, back, face, or other part that cannot be traced to any visceral abnormality. Supposedly all neurologic sources, such as a spinal cord tumor, have been excluded by repeated examinations and imaging procedures. A psychiatric disorder to which the patient’s symptoms and behavior might be attributed cannot be discerned. Yet the patient complains continuously of pain, is disabled, and spends a great deal of effort and money seeking medical aid.

In such a circumstance, some physicians and surgeons, rather than concede their helplessness, may resort to extreme measures, such as exploratory thoracotomy, laparotomy, or laminectomy. Or they may injudiciously attempt to alleviate the pain and avoid drug addiction by severing roots and spinal tracts, often with the result that the pain moves to an adjacent segment or to the other side of the body.

This type of patient should be seen frequently by the physician. All the medical facts should be reviewed and the clinical and laboratory examinations repeated if some time has elapsed since they were last done. Tumors in the hilum of the lung or mediastinum; in the retropharyngeal, retroperitoneal, and paravertebral spaces; or in the uterus, testicle, kidney, or prostate pose a special difficulty in diagnosis, often being undetected for many months. More than once, we have seen a patient for months before a kidney or pancreatic tumor became apparent. Neurofibroma causing pain in an unusual site, such as one side of the rectum or vagina, is another type of tumor that may defy diagnosis for a long time. Truly neurogenic pain is almost invariably accompanied by alterations in cutaneous sensation and other neurologic signs, the finding of which facilitates diagnosis; the appearance of the neurologic signs may be delayed, however—for example, in brachial neuritis.

The possibility of drug addiction as a motivation should be eliminated. It is impossible to assess pain in the addicted individual, for the patient's complaints are woven into his need for medication. Temperament and mood should be evaluated carefully from day to day; the physician must remember that the depressed patient often denies being depressed and may even occasionally smile. When no medical, neurologic, or psychiatric disease can be established, one must be resigned to managing the painful state by the use of non-narcotic medications and frequent clinical re-evaluations. Such a course, though not altogether satisfactory, is preferable to prescribing excessive opioids or subjecting the patient to ablative surgery.

Because of the complexity and difficulty in diagnosis and treatment of chronic pain, most medical centers have found it advisable to establish pain clinics. Here a staff of internists, anesthesiologists, neurologists, neurosurgeons, and psychiatrists can review each patient in terms of drug dependence, neurologic disease, and psychiatric problems. Success is achieved by treating each aspect of chronic pain, with emphasis on increasing the patient's tolerance of pain by means of biofeedback, meditation, and related techniques; by using special invasive anesthetic special procedures (discussed later in the chapter); by establishing a regimen of pain medication that does not lead to a rebound exaggeration of pain between doses; and by controlling depressive illness.

Rare and Unusual Disturbances of Pain Perception

Lesions of the parieto-occipital regions of one cerebral hemisphere sometimes have peculiar effects on the patient's capacity to feel and react to pain. Under the title of *pain hemianesthesia*, Hecaen and Ajuriaguerra described several cases of left-sided paralysis from a right parietal lesion, which, at the same time, rendered the patient hypersensitive to noxious stimuli. When pinched on the affected side, the patient, after a delay, became agitated, moaned, and seemed distressed but made no effort to fend off the painful stimulus with the other hand or to withdraw from it. In contrast, if the good side was pinched, the patient reacted normally and moved the normal hand at once to the site of the stimulus to remove it. The motor responses seem no longer to be guided by sensory information from one side of the body.

There are also two varieties of rare individuals who from birth are totally indifferent to pain coupled with anhidrosis ("congenital insensitivity to pain") or are incapable of feeling pain ("universal analgesia"). The former have been found by Indo and colleagues to have a mutation in the a neural tyrosine kinase receptor, a nerve growth factor receptor; those in the second group suffer from either

a congenital lack of pain neurons in dorsal root ganglia, a polyneuropathy, or a lack of pain receptors in the primary afferent neuron. A similar loss of pain sensibility is encountered in the Riley-Day syndrome (congenital dysautonomia, pages 464 and 1159).

The phenomenon of *asymbolia for pain* is another rare and unusual condition, wherein the patient, although capable of distinguishing the different types of pain stimuli from one another and from touch, is said to make none of the usual emotional, motor, or verbal responses to pain. The patient seems totally unaware of the painful or hurtful nature of stimuli delivered to any part of the body, whether on one side or the other. The current interpretation of asymbolia for pain is that it represents a particular type of agnosia (analagnosia) or apractagnosia (see Chap. 22), in which the organism loses its ability to adapt its emotional, motor, and verbal actions to the consciousness of a nociceptive impression. "*Le sujet a perdu la compréhension de la signification de la douleur.*" We have not had experience with this syndrome.

Treatment of Intractable Pain

Once the nature of the patient's pain and underlying disease have been determined, therapy must include some type of pain control. Initially, of course, attention is directed to the underlying disease, with the idea of eliminating the source of the pain by appropriate medical, surgical, or radiotherapeutic measures. When pain cannot be relieved because the primary disease is not tractable, the physician should, if time and the circumstances permit, attempt to use the milder measures for pain relief first—for example, nonnarcotic analgesics and antidepressants or anticonvulsants before resorting to narcotics and local nerve blocks before contemplating surgical approaches for pain relief. Not all situations allow this graduated approach, and large doses of narcotics may be required early in the course of illness—for example, to treat the pain of visceral and bone cancer. The same measured strategy is appropriate in the treatment of neuropathic pain and of pain of unclear origin except that one generally stops short of permanent ablative procedures that irrevocably damage nerves.

The entire field of pain relief has been changed by the introduction of analgesic procedures that block nerves, alter neural conduction, or administer conventional medications in unconventional ways. These have become the province of pain clinics and hospital pain services, usually run by departments of anesthesiology. In addition, a number of special procedures or unique medications are highly effective for pain relief but are unique to specific situations. These include certain forms of headache and limb pain (temporal arteritis and polymyalgia rheumatica treated with corticosteroids, or migraine relief with "triptan" drugs); trigeminal neuralgia, which may be relieved by microvascular decompression of a branch of the basilar artery or by controlled damage of the gasserian ganglion; painful dystonic disorders that are relieved by the injection of botulinum toxin, and so on. Special procedures that have been devised to treat various forms of spinal back pain fall into the same category. The following discussion provides some guidance for the physician who is asked to undertake the treatment of chronic pain or of neuropathic pain, which often falls primarily to the neurologist.

Use of Opioids and Opiates A useful way in which to undertake the management of chronic pain that affects several parts of the body, as in the patient with metastases, is with codeine, oxycodone, or propoxyphene taken together with aspirin, acetaminophen, or

another nonsteroidal anti-inflammatory drug (NSAID). The analgesic effects of these two types of drugs are additive, which is not the case when narcotics are combined with diazepam or phenothiazine. Antidepressants and anticonvulsants, as discussed further on, may have a beneficial effect on pain even in the absence of overt depression. This is true particularly in cases of neuropathic pain (painful polyneuropathy and some types of radicular pain). Sometimes these nonnarcotic agents may in themselves or in combination with these treatment modalities be sufficient to control the patient's pain; the use of narcotics can then be kept in reserve.

Should the foregoing measures prove to be ineffective, one must turn to more potent narcotic agents. Methadone and levorphanol are sometimes useful drugs with which to begin, because of their effectiveness by mouth and the relatively slow development of tolerance. Some pain clinics prefer the use of shorter acting drugs such as oxycodone, given more frequently through the day. The oral route should be utilized whenever possible, since it is more comfortable for the patient than the parenteral route. Also, the oral route is associated with fewer side effects except for nausea and vomiting, which tend to be worse than with parenteral administration. Should the latter become necessary, one must be aware of the ratios of oral to parenteral dosages required to produce equivalent analgesia. These are indicated in Table 8-3.

If oral medication fails to control the pain, the parenteral administration of codeine or more potent opioids becomes necessary. One may begin with methadone, dihydromorphine (Dilaudid), or levorphanol, given at intervals of 4 to 6 h, because of their rela-

tively long duration of action (particularly in comparison to meperidine). Alternatively, one may first resort to the use of transdermal patches of drugs such as fentanyl, which provide relief for 24 to 72 h and which we have found particularly useful in the treatment of pain from brachial or lumbosacral plexus invasion by tumor and of painful neuropathies such as those due to diabetes and systemic amyloidosis. Long-acting morphine preparations are useful alternatives. Should long-continued injections of opiates become necessary, the optimal dose for the relief of pain should be established and the drug then given at regular intervals around the clock, rather than "as needed." The administration of morphine (and other narcotics) in this way represents a laudable shift in attitude among physicians. For many years it was taught that the drug should be given in the smallest possible doses, spaced as far apart as possible, and repeated only when severe pain reasserted itself. It has become clear that this approach results in unnecessary discomfort and, in the end, the need to use larger doses. Most physicians now realize that the fear of creating narcotic dependence and the expected phenomenon of increasing tolerance must be balanced against the overriding need to relieve pain. The most pernicious aspect of addiction, that of compulsive drug-seeking behavior and self-administration of the drug, occurs only rarely in this setting and usually in patients with a previous history of addiction or alcoholism, with depression as the primary problem, or with certain character defects that have been loosely referred to as "addiction proneness." Even in patients with severe acute or postoperative pain, the best results are obtained by allowing the patient to deter-

Table 8-3
Common drugs for the management of chronic pain

GENERIC NAME	ORAL DOSE, MG	INTERVAL	COMMENTS
Nonopiod analgesics			
Acetylsalicylic acid	650	q4h	Enteric-coated preparations available
Acetaminophen	650	q4h	Side effects uncommon
Ibuprofen	400	q4–6h	
Naproxen	250–500	q12h	Delayed effects may be due to long half-life
Ketorolac	10–20	q4–6h	Useful postoperatively and for weaning from narcotics. Can be used IM
Trisalicylate	1000–1500	q12h	Fewer gastrointestinal or platelet effects than aspirin
Indomethacin	25–50	q8h	Gastrointestinal side effects common
Tramadol	50	q6h	Potent nonnarcotic with similar side effects but less respiratory depression
Narcotic analgesics			
Codeine	30–60	q4h	Nausea common
Oxycodone	—	5–10 q4–6h	Usually available combined with acetaminophen or aspirin
Morphine	10 q4h	60 q4h	
Morphine, sustained release	—	90 q12h	Oral slow-release preparation
Hydromorphone	1–2 q4h	2–4 q4h	Shorter-acting than morphine sulfate
Levorphanol	2 q6–8h	4 q6–8h	Longer-acting than morphine sulfate; absorbed well orally
Methadone	10 q6–8h	20 q6–8h	Delayed sedation due to long half-life
Meperidine	75–100 q3–4h	300 q4h	Poorly absorbed orally; normeperidine is a toxic metabolite
Fentanyl	25 to 100 µg	apply q 72h	Parenteral and transcutaneous ("patch") use
Anticonvulsants and related drugs			
Phenytoin	100	q6–8h	
Carbamazepine	200–300	q6h	
Clonazepam	1	q6h	
Mexiletine	150–200	q4–6h	
Gabapentin	300–2700	q8h	

mine the dose and frequency of intravenous medication, so-called patient-controlled analgesia (PCA). Again, the danger of producing addiction is minimal.

Excellent guidelines for the use of orally and parenterally administered opioids for cancer-related pain are contained in the article of Cherny and Foley and in the publication of the U.S. Department of Health and Human Services, which unfortunately, is no longer easily available.

The regimen outlined above conforms with current understanding about pain-control mechanisms. Aspirin and other NSAIDs are believed to prevent the activation of nociceptors by inhibiting the synthesis of prostaglandins in skin, joints, viscera, etc. Morphine and meperidine given orally, parenterally, or intrathecally presumably produce analgesia by acting as "false" neurotransmitters at receptor sites in the posterior horns of the spinal cord—sites that are normally activated by endogenous opioid peptides. The separate sites of action of NSAIDs and opioids provide an explanation for the therapeutic usefulness of combining these drugs. Opioids not only act directly on the central pain-conducting sensory systems but also exert a powerful action on the affective component of pain.

Supplemental Medications Tricyclic antidepressants, especially the methylated forms (imipramine, amitriptyline, and doxepin), block serotonin reuptake and thus enhance the action of this neurotransmitter at synapses and putatively facilitate the action of the intrinsic opiate analgesic system. As a general rule, relief is afforded with tricyclic antidepressants in the equivalent dose range of 75 to 125 mg daily of amitriptyline, but little benefit accrues with higher doses. The newer serotonergic antidepressants seem not to be as effective for the treatment of chronic neuropathic pain (see review by McQuay and colleagues), but these agents have not yet been extensively investigated in this clinical condition.

Anticonvulsants have a beneficial effect on many central and peripheral neuropathic pain syndromes but are generally less effective for causalgic pain due to partial injury of a peripheral nerve. The mode of action of phenytoin, carbamazepine, gabapentin, levetiracetam, and other anticonvulsants in suppressing the lancinating pains of tic douloureux and certain polyneuropathies as well as pain after spinal cord injury and myelitis is not fully understood, but they are widely used. Their action has been attributed to the blocking of excess sodium channels, thereby reducing the evoked and spontaneous activity in nerve fibers. The full explanation is certainly more complex and related to separate central and peripheral sites, as summarized by Jensen. Often, large doses must be attained—for example, more than 2400 mg per day for gabapentin for full effect—but the sedative and ataxic effects may be poorly tolerated.

The use of analgesic (nonnarcotic and narcotic), anticonvulsant, and antidepressant drugs in the management of chronic pain is summarized in Table 8-3.

Treatment of Cancer Pain If the patient is ridden with disease and will not live longer than a few weeks or months, is opposed to surgery, or has widespread pain, surgical measures are out of the question. However, pain from widespread osseous metastases, even in patients with hormone-insensitive tumors, may be relieved by radiation therapy or by hypophysectomy. If these are not feasible, opioid medications are required and are effective, but they must be utilized in adequate doses. Usually, nerve section is not a satisfactory way of relieving restricted pain of the trunk and limbs because the overlap of adjacent nerves prevents complete denervation.

Other procedures to be considered are the regional delivery of narcotic analogues, such as fentanyl or ketamine, by means of an external pump and a catheter that is implanted percutaneously in the epidural space in proximity to the dorsal nerve roots in the affected region; this device can be used safely at home.

Treatment of Neuropathic Pain

The treatment of pain induced by nerve root or intrinsic peripheral nerve disease is a great challenge for the neurologist and, as previously mentioned, utilizes several techniques that are generally administered by an anesthesiologist. One usually resorts first to one of the anticonvulsants discussed earlier and listed in Table 8-3. The next simplest treatments are topical; if the pain is regional and has a predominantly burning quality, capsaicin cream can be applied locally, care being taken to avoid contact with the eyes and mouth. The irritative effect of this chemical seems in some cases to mute the pain. We have also had success with several concoctions of "eutectic" mixtures of local anesthetic (EMLA) creams or the simpler lidocaine gel with ketorolac, gabapentin, and other medications; these are applied directly to the affected area, usually the feet. These preparations may provide considerable relief in postherpetic neuralgia and some painful peripheral neuropathies, but they are totally ineffective in others. Aspirin mixed with chloroform in cold cream is said to be very effective in the topical treatment of postherpetic neuralgia, as suggested by King (see Chap. 10).

Several types of spinal injection, epidural, root, and facet, have long been used for the treatment of pain. Injections of epidural corticosteroids or mixtures of analgesics and steroids are helpful in selected cases of lumbar or thoracic nerve root pain and occasionally in painful peripheral neuropathy, but precise criteria for the use of this measure are not well established. Several studies do not support a beneficial effect, but there is little doubt, in our view, that a few patients are helped, if only for several days or weeks (see Chap. 11). Root blocks with lidocaine or with longer-acting local anesthetics are sometimes helpful in establishing the precise source of radicular pain. Their main therapeutic use in our experience has been for thoracic radiculitis from shingles, chest wall pain after thoracotomy, and diabetic radiculopathy. Similar local injections are used in the treatment of occipital neuralgia. Injection of analgesic compounds into and around facet joints and the extension of this procedure, radiofrequency ablation of the small nerves that innervate the joint, are as controversial as epidural injections; most studies failing to find a consistent benefit. Despite these drawbacks, we have found both of these approaches very useful when pain can be traced to a derangement of these joints, as discussed in Chap. 11.

The intravenous infusion of lidocaine has a brief beneficial effect on many types of pain, including neuropathic varieties, localized headaches, and facial pain; it is said to be useful in predicting the response to longer-acting agents such as mexiletine, its oral analogue, although this relationship has been erratic in our experience (see Table 8-1). Mexiletine is given in an initial dose of 150 mg per day and slowly increased to a maximum of 300 mg three times daily; it should be used very cautiously in patients with heart block.

Reducing sympathetic activity within somatic nerves by direct injection of the sympathetic ganglia in affected regions of the body (stellate ganglion for arm pain and lumbar ganglia for leg pain) has met with mixed success in neuropathic pain, including that of cau-

salgia and reflex sympathetic dystrophy. A variant of this technique utilizes regional intravenous infusion of a sympathetic blocking drug (bretlyium, guanethidine, reserpine) into a limb that is isolated from the systemic circulation by the use of a tourniquet. This is known as a "Bier block," after the developer of regional anesthesia for single-limb surgery. The use of these techniques, as well as the administration of clonidine by several routes and the intravenous infusion of the adrenergic blocker phentolamine, is predicated on the concept of "sympathetically sustained pain," meaning pain that is mediated by the interaction of sympathetic and pain nerve fibers or by the sprouting of adrenergic axons in partially damaged nerves. This form of treatment is still under study, but the most consistent responses to sympathetic blockade are obtained in cases of true causalgia resulting from partial injury of a single nerve and in reflex sympathetic dystrophy. These pain syndromes have been referred to by a number of different names, most recently as the "complex regional pain syndrome," but all refer to the same constellation of burning and other regional pains that may or may not conform to a nerve or root distribution, as has been mentioned. A number of other treatments have proven successful in some patients with reflex sympathetic dystrophy and other neuropathic pains, but the clinician should be cautious about their chances of success over the long run. Perhaps the most novel of these has been the use of bisphosphonates (pamidronate, alendronate), which, as noted above, have been beneficial in painful disorders of bone, such as Paget disease and metastatic bone lesions. It is theorized that this class of drug reverses the bone loss consequent to reflex sympathetic dystrophy, but how this relates to pain control is unclear (see Schott 1997). Electrical stimulation of the posterior columns of the spinal cord by an implanted device, as discussed below, has become popular. Another treatment of last resort is the epidural infusion of drugs such as ketamine; sometimes this has a lasting effect on causalgic pain.

The therapeutic approaches enumerated here are usually undertaken in sequence; almost invariably, a combination of drugs—such as gabapentin, narcotics, and clonidine—in addition to anesthetic techniques is required. This reflects the general ineffectiveness of currently available treatments and our uncertainty as to the mechanisms of neuropathic pain. Nevertheless, the ongoing attention and support of the neurologist often becomes the patient's mainstay. There are occasional successes, some of them temporary. Further references can be found in the thorough review by Katz.

Ablative Surgery in the Control of Pain

It is the authors' considered opinion that a program of medical therapy should always precede ablative surgical measures. Only when a variety of analgesic medications (including opioids), and only when certain practical measures, such as regional analgesia or anesthesia, have completely failed should one turn to neurosurgical procedures. Also, one should be very cautious in suggesting a procedure of last resort for pain that has no established cause, as, for example, limb pain that has been incorrectly identified as causalgic because of a burning component but where there has been no nerve injury.

The least destructive procedure consists of surgical exploration for a neuroma if a prior injury or operation may have partially sectioned a peripheral nerve. Magnetic resonance imaging of the region should be performed first and will demonstrate most such lesions, but we are uncertain if very small neuromas are visualized, and it is this ambiguity that justifies exploration. Another nonde-

structive procedure is implantation of a spinal electrical stimulator, usually adjacent to the posterior columns. This procedure, in which there is now a resurgence of interest, has afforded only incomplete relief in our patients and may be difficult to maintain in place. However Kemler and colleagues found a sustained reduction in pain intensity and an improved quality of life in patients with intractable reflex sympathetic dystrophy, even after 2 years in a randomized trial. It has become clear that careful selection of patients is the best assurance of a good outcome. We can add from experience with our patients that a temporary trial of the stimulator is advisable before committing to its permanent use. The ill-advised use of nerve section and dorsal rhizotomy as definitive measures for the relief of regional pain has already been discussed, under "Treatment of Intractable Pain," above.

Spinothalamic tractotomy, in which the anterior half of the spinal cord on one side is sectioned at an upper thoracic level, effectively relieves pain in the opposite leg and lower trunk. This may be done as an open operation or as a transcutaneous procedure in which a radiofrequency lesion is produced by an electrode. The analgesia and thermoanesthesia may last a year or longer, after which the level of analgesia tends to descend and the pain tends to return. Bilateral tractotomy is also feasible, but with greater risk of loss of sphincteric control and, at higher levels, of respiratory paralysis. Motor power is nearly always spared because of the position of the corticospinal tract in the posterior part of the lateral funiculus.

Pain in the arm, shoulder, and neck is more difficult to relieve surgically. High cervical transcutaneous cordotomy has been used successfully, with achievement of analgesia up to the chin. Commissural myelotomy by longitudinal incision of the anterior or posterior commissure of the spinal cord over many segments has also been performed, with variable success. Lateral medullary tractotomy is another possibility but must be carried almost to the midline to relieve cervical pain. The risks of this latter procedure and also of lateral mesencephalic tractotomy (which may actually produce pain) are so great that neurosurgeons have abandoned these operations.

Stereotactic surgery on the thalamus for one-sided chronic pain is still used in a few clinics, and the results have been instructive. Lesions placed in the ventroposterior nucleus are said to diminish pain and thermal sensation over the contralateral side of the body while leaving the patient with all the misery or affect of pain; lesions in the intralaminar or parafascicular-centromedian nuclei relieve the painful state without altering sensation (Mark). Since these procedures have not yielded predictable benefits to the patient, they are now seldom used. The same unpredictability pertains to cortical ablations. Patients in whom a severe depression of mood is associated with a chronic pain syndrome have been subjected to bilateral stereotactic cingulotomy or the equivalent—subcaudate tractotomy. A considerable degree of success has been claimed for these operations, but the results are difficult to evaluate. Orbitofrontal leukotomy has been discarded because of the personality change that it produces.

Unconventional Methods for the Treatment of Pain

Included under this heading are certain techniques such as biofeedback, meditation, imagery, acupuncture, some forms of spinal manipulation, as well as transcutaneous electrical stimulation. Each of these may be of value in the context of a comprehensive pain

management program, conducted usually in a pain clinic, as a means of providing relief from pain and suffering, reducing anxiety, and diverting the patient's attention, even if only temporarily, from the painful body part. Attempts to quantify the benefits of these techniques—judged usually by a reduction of drug dosage in response to a particular form of treatment—have given mixed or negative results. Nevertheless, it is unwise for physicians to dismiss these methods out of hand, since well-motivated and ap-

parently well-balanced persons have reported subjective improvement with one or another of these methods and, in the final analysis, this is what really matters. Conventional psychotherapy in combination with the use of medication and, at times, of electroconvulsive therapy can be of great benefit in the treatment of associated depressive symptoms, as discussed above (under "Pain in Association with Psychiatric Disease"), but it should not otherwise be expected to change the experience of pain.

CHAPTER 9

OTHER SOMATIC SENSATION

Under normal conditions, sensory and motor functions are interdependent, as was dramatically illustrated by the early animal experiments of Claude Bernard and Sherrington, in which practically all effective movement of a limb was abolished by eliminating only its sensory innervation (sectioning of posterior roots). Interruption of other sensory pathways and destruction of the parietal cortex also has profound effects on motility. Sensory and motor neurons are intimately connected at all levels of the nervous system, from the spinal cord to the cerebrum. To a large extent, human motor activity depends on a constant influx of sensory impulses (most of them not consciously perceived). Truly, in a physiologic sense, movement is inextricably dependent on sensation.

However, under conditions of disease, motor or sensory functions may be affected independently. There may be loss or impairment of sensory function, and this can represent the principal manifestation of neurologic disease. The logic of this is clear enough, since the major anatomic pathways of the sensory system are distinct from those of the motor system and can be selectively disturbed by disease. The analysis of sensory symptoms involves the use of special tests, designed to elicit the nature of the sensory alteration and its location; it is from this point of view that disorders of sensory function are considered here.

This chapter deals with general somatic sensation, i.e., afferent impulses that arise in the skin, muscles, or joints. One form of somatic sensation—pain—has already been discussed in Chap. 8, and these two chapters should be read as a unit. Because of its overriding clinical importance, pain has been accorded a chapter of its own, but the two chapters are of one piece. The special senses—vision, hearing, taste, and smell—are considered in the next section (Chaps. 12 to 15), and visceral (interoceptive) sensation, most of which does not reach consciousness, is considered with the disorders of the autonomic nervous system (Chap. 26).

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

An understanding of sensory disorders depends upon a knowledge of functional anatomy. It is necessary to be familiar with the sensory receptors in the skin and deeper structures, the distribution of the peripheral nerves and roots, and the pathways by which sensory impulses are conveyed from the periphery and through the spinal cord and brain-stem to the thalamus and cerebral cortex. These aspects of sensory anatomy and physiology have already been touched upon in Chap. 8, in relation to the perception of pain, and are elaborated here to include all forms of somatic sensation. Charts showing

the cutaneous distribution of the peripheral nerves are included here (Fig. 9-1).

All sensation depends on impulses that are excited by adequate stimulation of receptors and conveyed to the central nervous system by afferent, or sensory, fibers. Sensory receptors are of two general types: those in the skin, mediating superficial sensation (*exteroceptors*), and those in the deeper somatic structures (*proprioceptors*). The skin receptors are particularly numerous and transduce four types of sensory experience: warmth, cold, touch, and pain; these are conventionally referred to as *sensations* or *senses*, e.g., tactile sensation or sense of touch. The proprioceptors

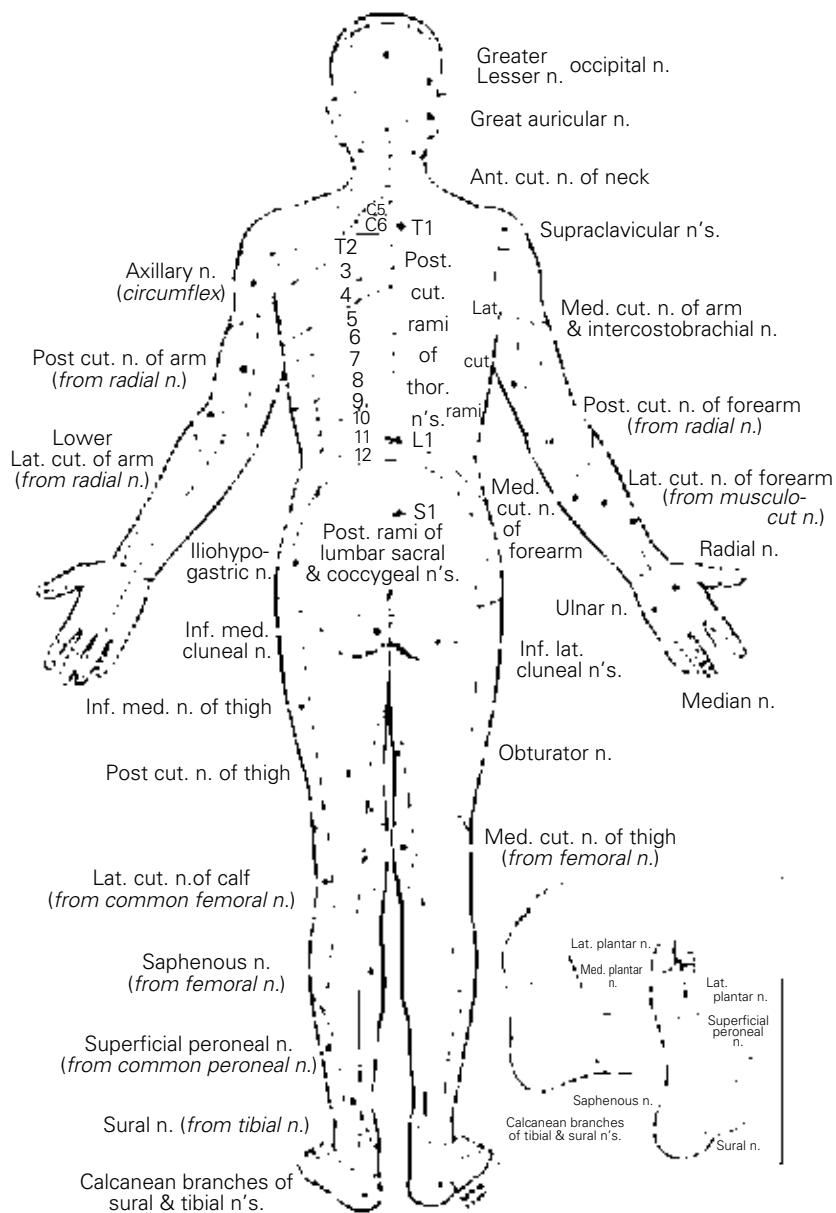

Figure 9-1 (Continued).

inform us of the position of our body or parts of our body; of the force, direction, and range of movement of the joints (kinesthetic sense); and of a sense of pressure, both painful and painless. Histologically, a wide variety of sensory receptors has been described, varying from simple, free axon terminals to highly branched and encapsulated structures, the latter bearing the names of the anatomicists who first described them (see below).

Mechanisms of Cutaneous Sensation

As indicated in the preceding chapter, it was common teaching for many years that each of the primary modalities of cutaneous sensation is subserved by a morphologically distinct end organ, each with its separate peripheral nerve fibers. According to this formulation, traditionally associated with the name of von Frey, each type of end organ was thought to respond only to a particular type of stimulus and to subserve a specific modality of sensation: Meissner

corpuscles, touch; Merkel discs, pressure; Ruffini plumes, warmth and skin stretch; Krause end bulbs, cold; pacinian corpuscles, vibration and tickle; and freely branching endings, pain.

This *specificity theory*, as it came to be called, has held up best in respect to the peripheral mechanisms for pain, insofar as certain primary afferent fibers, namely the C and A- δ fibers and their free nerve-ending type of receptors, respond maximally to noxious stimuli. But even these freely branching receptor endings and their so-called pain fibers convey considerable nonnoxious information; that is, their specificity as pain fibers is not absolute (Chap. 8). Nor has it been possible to ascribe a specific function to each of the many other types of receptors. Thus, Merkel discs, Meissner corpuscles, nerve plexuses around the hair follicles, and free nerve endings can all be activated by moving or stationary tactile stimuli. Conversely, a single type of receptor seems capable of generating more than one sensory modality. Lele and Weddell found that with appropriate stimulation of the cornea, each of the four primary modalities of somatic sensibility (touch, warmth, cold, pain) could be recognized, even though the cornea contains only fine, freely branching nerve filaments. In the outer ear, which is also sensitive to these four modalities, only two types of receptors—freely ending and perifollicular—are present. The lack of organized receptors—e.g., the end bulbs of Krause and Ruffini—in the cornea and ear makes it evident that these types of receptors are not essential for the recognition of cold and warmth, as von Frey and other early anatomists had postulated.

Particularly instructive in this regard are the observations of Kibler and Nathan, who studied the responses of warm and cold spots to different stimuli. (Warm and cold spots are those small areas of skin that respond most consistently to thermal stimuli with a sensation of warmth or cold.) They found that a cold stimulus applied to a warm spot gave rise to a sen-

sation of cold and that a noxious stimulus applied to a warm or cold spot gave rise only to a painful sensation; they also noted that mechanical stimulation of these spots gave rise to a sensation of touch or pressure. These observations indicate that cutaneous receptors, some not easily distinguishable from one another on morphologic grounds, are probably endowed with only a relative degree of specificity, in the sense that each responds *preferentially* (i.e., has a lower threshold) to one particular form of stimulation. However, among the freely branching nociceptors there is some degree of specialization, as discussed in Chap. 8. Such end organs can then be classed as mechanoreceptors, thermoreceptors, or nociceptors, depending on their selective sensitivity to mechanical, thermal, or noxious stimuli, respectively (Sinclair; Light and Perl).

Recent physiologic studies have shown that the *quality* of sensation depends on the type of nerve fiber that is activated. Different diseases therefore evoke a variety of sensory deficits. Microstimulation of single sensory fibers in a peripheral nerve of an

awake human subject arouses different sensations, depending on which fibers are stimulated and not on the frequency of stimulation. On the other hand, the frequency of stimulation does govern the *intensity* of sensation, as does the number of sensory units that are stimulated. Stated somewhat differently, afferent impulse frequency (*temporal summation*) is encoded by the brain in terms of magnitude or intensity of sensation. In addition, as the intensity of stimulation increases, more sensory units are activated (*spatial summation*).

Localization of a stimulus was formerly thought to depend on the simultaneous activation of overlapping sensory units. Tower defined a peripheral sensory unit as a monopolar dorsal root ganglion cell, its central and distal axon extensions, and all the sensory endings in the territory supplied by the distal extension (receptive field). In the very sensitive pulp of the finger, where the error of localization is less than 1.0 mm, there are 240 overlapping, low-threshold mechanoreceptors per square centimeter. Highly refined physiologic techniques have demonstrated that activation of even a single sensory unit is sufficient to localize the point stimulated and that the body map in the parietal lobe is capable, by its modular columnar organization, of encoding such refined topographic information. Noteworthy also is the fact that each point in the skin that is stimulated may involve more than one type of receptor. A stimulus, in order to gain access to its receptor, must pass through the skin and possess sufficient energy to transduce, i.e., depolarize, the nerve ending. Not only does the threshold of stimulation vary but the nerve impulse that is generated is a graded one, not an all-or-none phenomenon like an action potential in nerve. This poorly understood peripheral generator potential determines the frequency of impulse in the nerve and to what degree it is sustained or fades out (i.e., adapts to the stimulus or fatigues). The mechanism by which a stimulus is translated into a sensory experience, i.e., is encoded, is now partially understood. Special molecules transduce physical alterations by opening cationic channels. As mentioned in Chap. 8, these changes lead to the opening of voltage-gated sodium channels, which generates an action potential. It is probably fair to say that each type of specialized ending has a membrane structure that facilitates the transductive process for a particular type of stimulus. In general, the encapsulated endings are more deeply situated, are of low-threshold type, variably adaptable to continued stimulation (the Meissner and pacinian corpuscles are rapidly adapting; the Merkel disc and Ruffini endings are slowly adapting) and connected to large sensory fibers (see Lindblom and Ochoa). Pain receptors lie deeper in the skin than those for touch.

Sensory Pathways

Sensory Nerves Fibers that mediate superficial sensation are located in cutaneous sensory or mixed sensorimotor nerves. In cutaneous nerves, unmyelinated pain and autonomic fibers exceed myelinated fibers by a ratio of 3 or 4:1. In contrast, proprioceptive fibers are located in deeper, predominantly motor nerves. The myelinated fibers are of two types, small, lightly myelinated, A- δ fibers for pain and cold, as discussed in Chap. 8, and larger, faster-conducting A- α fibers for touch and pressure. The nonmyelinated autonomic fibers are efferent (postganglionic) and innervate piloerector muscles, sweat glands, and blood vessels. In addition, these nerves contain afferent and efferent spindle and Golgi tendon organ fibers and thinner pain afferents. The differing conduction velocities of these fibers are discussed in Chap. 45.

A single cutaneous (touch, pain, and temperature) axon con-

ncts to several receptors, all of one type, which are irregularly distributed in the skin and account for sensory spots. Stimuli from a given spot are conveyed by two or more fibers. The proprioceptive fibers subserve pressure sense and, with endings in articular structures, the sense of position and movement; they enable one to discriminate the form, size, texture, and weight of objects. Sensations of tickle, itch, and wetness are believed to arise from combinations of several types of receptors.

Itch is a distinctive sensation that can be separated on clinical and neurophysiologic grounds from pain. Two aspects are recognized: a brief primary localized itch at the site of stimulus or injury, and a subsequent more diffuse sensation that is greatly intensified by gentle touch. The itch sensation is transmitted by specific C fibers, similarly specific neurons in the dorsal horns of the cord and directly via the spinothalamic projections to the thalamus, all of which differ from the similar structures utilized by pain. There is, however, no specialized peripheral itch receptor, the sensation depending instead on the spinal connections to itch pathways. Several forebrain regions are activated by itch; i.e., there is no "itch center." From a neurologic rather than a dermatologic perspective, the main cause of itch is postherpetic neuralgia, but cases of paroxysmal itch of central origin are known to be due to multiple sclerosis. The pathophysiology of itching has been discussed by Greaves and Wall and is reviewed further by Yosipovitch and colleagues.

Spinal Roots All the sensory neurons have their cell bodies in the dorsal root ganglia. The peripheral extensions of these cells constitute the sensory nerves; the central projections of these same cells form the posterior (dorsal) roots and enter the spinal cord. Each dorsal root contains all the fibers from skin, muscles, connective tissue, ligaments, tendons, joints, bones, and viscera that lie within the distribution of a single body segment, or somite. This segmental innervation has been amply demonstrated in humans and animals by observing the effects of lesions that involve one or two spinal nerves, such as (1) herpes zoster, which also causes visible vesicles in the corresponding area of skin; (2) the effects of a prolapsed intervertebral disc, which causes hypalgesia in a single root zone; and (3) surgical section of several roots on each side of an intact root (method of remaining sensibility). Maps of the dermatomes derived from these several types of data are shown in Figs. 9-2 and 9-3. It should be noted that there is considerable overlap from one dermatomal segment to the other, more so for touch than for pain. By contrast, there is little overlap between branches of the trigeminal nerve. Also, the maps differ somewhat according to the methods used in constructing them. In contrast to most dermatomal charts, those of Keegan and Garrett (based on the injection of local anesthetic into single dorsal root ganglia) show bands of hypalgesia to be continuous longitudinally from the periphery to the spine (Fig. 9-3). The distribution of pain fibers from deep structures, though not exactly corresponding to that of pain fibers from the skin, also follows a segmental pattern.

Posterior Columns In the dorsal roots, the sensory fibers are first rearranged according to function. Large and heavily myelinated fibers enter the cord just medial to the dorsal horn and divide into ascending and descending branches. The descending fibers and some of the ascending ones enter the gray matter of the dorsal horn within a few segments of their entrance and synapse with nerve cells in the posterior horns as well as with large ventral horn cells that subserve segmental reflexes. Some of the ascending fibers run uninterruptedly in the dorsal columns of the *same side of the spinal*

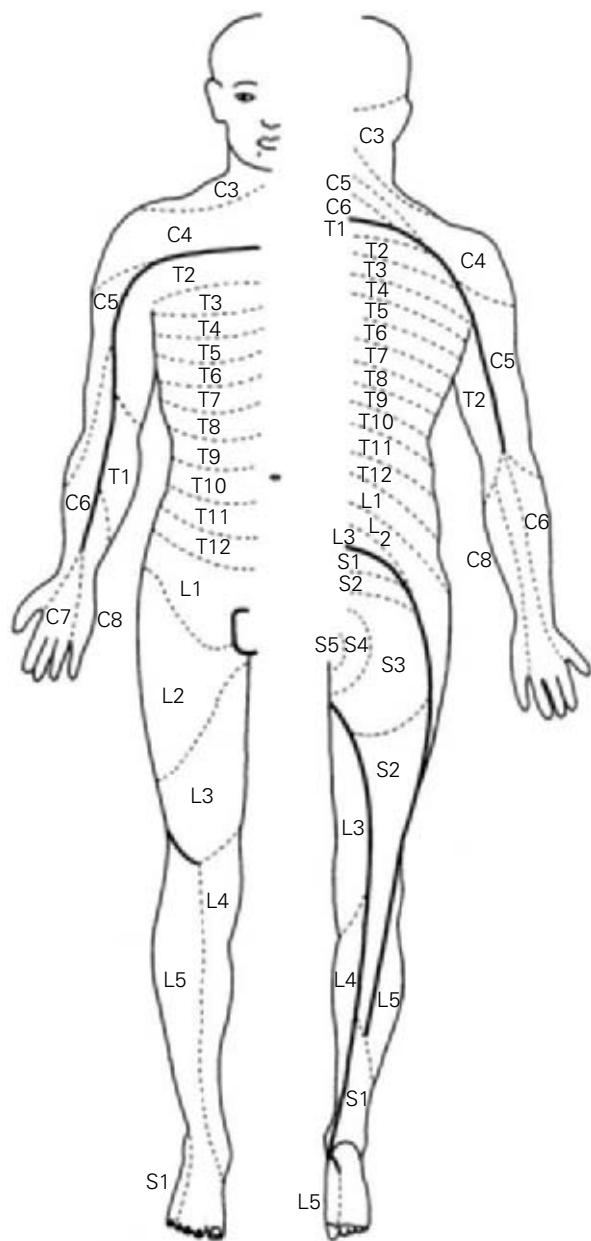

Figure 9-2. Distribution of the sensory spinal roots on the surface of the body. (Reproduced by permission from Sinclair.)

cord, terminating in the gracile and cuneate nuclei. The central axons of the primary sensory neurons are joined in the posterior columns by other secondary neurons whose cell bodies lie in the posterior horns of the spinal cord (see below). The fibers in the posterior columns are displaced medially as new fibers from each successively higher root are added, thereby creating somatotopic laminations (see Fig. 8-3).

Of the long ascending posterior column fibers, which are activated by mechanical stimuli of skin and subcutaneous tissues and by movement of joints, only about 25 percent (from the lumbar region) reach the gracile nuclei at the upper cervical cord. The rest off collaterals to or terminate in the dorsal horns of the spinal cord, at least in the cat (Davidoff). An estimated 20 percent of ascending fibers originate from cells in Rexed layers IV and V of the posterior horns (see Fig. 8-1) and convey impulses from low-threshold

mechanoreceptors that are sensitive to hair movement, skin pressure, or noxious stimuli. There are also descending fibers in the posterior columns, including fibers from cells in the dorsal column nuclei.

The posterior columns contain a portion of the fibers for the sense of touch as well as the fibers mediating the senses of touch-pressure, vibration, direction of movement and position of joints, and stereognosia—recognition of surface texture, shape, numbers and figures written on the skin, and two-point discrimination—all of which depend on patterns of touch-pressure (see Fig. 8-2). The nerve cells of the nuclei gracilis and cuneatus and accessory cuneate nuclei give rise to a secondary afferent path, which crosses the midline in the medulla and ascends as the medial lemniscus to the posterior thalamus. However, the fiber pathways in the posterior columns are not the sole mediators of proprioception in the spinal cord [see “Posterior (Dorsal) Column Syndrome,” further on].

In addition to these well-defined posterior column pathways, there are cells in the “reticular” part of the dorsal column nuclei that receive secondary ascending fibers from the dorsal horns of the spinal cord and from ascending fibers in the posterolateral columns. These dorsal column fibers project to brainstem nuclei, cerebellum, and

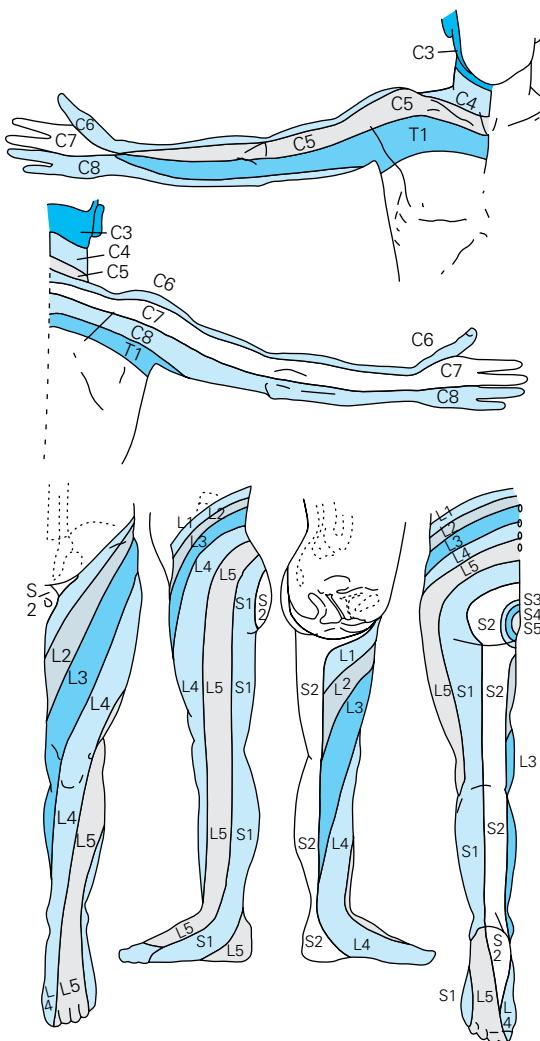

Figure 9-3. Dermatomes of the upper and lower extremities, outlined by the pattern of sensory loss following lesions of single nerve roots. (Reproduced by permission from Keegan and Garrett.)

thalamic nuclei. Many other cells of the dorsal column nuclei are interneurons, with both excitatory and inhibitory effects on local reflexes or on the primary ascending neurons. They are also under the influence of the sensorimotor cortex. Some act on descending corticospinal motor neurons. The functions of many of the extrathalamic projections of dorsal column cells are unknown (Davidoff).

Thinly myelinated or unmyelinated fibers, subserving mainly pain sensibility, but some sensitive to touch and pressure, enter the cord on the lateral aspect of the dorsal horn and synapse with dorsal horn cells, mainly within a segment or two of their point of entry into the cord. The dorsal horn cells, in turn, give rise to secondary sensory fibers, some of which may ascend ipsilaterally but most of which decussate and ascend in the spinothalamic tracts, as described in Chap. 8 (see Figs. 8-1 and 8-2). Observations based on surgical interruption of the anterolateral funiculus indicate that fibers mediating touch and deep pressure occupy the ventromedial part (anterior spinothalamic tract). Also as remarked in Chap. 8, an ascending tract of secondary sensory axons lies in or medial to the descending corticospinal system.

After the posterior columns terminate in the gracile and cuneate nuclei of the rostral cervical cord and medulla, synapses are made with fibers that cross the midline and ascend to form the medial lemniscal tracts in the brainstem. The lemniscal system is situated in a paramedian position, changing orientation slightly at different levels of the brainstem, and joining the spinothalamic system in the rostral midbrain to terminate in the posterior thalamic nuclei (see below and also Fig. 8-2).

Trigeminal Connections The pathways mediating cutaneous sensation from the face and head—especially touch, pain, and temperature—are conveyed to the brainstem by the trigeminal nerve. After entering the pons, the pain and temperature fibers turn caudally and run through the medulla as the descending trigeminal tract, terminating in a long, vertically oriented nucleus that lies beside it and extends to the second or third cervical segment of the cord, where it becomes continuous with the posterior horn of the spinal gray matter. Axons from the neurons of this nucleus cross the midline and ascend as the trigeminal lemniscus along the medial side of the spinothalamic tract (Fig. 8-2).

Thalamocortical Connections The posterior thalamic complex receives the fibers from the medial lemniscal, trigeminal lemniscal, and spinothalamic tracts and projects mainly to two somatosensory cortical areas. The first area (S1) corresponds to the postcentral cortex or Brodmann's areas 3, 1, and 2. S1 afferents are derived primarily from the ventral posterolateral nucleus (VPL) and VPM (ventral posteromedial nucleus—the terminus of trigeminal fibers) and are distributed somatotopically, with the leg represented uppermost and the face lowermost (face and hand are juxtaposed). Electrical stimulation of this area yields sensations of tingling, numbness, and warmth in specific regions on the *opposite* side of the body. The information transmitted to S1 is tactile and proprioceptive, derived mainly from the dorsal column–medial lemniscus system and concerned mainly with sensory discrimination. The second somatosensory area (S2) lies on the upper bank of the sylvian fissure, adjacent to the insula. Localization of function is less discrete in S2 than in S1, but S2 is also organized somatotopically, with the face rostrally and the leg caudally. The sensations evoked by electrical stimulation of S2 are much the same as those of S1 but, in distinction to the latter, may be felt bilaterally. Of note is the failure of cortical stimulation to evoke pain sensation.

Undoubtedly, the perception of sensory stimuli involves more of the cerebral cortex than the two discrete areas described above. Some sensory fibers probably project to the precentral gyrus and others to the superior parietal lobule. Moreover, S1 and S2 are not purely sensory in function; motor effects can be obtained by stimulating them electrically. It has been shown that sensory neurons in VPL, cuneate and gracile nuclei, and sensory neurons in the dorsal horns of the spinal cord all receive descending cortical projections as well as ascending ones. This reciprocal arrangement probably influences movement and the transmission and interpretation of pain, as discussed in Chap. 8.

Provided that the subcortical structures, especially the thalamus, are intact, certain sensations such as pain, touch, pressure, and extremes of temperature can reach consciousness. Their accurate localization, however, as well as the patient's ability to make other fine sensory discriminations, depends to a large extent on the integrity of the sensory cortex. This clinical distinction is elaborated in the discussion of the sensory syndromes, further on.

The cortical representation of sensory information in the postcentral gyrus is shown in Fig. 9-4 ("sensory homunculus"). As in the case of the motor representation (Fig. 3-4), a disproportionate area is devoted to localization in the fingers, lips, and face.

From this brief account of the various channels of sensory information, one must conclude that at every level there is the possibility of feedback control from higher levels. Most external and some internal stimuli are highly complex and induce activity in more than one sensory system. In every system, there is sufficient redundancy to allow lesser used systems to compensate partially for the deficits incurred by disease.

EXAMINATION OF SENSATION

Most neurologists would agree that sensory testing is the most difficult part of the neurologic examination. For one thing, test procedures are relatively crude and inadequate and are unlike those natural modes of stimulation with which the patient is familiar. It is also fair to say that few diagnoses are made solely on the basis of the sensory examination; more often the exercise serves simply to complement the motor examination. Quite often, no objective sensory loss can be demonstrated despite symptoms that suggest the presence of such an abnormality. Only rarely does the opposite pertain, i.e., one discovers a sensory deficit when there has been no complaint of sensory symptoms. In the former instance, sensory symptoms in the nature of paresthesias or dysesthesias may be generated along axons of nerves not sufficiently diseased to impair or reduce sensory function; in the latter instance, loss of function may have been so mild and gradual as to pass unnoticed. Always there is some difficulty in evaluating the response to sensory stimuli, since it depends on the patient's interpretation of sensory experiences. This, in turn, will depend on the patient's general awareness and responsiveness and ability to cooperate as well as his intelligence, education, and suggestibility. At times, children and relatively uneducated persons, by virtue of their simple and direct responses, are better witnesses than more sophisticated individuals, who are likely to analyze their feelings minutely and report small and insignificant differences in stimulus intensity.

General Considerations

Before proceeding to sensory testing, the physician should question patients about their symptoms, and this too poses special problems.

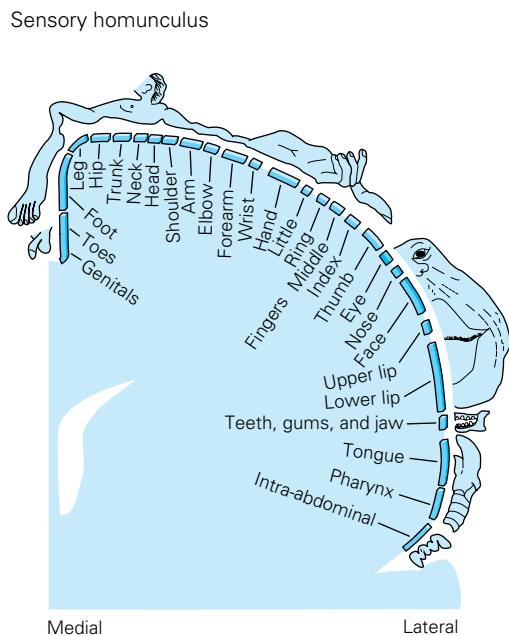

Figure 9-4. The “sensory homunculus,” or cortical representation of sensation in the postcentral gyrus; compare this to the distribution of body areas in the motor cortex (see also Fig. 3-4). (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM: *Principle of Neural Science*, 4th ed. New York, McGraw-Hill, 2000.)

Patients may be confronted with derangements of sensation that are unlike anything they have previously experienced, and they have limited terms to describe what they feel. They may say that a limb feels “numb” and “dead” when in fact they mean that it is weak. Occasionally a loss of sensation is discovered almost accidentally, e.g., by a lack of pain on touching an object hot enough to blister the skin or unawareness of articles of clothing and other objects in contact with the skin. But more often disease induces new and unnatural sensory experiences such as a band of tightness, a feeling of the feet being encased in cement, lancinating pains, an unnatural feeling when stroking the skin, and so on.

If nerves, sensory roots, or spinal tracts are damaged or partially interrupted, the patient may complain of tingling or prickling feelings (“like Novocain” or like the feelings in a limb that has “fallen asleep,” the common colloquialism for nerve compression), cramp-like sensations, or burning or cutting pain occurring either spontaneously or in response to stimulation.

Experimental data support the view that partially damaged touch, pressure, thermal, and pain fibers become hyperexcitable and generate ectopic impulses along their course, either spontaneously or in response to a natural volley of stimulus-evoked impulses (Ochoa and Torebjork). These abnormal sensations are called *paresthesias*, or *dysesthesia* if they are severe and distressing, as alluded to in Table 8-2 in the prior chapter. Another positive sensory symptom is *allodynia*, referring to a phenomenon in which one type of stimulus evokes another type of sensation—e.g., touch may induce pain.

The clinical characteristics of a sensation may divulge the particular sensory fibers involved (Table 9-1). It is known that stimulation of touch fibers gives rise to a sensation of tingling and buzzing; of muscle proprioceptors, to pseudocramp (the sensation of cramping without actual muscle contraction); of thermal fibers, to hotness (including burning) and coldness; and of A- δ fibers, to

prickling and pain. Paresthesias arising from ectopic discharges in large sensory fibers can be induced by nerve compression, hypocalcemia, and diverse diseases of nerves. Band-like sensations are the result of dysfunction in large sensory fibers, either in the periphery or their continuation in the posterior columns. Also, *certain sensory symptoms suggest an anatomical location of nerve disease*; for example, lancinating pains that radiate to the back or neck implicate root or, less often, sensory ganglion disease.

The presence of persistent paresthesias should always raise the suspicion of a lesion involving sensory pathways in nerves, spinal cord, or higher structures. Most often, the large fibers in the peripheral nerves or posterior columns are implicated. Evanescent paresthesias, of course, may be of no significance. Every person has had the experience of resting a limb on the ulnar, sciatic, or peroneal nerve and having the extremity “fall asleep.” This is due to compressive interruption of axonal transport and not to ischemia of the nerves or other components of the limb, as is commonly assumed. The hyperventilation of anxiety may cause paresthesias of the lips and hands (sometimes unilateral) from diminution of CO₂ and thereby of ionized calcium; tetany may also occur, with carpopedal spasms. However, these sensory experiences are transient and should not be confused with the persistent, albeit frequently fluctuating, paresthesias of structural disease of the nervous system. Severe acral and peripheral paresthesias with perversion of hot and cold sensations are characteristic of certain neurotoxic shellfish poisonings (*ciguatera*).

Also worth comment are vibratory paresthesias, which we have encountered in only a handful of patients. One articulate physician described the sensation as a high-amplitude, low-frequency “buzz” that was distinctly different from the more common prickling paresthesias, burning, numbness, etc. We have the impression that these sensations are almost always a manifestation of central sensory disease, in one case probably attributable to the posterior columns and in another to cerebral disease. Beyond this, little is known about this symptom.

Effect of Age on Sensory Function A matter of importance in the testing of sensation is the progressive impairment of sensory perception that occurs with advancing age. This requires that sensory thresholds, particularly in the feet and legs, always be assessed in relation to age standards. The effect of aging is most evident in relation to vibratory sense, but proprioception, as well as the perception of touch, and fast pain are also diminished with age. Sweating and vasomotor reflexes are reduced as well. These changes, which are discussed further in Chap. 29, are probably due to neu-

Table 9-1
Origin of aberrant sensations

SYMPTOMS	STRUCTURES AFFECTED
Paresthesias, tingling, buzzing	Large fibers (in nerve or posterior columns)
Burning, heat, cold	Small fibers
Prickling pain	Combined small- and large-fiber
Pseudocramp	A type of paresthesia, probably related to large-fiber dysfunction
Band tightness	Lemniscal system of cord
Lancinating pain	Small-fiber neuropathy and radiculopathy
Hyperalgesia	Partial peripheral nerve damage

ronal loss in dorsal root ganglia and are reflected in a progressive depletion of fibers in the posterior columns. Receptors in the skin and special sense organs (taste, smell) also wither with age.

Terminology (See also Table 8-1) A few additional terms require definition, since they may be encountered in discussions of sensation. Some of these, relating to pain sensation, were mentioned in Chap. 8 and are listed in Table 8-1. *Anesthesia* refers to a complete loss and *hypesthesia* to a partial loss of all forms of sensation. Loss or impairment of specific cutaneous sensations may be indicated by an appropriate prefix or suffix, e.g., *thermoanesthesia* or *thermohypesthesia*, *analgesia* (loss of pain sense), *hypalgesia* (reduction in pain sensibility), *tactile anesthesia*, and *pallanesthesia* (loss of vibratory sense). The term *hyperesthesia*, as explained in Chap. 8, refers to an increased sensitivity to various stimuli and is usually used with respect to cutaneous sensation. It implies a heightened activity of the sensory apparatus. Under certain conditions (e.g., sunburn), there does appear to be an enhanced sensitivity of cutaneous receptors, but usually the presence of hyperesthesia betrays an underlying sensory defect. Careful testing will demonstrate an elevated threshold to tactile, painful, or thermal stimuli; but once the stimulus is perceived, it may have a severely painful or unpleasant quality (*hyperpathia*). Some clinicians use this last term to denote an exaggerated response to a painful stimulus (*hyperalgesia* which is subtly different from *hyperpathia*). In *alloesthesia*, or *allesthesia*, a tactile or painful stimulus delivered on the side of hemisensory loss is experienced in a corresponding area of the opposite side or at a distant site on the same side. This phenomenon is observed most frequently with right-sided putaminal lesions (usually hemorrhage) and with anterolateral lesions of the cervical spinal cord; it presumably depends on the existence of an uncrossed ipsilateral spinothalamic pathway (see the original studies of Ray and Wolff).

Testing of Sensory Function

The detail with which sensation is tested is determined by the clinical situation. If the patient has no sensory complaints, it is sufficient to test vibration and position sense in the fingers and toes and the perception of pinprick over the face, trunk, and extremities as well as to determine whether the findings are the same in symmetrical parts of the body. A rough survey of this sort occasionally detects sensory defects of which the patient was unaware. On the other hand, more thorough testing is in order if the patient has complaints referable to the sensory system or if one finds localized atrophy or weakness, ataxia, trophic changes of joints, or painless ulcers.

A few other general rules should be mentioned. It is generally easier for a patient to perceive the boundary of an abnormal area of sensation if the examiner proceeds from an area of reduced sensation toward the normal area. One should not press the sensory examination in the presence of fatigue, for an inattentive patient is a poor witness. Also, the examiner must avoid suggesting symptoms to the patient. After explaining in the simplest terms what is required, the examiner interposes a few questions and remarks as possible. Consequently patients should not be asked, "Do you feel that?" each time they are touched; they are simply told to say "yes" or "sharp" every time they are touched or feel pain. Repetitive pinpricks within a small area of skin should be avoided, since this will make inapparent a subtle hypalgesia. In patients who may be overinterpreting subtle changes in pinprick, differentiating between warm and cold is often more informative than differentiating be-

tween "sharp" and "dull." The patient should not directly observe the part under examination. However, a cooperative patient may, if asked to use a pin or his fingertips, outline an analgesic or anesthetic area or determine whether there is a graduated loss of sensation in the distal parts of a leg or arm. Finally, the findings of the sensory examination should be accurately recorded on a chart by shading affected regions on a preprinted figure of the body or a sketch of a hand, foot, face, or limb.

Described below are the usual bedside methods of testing sensory function. With attention to certain details of procedure, these tests are quite sufficient for most clinical purposes. For clinical investigation and research into the physiology of pain, which require the detection of threshold values and quantification of sensory impairment, a wide range of instruments are available. Their use has been described by Dyck et al (see also Lindblom and Ochoa and Bertelsmann et al).

Testing of Tactile Sensation This is usually done with a wisp of cotton. The patient is first acquainted with the nature of the stimulus by applying it to a normal part of the body. Then, with eyes closed, he is asked to say "yes" each time various other parts are touched. A patient who is simulating sensory loss may say no in response to a tactile stimulus. Cornified areas of skin, such as the soles and palms, will require a heavier stimulus than other areas and the hair-clad parts a lighter one because of the numerous nerve endings around the follicles. Patients will be more sensitive to a moving contactual stimulus of any kind than to a stationary one. The deft application of the examiner's or preferably the patient's roving fingertips is a useful refinement and aids in demarcating an area of tactile loss, as Trotter and Davies originally showed.

More precise testing is possible by using a von Frey hair. By this method, a stimulus of constant strength can be applied and the threshold for tactile sensation determined by measuring the force required to bend a hair of known length. Special difficulties arise in the testing of tactile perception, when a series of contactual stimuli lead to a decrement of sensation, either through adaptation of the end organ or because the initial sensation outlasts the stimulus and seems to spread. The patient may then fail to report tactile stimuli in an area where they were previously present, or he may report contact without being touched.

Testing of Pain Perception This is most efficiently assessed by pinprick, although it may be evoked by a variety of noxious stimuli. Patients must understand that they are to report the feeling of sharpness, not simply the feeling of contact or pressure of the pinpoint. If pinpricks are applied rapidly in one area, their effect may be summated and a heightened perception of pain may result; therefore they should be delivered about one per second and not over the same spot. Small differences in intensity can be discounted. An effective approach is to ask the patient to compare the pin sensation in two areas on a scale of 1 to 10; a report of "8 or 9" as compared to "10" is usually insignificant.

It is almost impossible, using an ordinary pin, to apply each stimulus with equal intensity. A pinwheel is sometimes more effective because it allows the application of a more constant pressure. This difficulty can be overcome to some extent by the use of an algosimeter, which enables one to deliver stimuli of constant intensity and also to grade the intensity and determine threshold values. Even with this instrument, an isolated stimulus may be reported as being excessively sharp, apparently because of direct contact with a pain spot.

If an area of diminished or absent touch or pain sensation is encountered, its boundaries should be demarcated to determine whether it has a segmental or peripheral nerve distribution or is lost below a certain level on the trunk. As mentioned, such areas are best delineated by proceeding from the region of impaired sensation toward the normal. The changes may be confirmed by dragging a pin lightly over the parts in question.

Testing of Deep Pressure-Pain One can estimate the perception of this modality simply by lightly pinching or pressing deeply on the tendons, muscles, or bony prominences. Pain can often be elicited by heavy pressure even when superficial sensation is diminished; conversely, in some diseases, such as tabetic neurosyphilis, loss of deep pressure-pain may be more striking than loss of superficial pain.

Testing of Thermal Sense A quick but rough way to assess thermal loss (or to corroborate a previously found zone of hypalgesia) is to warm one side of a tuning fork by rubbing it briskly against the palm and apply its alternate sides to the patient's skin. This suffices for most bedside examinations.

If more careful examination is required, the skin should first be exposed to room air for a brief time before the examination. The test objects should be large, ideally, two stoppered test tubes containing hot (45°C) and cold (20°C) tap water with thermometers that extend into the water through the flask stoppers. Extreme degrees of heat and cold (e.g., 10 and 45°C) are employed first to delineate roughly an area of thermal sensory impairment. The side of each tube is applied successively to the skin for a few seconds and the patient is asked to report whether the flask feels "less hot" or "less cold" in comparison to a normal part. The qualitative change should then be quantitated as far as possible by recording the differences in temperature that the patient is able to recognize as the difference in temperature between the two tubes is gradually reduced. A normal person can detect a difference of 1°C or even less in the range of 28 to 32°C; in the warm range, differences between 35 and 40°C can be recognized, and in the cold range, between 10 and 20°C. If the temperature of the test object is below 10°C or above 50°C, sensations of cold or heat become confused with pain. This technique has been largely supplanted by commercially manufactured electronic devices that can present a series of slightly differing thermal stimuli in sequence to a probe placed on the finger or toe. Special algorithms are used for the order and magnitude of temperature change and to determine whether the patient's reports are consistent and valid. The results are reported in the form of a "just noticeable difference" (JND) between temperatures or intensities of pain.

Testing of Proprioceptive Sense Awareness of the position and movements of our limbs, fingers, and toes is derived from receptors in the muscles, tendons (Golgi tendon organs, according to Roland et al), and joints and is probably facilitated by the activation of skin receptors (Moberg). The two modalities comprised by proprioception, i.e., sense of movement and of position, are usually lost together, although clinical situations do arise in which perception of the position of a limb or digits is lost while that of passive and active movement (kinesthesia) of these parts is retained. The opposite occurs but is infrequent.

Abnormalities of position sense may be disclosed in several ways. When the patient has his arms outstretched and eyes closed, the affected arm will wander from its original position; if the pa-

tient's fingers are spread apart, they may undergo a series of changing postures ("piano-playing" movements, or pseudoathetosis); in attempting to touch the tip of his nose with his index finger, the patient may miss the target repeatedly, but he corrects his performance with his eyes open.

The lack of position sense in the legs is demonstrated by displacing the limb from its original position and having the patient, with eyes closed, place the other leg in the same position or point to the great toe. If position sense is defective in both legs, the patient will be unable to maintain his balance with feet together and eyes closed (*Romberg sign*). This test is often interpreted imprecisely. In the Romberg position, even a normal person whose eyes are closed will sway slightly, and the patient who lacks balance due to cerebellar ataxia or vestibulopathy or to some other motor disorder will sway considerably more if his visual cues are removed. Only a marked discrepancy in balance with eyes open and with eyes closed qualifies as a Romberg sign. The most certain indication of abnormality is the need to step to the side or backward in order to avoid falling. Mild degrees of unsteadiness in a nervous or suggestible patient may be overcome by diverting his attention, e.g., by having him touch the index finger of each hand alternately to his nose while standing with eyes closed or by following the examiner's finger with his eyes.

Perception of passive movement is first tested in the fingers and toes, since the defect, when present, is reflected maximally in these parts. It is important to grasp the digit firmly at the sides, perpendicular to the plane of movement; otherwise the pressure applied by the examiner may allow the patient to identify the direction of movement. This applies as well to testing of the more proximal segments of the limb. The patient should be instructed to report each movement as being "up" or "down" from the previous position (directional kinesthesia). It is useful to demonstrate the test with a large and easily identified movement, but once the idea is clear to the patient, the smallest detectable changes should be determined. The sensitivity of testing is enhanced by using the third and fourth fingers and toes. The part being tested should be moved rapidly. Normally, a very slight degree of movement is appreciated in the digits (as little as 1 degree of an arc). The test should be repeated enough times to eliminate chance (50 percent of responses). Defective perception of passive movement is judged by comparison with a normal limb or, if perception is bilaterally defective, on the basis of what the examiner has learned through experience to be normal. Rapid movements are more easily detected than are slow ones. Slight impairment may be disclosed by a slowness of response or, if the digit is displaced very slowly, by an unawareness or uncertainty that movement has occurred; or, after the digit has been displaced in the same direction several times, the patient may misjudge the first movement in the opposite direction; or, after the examiner has moved the toe, the patient may make a number of small voluntary movements of the toe in an apparent attempt to determine its position or the direction of the movement. Inattentiveness will also cause some of these errors.

Testing of Vibratory Sense This is a composite sensation comprising touch and rapid alterations of deep-pressure sense. The only cutaneous structure capable of registering such stimuli of this frequency is the rapidly adapting pacinian corpuscle. The conduction of vibratory sense depends on both cutaneous and deep afferent fibers that ascend mainly in the dorsal columns of the cord. It is therefore rarely affected by lesions of single nerves but will be disturbed in patients with disease of multiple peripheral nerves,

dorsal columns, medial lemniscus, and thalamus. Vibration and position sense are usually lost together, although one of them (most often vibration sense) may be affected disproportionately. With advancing age, vibration is the sensation most commonly diminished, especially at the toes and ankles (see further on).

Vibration sense is tested by placing a tuning fork with a low rate and long duration of vibration (128 Hz) over the bony prominences, making sure that the patient responds to the vibration, not simply to the pressure of the fork, and that he is not trying to listen to it. As with thermal and pain testing, there are mechanical devices that quantitate vibration sense, but it is sufficient for clinical purposes to compare the point tested with a normal part of the patient or the examiner. The examiner may detect the vibration after it ceases for the patient by holding a finger under the distal interphalangeal joint, the handle of the tuning fork being placed on the dorsal aspect of the joint. Or, the vibrating fork is allowed to run down until the moment that vibration is no longer perceived, at which point the fork is transferred quickly to the corresponding part of the examiner and the time to extinction is noted. There is a small degree of accommodation to the vibration stimulus, so that slight asymmetries detected by rapid shifting from a body part on one side to the other should be interpreted accordingly. The perception of vibration at the patella after it has disappeared at the ankle or at the anterior iliac spine after it has disappeared at the knee is indicative of a peripheral neuropathy. The approximate level of a spinal cord lesion can be corroborated by testing vibratory sensation over the iliac crests and successive vertebral spines.

Testing of Discriminative Sensation Damage to the parietal lobe sensory cortex or to the thalamocortical projections results in a special type of disturbance—namely, an inability to make sensory discriminations and to integrate spatial and temporal sensory information (see further under “Sensory Loss Due to Lesions of the Parietal Lobe” and Chap. 22). Lesions in these structures usually disturb position sense but leave the so-called primary modalities (touch, pain, temperature, and vibration sense) relatively little affected. The integrity of discriminative sensory functions can be assessed only if it is first established that the primary sensory modalities on which they depend (mainly touch) are largely normal. If a cerebral lesion is suspected, discriminative function should be tested further in the following ways.

Two-Point Discrimination The ability to distinguish two points from one is tested by using a compass, the points of which should be blunt and applied simultaneously and painlessly. The distance at which such stimuli can be recognized as a distinct pair varies but is roughly 1 mm at the tip of the tongue, 2 to 3 mm on the lips, 3 to 5 mm at the fingertips, 8 to 15 mm on the palm, 20 to 30 mm on the dorsa of the hands and feet, and 4 to 7 cm on the body surface. It is characteristic of the patient with a lesion of the sensory cortex to mistake two points for one, although occasionally the opposite occurs.

Cutaneous Localization and Figure Writing (Graphesthesia) Localization of cutaneous tactile or painful stimuli is tested by touching various points on the body and asking the patient to place the tip of his index finger on the point stimulated or on the corresponding point of the examiner’s limb. Recognition of numbers or letters traced on the skin (these should be larger than 4 cm on the palm) with a pencil or similar object or the direction of a line drawn across the skin also depends on localization of tactile stimuli. Normally, traced numbers as small as 1 cm can be detected on the pulp of the finger if drawn with a sharp pencil. According to Wall and

Noordenbos, these are also the most useful and simple tests of posterior column function.

Appreciation of Texture, Size, and Shape Appreciation of texture depends mainly on cutaneous impressions, but recognition of the shapes and sizes of objects is based on impressions from deeper receptors as well. Inability to recognize shape and form is frequently a manifestation of cortical disease, but a similar clinical defect will occur if tracts that transmit proprioceptive and tactile sensation are interrupted by lesions of the spinal cord and brainstem (and, of course, of the peripheral nerves). This type of sensory defect is called *stereognosis* [see further on, under “Posterior (Dorsal) Column Syndrome”] and is distinguished from *astereognosis*, which connotes an inability to identify an object by palpation, even though the primary sense data (touch, pain, temperature, and vibration) are intact. In practice, a pure astereognosis is rarely encountered, and the term is employed when the impairment of superficial and vibratory sensation in the hands seems to be of insufficient severity to account for the defect in tactile object identification. Defined in this way, astereognosis is either right- or left-sided and, with the qualifications mentioned below, is the product of a lesion in the opposite hemisphere, involving the sensory cortex, particularly S2 or the thalamoparietal projections.

The classic doctrine that somatic sensation is represented only in the contralateral parietal lobe is not absolute. Beginning with the report by Oppenheim in 1906, there have been sporadic patients who showed bilateral astereognosis or loss of tactile sensation as a result of an apparently unilateral cerebral lesion. The correctness of these observations was corroborated by Semmes and colleagues, who tested a large series of patients with traumatic lesions involving either the right or left cerebral hemisphere. They found that the impairment of sensation (particularly discriminative sensation) following right- and left-sided lesions was not strictly comparable; the left hand as well as the right tended to be impaired by injury to the left sensorimotor region, whereas only the left hand tended to be affected by injury to the right sensorimotor region. These observations, with minor qualifications, were also confirmed by Carmon and by Corkin and associates, who investigated the sensory effects of cortical excisions in patients with focal epilepsy. Caselli has described six patients with extensive right-sided cerebral infarctions, associated in each case with bilateral impairment of tactile object recognition but without impairment of the primary sense modalities in the right hand. In each of these patients, there was also a profound hemineglect, which confounded the interpretation of left-sided sensory signs. Thus it appears that certain somatosensory functions in some patients are mediated not only by the contralateral hemisphere but also by the ipsilateral one, although the contribution of the former is undoubtedly the more significant.

The traditional concept of left hemispheric dominance in respect to tactile perception has been questioned by Carmon and Benton, who found that the right hemisphere is particularly important in perceiving the direction of tactile stimuli. Also, Corkin observed that patients with lesions of the right hemisphere show a consistently greater failure of tactile-maze learning than those with left-sided lesions, pointing to a relative dominance of the right hemisphere in the mediation of tactile performance involving a spatial component. Certainly the phenomenon of sensory inattention or extinction is more prominent with lesions of the right as opposed to the left parietal lobe and is most informative if the primary and secondary sensory cortical areas are spared. These matters are considered further on in this chapter and in Chap. 22.

Finally, there is a distinction to be made between astereognosis and tactile agnosia. Some authors (e.g., Caselli) have defined tactile agnosia as a strictly unilateral disorder, right or left, in which the impairment of tactile object recognition is unencumbered by a disturbance of the primary sensory modalities. Such a disorder would be designated by others as a pure form of astereognosis (see above). In our view, *tactile agnosia* is a disturbance in which a one-sided lesion lying posterior to the postcentral gyrus of the *dominant* parietal lobe results in an inability to recognize an object by touch in *both* hands. According to this view, tactile agnosia is a disorder of apperception of stimuli and of translating them into symbols, akin to the defect in naming parts of the body, visualizing a plan or a route, or understanding the meaning of the printed or spoken word (visual or auditory verbal agnosia). These and other agnosias are discussed in Chap. 22.

SENSORY SYNDROMES

Sensory Changes Due to Interruption of a Single Peripheral Nerve

In these cases, the distribution of sensory loss will vary, depending on whether the nerve involved is predominantly muscular, cutaneous, or mixed. Following division of a *cutaneous nerve*, the area of sensory loss is always less than its anatomic distribution because of overlap from adjacent nerves. That the area of tactile loss is greater than that for pain relates both to a lack of collateralization (regeneration) from adjacent tactile fibers (in contrast to rapid collateral regeneration of pain fibers) and to a greater overlap of pain sensory units. If a large area of skin is involved, the sensory defect characteristically consists of a central portion in which all forms of cutaneous sensation are lost surrounded by a zone of partial loss, which becomes less marked as one proceeds from the center to the periphery. Perceptions of deep pressure and passive movement are intact because these modalities are mediated by nerve fibers from subcutaneous structures and joints. Along the margin of the hypesthetic zone, the skin becomes excessively sensitive (dysesthetic); light contact may be felt as smarting and mildly painful, more so as one proceeds from the periphery of the area to its center. According to Weddell, the dysesthesias are attributable to the greater sensitivity of collateral regenerating fibers that have made their way from surrounding healthy pain fibers into the denervated region.

Particular types of lesions have differing effects on sensory nerve fibers, as discussed earlier, but are they nearly always to some extent multimodal. *Compression* ablates mainly the function of large touch and pressure fibers and leave the function of small pain, thermal, and autonomic fibers intact; procaine and ischemia have the opposite effect. The tourniquet test is instructive in this respect. A sphygmomanometer cuff is applied above the elbow, inflated to a point well above the systolic pressure, and maintained there for as long as 30 min. (This is not particularly painful if the patient does not contract the forearm and hand muscles.) Paresthesias appear within a few minutes, followed by sensory loss—first of touch and vibration, then of cold, fast pain, heat, and slow pain, in that order and spreading centripetally. Physiologic studies have confirmed the theory of Lewis and colleagues that compression blocks the function of nerve fibers in order of their size. Release of the cuff results in postcompression paresthesias, which have been shown to arise from spontaneous activity that is generated along

the myelinated nerve fibers from ectopic sites at a distance from the compression. Within seconds of releasing the cuff, other changes appear—the cold, blanched hand becomes red and hot and there is an array of tingling, stinging, cramp-like sensations that reach maximum intensity in 90 to 120 s and slowly fade (Lewis). Sensory function is recovered in an order inverse to that in which it was lost. Similar spontaneous and ectopic discharges probably explain the paresthetic symptoms early in the acute demyelinating neuropathies, even before the appearance of sensory loss or numbness. It is worth emphasizing that these features of compression are not due to nerve ischemia, as commonly stated; instead, they result from reversible physiologic changes in the myelin and underlying axon.

Certain classic maneuvers for the provocation of positive sensory phenomena—the *Tinel sign* of tingling upon percussion of a regenerating peripheral nerve and the *Phalen sign* of paresthesias in the territory of the median nerve on wrist flexion—exemplify the susceptibility of a damaged nerve to pressure. In the case of a severed nerve, regeneration from the proximal end begins within days. The thin, regenerating sprouts are unusually sensitive to mechanical stimulation, which produces tingling or Tinel's sign, and to certain endogenous chemicals such as substance P.

Sensory Changes Due to Involvement of Multiple Nerves (Polyneuropathy)

(Table 9-2)

In most instances of polyneuropathy, the sensory changes are accompanied by varying degrees of motor and reflex loss. Usually the sensory impairment is bilaterally symmetrical. Since in most types of polyneuropathy the longest and largest fibers are the most affected, sensory loss is most severe over the feet and legs and, if the upper limbs are affected, over the hands. The term *glove-and stocking*, frequently employed to describe the distribution of sensory loss of polyneuropathy, draws attention to the predominantly distal pattern of involvement but fails to indicate that the change from normal to impaired sensation is characteristically gradual. (In hysteria, by contrast, the border between normal and absent sensation is usually sharply defined.) The abdomen, thorax, and face are spared except in the most severe cases, in which sensory changes may be found over the anterior thoracoabdominal escutcheon and around the mouth.

When the neuropathy is primarily demyelinative rather than axonal, paresthesias are an early feature, and they are reported in the distal territories of nerves; when short nerves (e.g., the trigeminal) are involved, the paresthesias appear in proximal body parts, such as the perioral region.

The sensory loss of polyneuropathy usually involves all modalities of sensation, but to varying degrees, and—although it is difficult to equate the degrees of impairment of pain, touch, temperature, vibration, and position senses—one modality may be impaired out of proportion to the others. This clinical feature is explained by the fact that particular diseases of the peripheral nerves selectively damage sensory fibers of different size. For example, degeneration or demyelination of the large fibers that subserve kinesthetic sense causes a loss of vibratory and position sense and relative sparing of pain, temperature, and to some degree tactile perception. When extreme, such a polyneuropathy results in pseudoathetoid movements of the outstretched fingers or toes; it may also result in a sensory ataxia that is due to affec-

Table 9-2

Examination features of the peripheral and spinal cord sensory syndromes (see text and also Chap. 46)

Polyneuropathy

- Symmetrical distal sensory loss
- Sensory loss may affect one modality preferentially
- Areflexia or hyporeflexia
- Weakness, if present, symmetrical

Polyradiculopathy

- Asymmetrical sensory and motor loss
- Proximal and distal parts of limb differentially affected
- Reflex loss limited to region of affected root(s)

Ganglionopathy

- Implicates all sensory modalities
- Proximal body parts affected
- Ataxia

Tabetic syndrome

- Prominent loss of vibratory and position sense in feet
- Romberg sign

Secondary (Charcot) joint deformities

Areflexia

Myelopathy

- Complete transverse lesion: loss of all sensory modalities below level of lesion
- Syringomyelia: loss of pain and thermal sense with preservation of touch and joint position/vibration over restricted region of neck, cape, arms, hands
- Anterior spinal artery syndrome: loss of pain sense with preservation of vibration and joint position below level of lesion
- Posterior column: same as tabetic but reflexes preserved
- Hemicord (Brown-Séquard): loss of pain sense opposite to the lesion and beginning several levels below it; loss of vibration and joint position sense on the side of the lesion and below it

tion of the large-diameter nerves destined for the spinocerebellar tracts.

By contrast, involvement of the small-caliber myelinated and unmyelinated axons affects pain, temperature, and autonomic sensation, with preservation of proprioceptive, vibration, and tactile sense—producing a syndrome called “pseudosyringomyelic,” since it simulates the dissociated pain from tactile sensory loss that is seen in this disease of the spinal cord (see further on, under “Sensory Spinal Cord Syndromes”). Prolonged analgesia may lead to trophic ulcers and Charcot joints. These special patterns of loss as well as those produced by the plexopathies and mononeuritis multiplex are discussed further in Chap. 46.

Sensory Changes Due to Involvement of Nerve Roots (Radiculopathy) (Figs. 9-1 to 9-3 and Table 9-2)

The surface innervation of the sensory nerve roots serves as one of the most useful and dependable guides to localization in neurology, and the several main dermatomes are known to all physicians. Because of considerable overlap from adjacent roots, division of a single sensory root does not produce complete loss of sensation in

any area of skin. However, compression of a single sensory cervical or lumbar root (e.g., by a herniated intervertebral disc) can cause a segmental impairment of cutaneous sensation. When two or more contiguous roots have been completely divided, a zone of sensory loss can be demonstrated; this is surrounded by a narrow zone of partial loss in which a raised threshold accompanied by excessive sensitivity (dysesthesia) may or may not be evident. For reasons not altogether clear, partial sensory loss from root lesions is easier to demonstrate by the use of a painful stimulus than by a tactile or pressure stimulus. Tendon and cutaneomuscular (abdominal, cremasteric) reflexes may be lost, but only in the region of innervation of the affected root(s). If pain is present, it may be intensified by movement of the spine and then radiate in a proximal-distal direction.

Disease of the nerve roots frequently gives rise to “shooting” (lancinating) pains and burning sensations that project down the course of their sensory nerves. The common examples are sciatica, from lower lumbar or upper sacral root compression, and sharp pain radiating from the shoulder and down the upper arm, from cervical disc protrusion.

When multiple roots are affected (*polyradiculopathy*) by an infiltrative, inflammatory, or compressive process, the syndrome is more complex and must be differentiated from polyneuropathy. The distinguishing features of a polyradiculopathy, aside from pain, are asymmetrical muscle weakness that involves both proximal and distal parts differentially in each limb and a pattern of sensory loss that is consistent with affection of several roots, not necessarily contiguous ones. Details will be found in Chap. 46.

Sensory Changes Due to Involvement of Sensory Ganglia (Sensory Neuronopathy, Ganglionopathy)

(Table 9-2)

Widespread disease of the dorsal root ganglia produces many of the same sensory defects as disease of the posterior nerve roots, but it is unique in that proximal areas of the body also show pronounced sensory loss; the face, oral mucosa, scalp, trunk, and genitalia may be sites of hypesthesia and hypalgesia. Proprioception is diminished or lost in distal and, to some extent, proximal body parts, giving rise also to ataxic movements, often quite severe, and to pseudoathetosis. Tendon reflexes are lost. Sometimes there are additional features of dysautonomia, but strength is entirely spared. Recognition of this unusual pattern of sensory loss is of considerable diagnostic importance, since it raises for consideration a number of underlying diseases that might otherwise be missed; these are discussed in Chap. 46. The main causes of this syndrome are paraneoplastic, connective tissue disease, particularly Sjögren syndrome, toxic exposure, and idiopathic inflammation.

Tabetic Syndrome The tabetic syndrome may be considered a special type of polyradiculopathy or ganglionopathy, but it is often listed with diseases of the spinal cord. It results from damage to the large proprioceptive and other fibers of the posterior lumbosacral (and sometimes cervical) roots. It is typically caused by neurosyphilis but also by diabetes mellitus and other diseases that involve the posterior roots or dorsal root ganglia. Numbness or paresthesias and “lightning” or lancinating pains are frequent complaints; areflexia, abnormalities of gait (page 103), and hypotonia without significant muscle weakness are found on examination. The sensory loss may involve only vibration and position senses

in the lower extremities, but loss or impairment of superficial or deep pain sense or of touch may be added in severe cases. The feet and legs are most affected, much less often the arms and trunk. The Romberg sign is prominent. Frequently, atony of the bladder with retention of urine and trophic joint changes (Charcot joints) and crises of “gastric pains” are associated.

Also mentioned here are rare cases of congenital absence of all cutaneous sensation resulting from the lack of development of small sensory ganglion cells. A similar but partial defect may be found in the Riley-Day syndrome (pages 464 and 1159). There are also forms of hereditary polyneuropathy that cause universal insensitivity. Our colleague R.D. Adams has commented on an adolescent brother and sister that he observed with such a disorder.

Sensory Spinal Cord Syndromes

(Fig. 9-5)

See also Chap. 44.

Complete Spinal Sensory Syndrome With a complete transverse disruption of the spinal cord, the most striking loss is of motor power; most characteristic, however, is a loss of all forms of sensation below a level that corresponds to the lesion. There may be a narrow zone of hyperesthesia at the upper margin of the anesthetic zone. Loss of pain, temperature, and touch sensation begins one or two segments below the level of the lesion; vibratory and position senses have less discrete levels. The sensory (and motor) loss in spinal cord lesions that involve both gray and white matter is expressed in patterns corresponding to bodily segments or dermatomes. These are shown in Figs. 9-2 and 9-3 and are most obvious on the trunk, where each intercostal nerve has a transverse distribution.

Also, it is important to remember that during the subacute evolution of a transverse spinal cord lesion, there may be a dis-

crepancy between the level of the lesion and that of the sensory loss, the latter ascending as the lesion progresses. This can be understood if one conceives of a lesion as evolving from the periphery to the center of the cord, affecting first the outermost fibers carrying pain and temperature sensation from the legs. Conversely, a lesion advancing from the center of the cord will affect these modalities in the reverse order, with so-called sacral sparing.

Hemisection of the Spinal Cord (Brown-Séquard Syndrome)

In rare instances, disease is confined to or predominates on one side of the spinal cord; pain and thermal sensation are affected on the opposite side of the body, and proprioceptive sensation is affected on the same side as the lesion. The loss of pain and temperature sensation begins one or two segments below the lesion. An associated spastic motor paralysis on the side of the lesion completes the syndrome (Fig. 9-5). Tactile sensation is not greatly affected, since the fibers from one side of the body are distributed in tracts (posterior columns, anterior and lateral spinothalamic) on both sides of the cord.

Syringomyelic Syndrome (Lesion of the Central Gray Matter)

Since fibers conducting pain and temperature sensation cross the cord in the anterior commissure, a lesion of considerable vertical extent in this location will characteristically abolish these modalities on one or both sides over several segments (dermatomes) but will spare tactile sensation (Fig. 9-5). This type of *dissociated sensory loss* usually occurs in a segmental distribution, and since the lesion frequently involves other parts of the gray matter, varying degrees of segmental amyotrophy and reflex loss are usually present as well. If the lesion has spread to the white matter, corticospinal, spinothalamic, and posterior column signs will be conjoined. The most common cause of such a lesion in the cervical region is the centrally situated developmental syringomyelia; less common causes are intramedullary tumor, trauma, and hemorrhage.

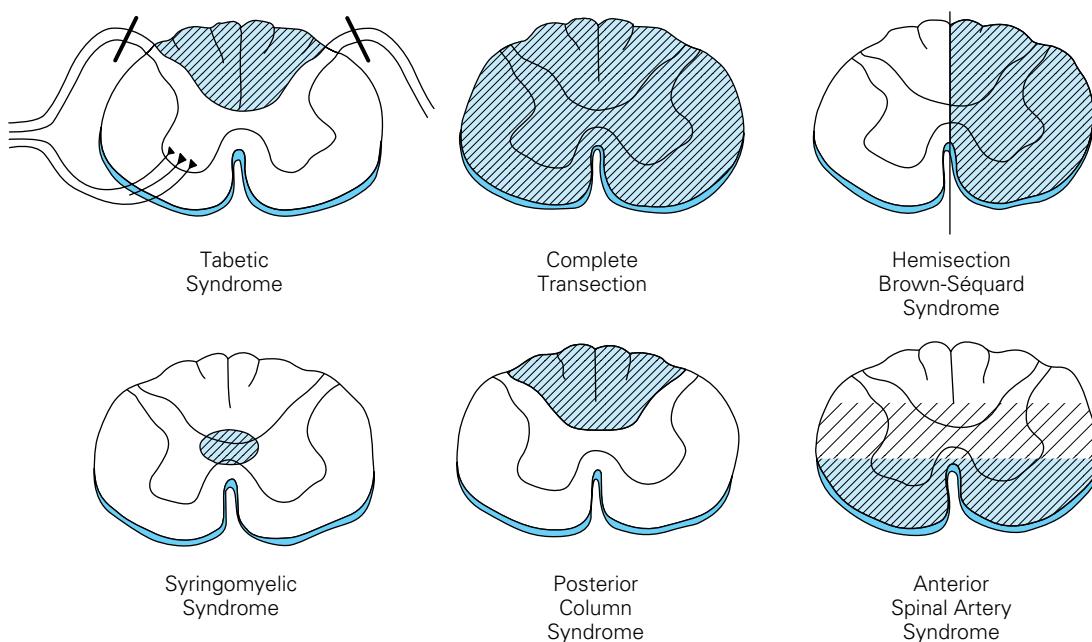

Figure 9-5. The sites of the lesions of the characteristic spinal cord sensory syndromes (shaded areas indicate lesions).

A *pseudosyringomyelic* syndrome has been mentioned earlier in relation to small-fiber neuropathies that simulate syringomyelia (see also page 1114).

Posterior (Dorsal) Column Syndrome Paresthesias in the form of tingling and pins-and-needles sensations or girdle- and band-like sensations are common complaints with posterior column disease. In some cases there may be the additional feature of a diffuse, burning, unpleasant sensation in response to pinprick. Loss of vibratory and position sense occurs below the level of the lesion, but the perception of pain and temperature is affected relatively little or not at all. Since posterior column lesions are due to the interruption of central projections of the dorsal root ganglia cells, they may be difficult to distinguish from a process that affects large fibers in sensory roots (tabetic syndrome); however, the tendon reflexes are spared in the former and eliminated in tabes. In some diseases that involve the dorsal columns, vibratory sensation may be involved predominantly, whereas in others position sense is more affected. With complete posterior column lesions, only a few of which have been verified by postmortem examinations, not only is the patient deprived of knowledge of movement and position of parts of the body below the lesion but all types of sensory discrimination are impaired as well (see Nathan et al for a review of the subject). If the lesion is in the high cervical region, there is clumsiness in the palpation of objects and an inability to recognize the qualities of objects by touch, even though touch-pressure sensation is relatively intact. The stereognosia is expressed also by impaired graphesthesia and tactile localization. There may be unusual disturbances of touch and pressure, manifest as lability of threshold, persistence of sensation after removal of the stimulus, and sometimes tactile and postural hallucinations. Nathan and colleagues have confirmed this counterintuitive observation that lesions of the posterior columns cause only slight defects in touch and pressure sensation and that lesions of the anterolateral spinothalamic tracts also cause minimal or no defects in these modalities. However, a combined lesion in both pathways causes a total loss of tactile and pressure sensibility below the lesion. This is not easily reconciled with the above-noted clinical observations.

The loss of sensory functions that follows a posterior column lesion—such as impaired two-point discrimination; figure writing; detection of size, shape, weight, and texture of objects; and ability to detect the direction and speed of a moving stimulus on the skin—may simulate a parietal “cortical” lesion but differs in that vibratory sense is also lost in spinal cord syndromes. In several cases on record, interruption of the posterior columns by surgical incision or other type of injury did not cause a permanent loss of the sensory modalities thought to be subserved by these pathways (Cook and Browder, Wall and Noordenbos). Since postmortem studies of these cases were not carried out, it is possible that some of the posterior column fibers had been spared. Also, it should be realized that not all proprioceptive fibers ascend to the gracile and cuneate nuclei; some proprioceptive fibers leave the posterior columns in the lumbar region and synapse with secondary neurons in the spinal gray matter and ascend in the ipsilateral posterolateral funiculus. Only cutaneous fibers continue to the gracile and cuneate nuclei. The proposition of Wall and Noordenbos, which is debatable, is that such patients lose not the modalities conventionally attributed to the posterior columns but the ability to perform tasks that demand simultaneous analysis of spatial and temporal characteristics of the stimulus.

The usual causes of the posterior column syndrome are multiple sclerosis, vitamin B₁₂ deficiency, tabes dorsalis, and HIV and HTLV-1 infection.

Anterior Myelopathy (Anterior Spinal Artery Syndrome)

With infarction of the spinal cord in the territory of supply of the anterior spinal artery or with other lesions that affect the ventral portion of the cord predominantly, as in some cases of myelitis, one finds a loss of pain and temperature sensation below the level of the lesion but with relative or absolute sparing of proprioceptive sensation (see also page 1068). Since the corticospinal tracts and the ventral gray matter also lie within the area of distribution of the anterior spinal artery, spastic paralysis is a prominent feature (Fig. 9-5).

Disturbances of Sensation Due to Lesions of the Brainstem

A characteristic feature of medullary lesions is the occurrence, in many instances, of a crossed sensory disturbance, i.e., a loss of pain and temperature sensation on one side of the face and on the opposite side of the body. This is accounted for by involvement of the descending trigeminal tract or its nucleus and the crossed lateral spinothalamic tract on one side of the brainstem and is nearly always caused by a lateral medullary infarction (Wallenberg syndrome). In the upper medulla, pons, and midbrain, the crossed trigeminothalamic and lateral spinothalamic tracts run together; a lesion at these levels causes loss of pain and temperature sense on the opposite half of the face and body. There are no tactile paresthesias, only thermal or painful dysesthesias. In the upper brainstem, the spinothalamic tract and the medial lemniscus become confluent, so that an appropriately placed lesion causes a contralateral loss of all superficial and deep sensation. Cranial nerve palsies, cerebellar ataxia, and motor paralysis are almost invariably associated, as indicated in the discussion of strokes in this region (Chap. 34). In other words, a lesion in the brainstem at any level is unlikely to cause an isolated sensory disturbance.

Hemisensory Loss Due to a Lesion of the Thalamus (Syndrome of Déjerine-Roussy)

Involvement of the ventral posterolateral (VPL) and posteromedial (VPM) nuclei of the thalamus, usually due to a vascular lesion, less often to a tumor, causes loss or diminution of all forms of sensation on the opposite side of the body. Position sense is affected more frequently than any other sensory function and is usually but not always more profoundly affected than loss of touch and pinprick. With partial recovery of sensation, or with an acute but incomplete lesion, spontaneous pain or discomfort (thalamic pain), sometimes of the most distressing type, may appear on the affected side of the body, and any stimulus may then have a diffuse, unpleasant, lingering quality (page 676). Thermal—especially cold—stimuli, emotional disturbance, loud sounds, and even certain types of music may aggravate the painful state. In spite of this overresponse to stimuli, the patient usually shows an elevated pain threshold, i.e., a stronger stimulus than normal is necessary to produce a sensation of pain (hypalgesia with hyperpathia). The same type of pain syndrome may occasionally accompany lesions of the white matter of the parietal lobe, the medial lemniscus, or even the posterior columns of the spinal cord.

It should be pointed out that a symptomatic hemisensory syndrome, usually with few objective changes, occurs frequently without manifest evidence of thalamic or spinal cord damage. This occurs particularly in young women, as pointed out by Toth. A number of our patients with this benign condition have had migraine, and one, as in Toth's series, had the antiphospholipid syndrome.

Sensory Loss Due to Lesions of the Parietal Lobe

In the anterior parietal lobe syndrome (Verger-Déjerine syndrome), there are disturbances mainly of discriminative sensory functions of the opposite arm, leg, and side of the face without impairment of the primary modalities of sensation (unless the lesion is extensive and deep). Loss of position sense and sense of movement, impaired ability to localize touch and pain stimuli (topagnosia), widening of two-point threshold, and astereognosis are the most prominent findings, as described earlier in this chapter and on page 400.

Another characteristic manifestation of parietal lobe lesions is *sensory inattention, extinction, or neglect*. In response to bilateral simultaneous testing of symmetrical parts, using either tactile or painful stimuli, the patient may acknowledge only the stimulus on the sound side; or, if the face and hand or foot on the affected side is touched or pricked, only the stimulus to the face may be noticed. Apparently cranial structures command more attention than other less richly innervated parts. A similar phenomenon of extinction occurs when visual stimuli are simultaneously delivered to both right and left peripheral fields. Yet each stimulus, when applied separately to each side or to each part of the affected side, is properly perceived and localized. In the case of sensory neglect, the patient ignores one side of the body and extrapersonal space contralateral to the parietal lesion, which is usually in the nondominant hemisphere. Left parietal lesions may also cause (right) sensory neglect, but less frequently. Sensory neglect or extinction, which may also occur occasionally with posterior column and medial lemniscus lesions, may be detected in persons who disclaim any sensory symptoms. These phenomena and other features of parietal lobe lesions are considered further in Chap. 22.

Yet another parietal lobe syndrome (Déjerine-Mouzon) is featured by a severe impairment of the primary modalities of sensation (pain, thermal, tactile, and vibratory sense) over half of the body. Motor paralysis is variable; with partial recovery, there may be a clumsiness that resembles cerebellar ataxia. Since the sensory disorder simulates that due to a thalamic lesion, it was called *pseudothalamic* by Foix and coworkers. Hyperpathia, much like that of the Déjerine-Roussy syndrome (see above), has also been observed in patients with cortical-subcortical parietal lesions. The pseudothalamic syndrome was related by Foix and colleagues to a sylvian infarct; Bogousslavsky and associates have traced it to a parietal infarct due to occlusion of the ascending parietal branch of the middle cerebral artery. In each of the aforementioned parietal lobe syndromes, if the dominant hemisphere is involved, there may be an aphasia, a bimanual tactile agnosia, or a Gerstmann syndrome; with nondominant lesions, there may be ananosognosia (page 401).

Often with parietal lesions, the patient's responses to sensory stimuli are variable. A common mistake is to attribute this abnormality to hysteria. A lesion confined to only a part of the parietal cortex (the best examples have been due to glancing bullet or shrapnel wounds of the skull) may result in a circumscribed loss of

superficial sensation in an opposite limb, mimicking a root or peripheral nerve lesion.

Sensory Loss Due to Suggestability and Hysteria (See also Chap. 56)

The possibility of suggesting sensory loss to a patient is a very real one, as has already been indicated. Hysterical patients rarely complain spontaneously of cutaneous sensory loss, although they may use the term *numbness* to indicate paralysis of a limb. Examination, on the other hand, may disclose a complete hemianesthesia—sometimes with the overtly hysterical findings of reduced hearing, sight, smell, and taste on one side—as well as impaired vibration sense over only half the skull and sternum, most of these being anatomic impossibilities. Anesthesia of an entire limb or a sharply defined sensory loss over part of a limb, not conforming to the distribution of a root or cutaneous nerve, may also be observed. The diagnosis of hysterical hemianesthesia is best made by eliciting the other relevant symptoms of hysteria or, if this is not possible, by noting the discrepancies between this type of sensory loss and that which occurs as part of the known, anatomically verified sensory syndromes.

Sometimes, in a patient with no other neurologic abnormality or in one with a definite neurologic syndrome, one is dismayed by sensory findings that are completely inexplicable and discordant. In such cases one must try to reason through to the diagnosis by disregarding the sensory findings.

Diagnosis of Somatosensory Syndromes

Affirmation of the clinical sensory syndromes is often possible by the application of *electrophysiologic testing*. Slowing and reduced amplitude of sensory nerve conduction is found with lesions of nerve, but only if the lesion lies distal to (or within) the sensory ganglion. Severe sensory loss in a neuropathic pattern with preserved sensory nerve action potentials therefore indicates a radiculopathy. Loss or slowing of H and F responses corroborates the presence of lesions in proximal parts of nerves, plexuses, and roots. By the use of somatosensory evoked potentials, it is possible to demonstrate slowing of conduction in the peripheral nerves or roots, in the pathways from spinal cord to a point in the lower medulla, in the medial lemniscus to the thalamus, and in the pathway from the thalamus to the cerebral cortex. In the context of regional sensory loss, evoked potentials find their greatest utility in demonstrating root disease when sensory nerve conduction studies are normal; otherwise, they are used most frequently to support the diagnosis of multiple sclerosis, in which case there may or may not be corresponding sensory features. (See Chap. 2 for further discussion.)

In practice, it is seldom necessary to examine all modalities of sensation and perception. With single peripheral nerve lesions, touch and pinprick testing are the most informative. With spinal cord disease, pinprick and thermal stimuli are most revealing of lateral column lesions; testing the senses of vibration, position, and movement, and particularly the sense of direction of a dermal stimulus, reliably indicates posterior column lesions. Touch is the least useful. In brainstem lesions, all modes of sensation including touch may be affected, and this applies in general to thalamic lesions. Thus, one is guided in the selection of tests by the suspected locale of the disease.

CHAPTER 10

HEADACHE AND OTHER CRANIOFACIAL PAINS

Of all the painful states that afflict humans, headache is undoubtedly the most frequent and rivals backache as the most common reason for seeking medical help. In fact, there are so many cases of headache that special headache clinics have been established in many medical centers. Insofar as many headaches are due to medical rather than neurologic diseases, the subject is the legitimate concern of the general physician. Yet there is always the question of intracranial disease, so that it is difficult to approach the subject without a knowledge of neurologic medicine.

Why so many pains are centered in the head is a question of some interest. Several explanations come to mind. For one thing, the face and scalp are more richly supplied with pain receptors than many other parts of the body, perhaps in order to protect the precious contents of the skull. Also, the nasal and oral passages, the eye, and the ear—all delicate and highly sensitive structures—reside here and must be protected; when afflicted by disease, each is capable of inducing pain in its own way. Finally, for the intelligent person, there is greater concern about what happens to the head than to other parts of the body, since the former houses the brain, and headache frequently raises the specter of brain tumor or other cerebral disease.

Semantically, the term *headache* should encompass all aches and pains located in the head, but in practice its application is restricted to discomfort in the region of the cranial vault. Facial, lingual, and pharyngeal pains are put aside as something different and are discussed separately in the latter part of this chapter and in Chap. 47, on the cranial nerves.

GENERAL CONSIDERATIONS

In the introductory chapter on pain, reference was made to the necessity, in dealing with any painful state, of determining its quality, severity, location, duration, and time course as well as the conditions that produce, exacerbate, or relieve it. When headache is considered in these terms, a certain amount of useful information is obtained, but often less than one might expect. Nor is the examination likely to be revealing. Auscultation of the skull may disclose a bruit (with large arteriovenous malformations), and palpation may disclose the tender, hardened or elevated arteries of temporal arteritis, sensitive areas overlying a cranial metastasis, an inflamed paranasal sinus, or a tender occipital nerve; however, apart from such special instances, examination of the head itself, though necessary, seldom discloses the diagnosis.

As to the *quality* of cephalic pain, the patient's description may or may not be helpful. Persistent questioning on this point may even occasion surprise, for the patient often assumes that the word *headache* should have conveyed enough information to the examiner about the nature of the discomfort. Most headaches, regardless of type, tend to be dull, aching, and not sharply localized, as is usually the case with disease of structures deep to the skin. Seldom does the patient describe the pricking or stinging type of pain that arises from the skin. When asked to compare the pain to some other sensory experience, the patient may allude to tightness,

aching, pressure, bursting, sharpness, or stabbing. The most important information to be obtained is whether the headache throbs, indicating a vascular source. But one must keep in mind that patients often use the word *throbbing* to refer to a waxing and waning of the headache without any relation to the pulse, whereas authentic pulsatile throbbing, especially if hemicranial, is highly characteristic of migraine.

Similarly, statements about the *intensity* of the pain must be accepted with caution, since they reflect as much the patient's attitudes and customary ways of experiencing and reacting to pain as its true severity. By temperament, some persons tend to minimize discomfort and others to dramatize it. A better index of severity is the degree to which the pain has incapacitated the patient, especially if he or she is not prone to illness. A severe migraine attack seldom allows the migraineur to perform the day's work. Another rough index of the severity of headache is its propensity to awaken the patient from sleep or to prevent sleep. The most intense cranial pains are those associated with meningitis and subarachnoid hemorrhage, which have grave implications, and with migraine, cluster headache, or tic douloureux, which do not.

Data regarding the *location* of a headache are apt to be more informative. Inflammation of an extracranial artery causes pain localized to the site of the vessel. Lesions of the paranasal sinuses, teeth, eyes, and upper cervical vertebrae induce a less sharply localized pain but still one that is referred to a certain region, usually the forehead or maxilla or around the eyes. Intracranial lesions in the posterior fossa generally cause pain in the occipitomastoid region and usually are homolateral if the lesion is one-sided. Supratentorial lesions induce frontotemporal pain, again approximating the site of the lesion. Localization, however, may also be deceiving. Pain in the frontal regions may be due to such diverse lesions and mechanisms as glaucoma, sinusitis, thrombosis of the vertebral or basilar artery, pressure on the tentorium, or increased intracranial pressure. Similarly, ear pain may signify disease of the ear itself, but more often it is referred from other regions, such as the throat, cervical muscles, spine, or structures in the posterior fossa. Periorbital and supraorbital pain, while sometimes indicative of local disease, may reflect dissection of the cervical portion of the internal carotid artery. Headaches localized to the vertex or biparietal regions are infrequent and should raise the suspicion of sphenoid or ethmoid sinus disease or thrombosis of the superior sagittal venous sinus.

The *mode of onset*, *time-intensity curve*, and *duration* of the headache, with respect both to a single attack and to the temporal profile of the headache over a period of years, are also useful data. At one extreme, the headache of subarachnoid hemorrhage (due to a ruptured aneurysm) occurs as an abrupt attack that attains its maximal severity in a matter of seconds or minutes; or, in the case of meningitis, it may come on more gradually, over several hours or days. Brief sharp pain, lasting a few seconds, in the eyeball (ophthalmodynia) or cranium ("icepick" pain) and "ice-cream headache" due to pharyngeal cooling is more common in migraineurs, with or without the characteristic headache, but otherwise

cannot be interpreted and is significant only by reason of its benignity. Migraine of the classic type usually has its onset in the early morning hours or in the daytime, reaches its peak of severity typically over several to 30 min, and lasts, unless treated, for 4 to 24 h, occasionally for as long as 72 h. Often it is terminated by sleep. More than a single attack of migraine every few weeks is exceptional. A migrainous patient having several attacks per week usually proves to have a combination of migraine and tension headaches, an analgesic “rebound headache,” or, rarely, some new, unexpected intracranial lesion. By contrast, the occurrence of unbearably severe unilateral orbitotemporal pain coming on within an hour or two after falling asleep or at predictable times during the day and recurring nightly or daily for a period of several weeks to months is typical of cluster headache; usually an individual attack dissipates in 30 to 45 min. The headaches of intracranial tumor may appear at any time of the day or night; they will interrupt sleep, vary in intensity, and last a few minutes to hours; as the tumor raises intracranial pressure. With posterior fossa masses, the headache tends to be worse in the morning, on awakening. Tension headaches, described further on, may persist with varying intensity for weeks to months or even longer; when such headaches are protracted, there is usually an associated depressive illness. In general, headaches that have recurred regularly for many years prove to be vascular or tension in type.

The more or less constant relationship of headache to certain biologic events and also to certain precipitating or aggravating (or relieving) factors must always be noted. Headaches that occur regularly in the premenstrual period are usually generalized and mild in degree (“premenstrual tension”), but attacks of migraine may also occur at this time. Headaches that have their origin in cervical spine disease are most typically intense after a period of inactivity, such as a night’s sleep, and the first movements of the neck are stiff and painful. Headache from infection of the nasal sinuses may appear, with clocklike regularity, upon awakening or in midmorning; it is characteristically worsened by stooping and changes in atmospheric pressure. Eyestrain headaches, of course, follow prolonged use of the eyes, as after long-sustained periods of reading, peering into glaring headlights, or exposure to the glare of video displays. In certain individuals, alcohol, intense exercise (such as weight-lifting), stooping, straining, coughing, and sexual intercourse are known to initiate a special type of bursting headache, lasting a few seconds to minutes. If the headache is made worse by sudden movement or by coughing or straining, an intracranial source is suggested. Anger, excitement, or worry may initiate migraine in certain disposed persons. In other patients, migraine occurs several hours or a day following a period of intense activity and stress (“weekend migraine”). Some patients have discovered that their migraine is relieved momentarily by gentle compression of the carotid or superficial temporal artery on the painful side, and others report that the carotid itself is tender during the headache. Or, pain is noticed when the scalp is stroked in fixing the hair, suggesting inflammation of the temporal arteries (temporal arteritis).

Pain-Sensitive Cranial Structures

Our understanding of headache has been greatly augmented by observations made during operations on the brain (Ray and Wolff). These observations inform us that only certain cranial structures are sensitive to pain: (1) skin, subcutaneous tissue, muscles, extracranial arteries, and periosteum of the skull; (2) delicate structures

of the eye, ear, nasal cavities, and paranasal sinuses; (3) intracranial venous sinuses and their large tributaries, especially pericavernous structures; (4) parts of the dura at the base of the brain and the arteries within the dura and pia-arachnoid, particularly the proximal parts of the anterior and middle cerebral arteries and the intracranial segment of the internal carotid artery; (5) the middle meningeal and superficial temporal arteries; and (6) the optic, oculomotor, trigeminal, glossopharyngeal, vagus, and first three cervical nerves. Interestingly, pain is practically the only sensation produced by stimulation of these structures; the pain arises in the walls of small blood vessels containing pain fibers (the nature of vascular pain is discussed further on).

Of importance also are the reference sites of pain from the aforementioned structures. Pain impulses that arise from distention of the middle meningeal artery are projected to the back of the eye and temporal area. Pain from the intracranial segment of the internal carotid artery and proximal parts of the middle and anterior cerebral arteries is felt in the eye and orbitotemporal regions. The bony skull, much of the pia-arachnoid and dura over the convexity of the brain, the parenchyma of the brain, and the ependyma and choroid plexuses lack sensitivity.

The pathways whereby sensory stimuli, whatever their nature, are transmitted to the central nervous system (CNS) are the trigeminal nerves, particularly their first and, to some extent, second divisions, which convey impulses from the forehead, orbit, anterior and middle fossae of the skull, and the upper surface of the tentorium. The sphenopalatine branches of the facial nerve convey impulses from the naso-orbital region. The ninth and tenth cranial nerves and the first three cervical nerves transmit impulses from the inferior surface of the tentorium and all of the posterior fossa. Sympathetic fibers from the three cervical ganglia and parasympathetic fibers from the sphenopalatine ganglia are mixed with the trigeminal and other sensory fibers. The tentorium roughly demarcates the trigeminal and cervical innervation zones. The central sensory connections, which ascend through the cervical spinal cord and brainstem to the thalamus, are described in the preceding chapter.

To summarize, pain from supratentorial structures is referred to the anterior two-thirds of the head, i.e., to the territory of sensory supply of the first and second divisions of the trigeminal nerve; pain from infratentorial structures is referred to the vertex and back of the head and neck by the upper cervical roots. The seventh, ninth, and tenth cranial nerves refer pain to the naso-orbital region, ear, and throat. There may be local tenderness of the scalp at the site of the referred pain. Dental or temporomandibular joint pain may also have cranial reference. With the exception of the cervical portion of the internal carotid artery, from which pain is referred to the eyebrow and supraorbital region, and the upper cervical spine, from which pain may be referred to the occiput, pain due to disease in extracranial parts of the body is not referred to the head. There are, however, rare instances of angina pectoris that may produce discomfort at the cranial vertex or adjacent sites and, of course, in the jaw.

Mechanisms of Cranial Pain

The studies of Ray and Wolff demonstrated that relatively few mechanisms are operative in the genesis of cranial pain. More specifically, *intracranial mass lesions* cause headache only if in a position to deform, displace, or exert traction on vessels and dural structures at the base of the brain, and this may happen long before

intracranial pressure rises. In fact, artificially raising the intraspinal and intracranial pressure by the subarachnoid or intraventricular injection of sterile saline solution does not consistently result in headache. This has been interpreted to mean that raised intracranial pressure does not cause headache—a questionable conclusion when one considers the relief of headache in some patients that follows lumbar puncture and lowering of the cerebrospinal fluid (CSF) pressure, particularly after subarachnoid hemorrhage. Actually, most patients with high intracranial pressure complain of bioccipital and bifrontal headaches that fluctuate in severity, probably because of traction on vessels or dura.

Dilatation of intracranial or extracranial arteries (and possibly sensitization of these vessels), of whatever cause, is likely to produce headache. The headaches that follow seizures, infusion of histamine, and ingestion of alcohol are probably all due to cerebral vasodilatation. Nitroglycerin, nitrates in cured meats (“hot-dog headache”), and monosodium glutamate in Chinese food may cause headache by the same mechanism. It seems probable that the throbbing or steady headache that accompanies febrile illnesses has a vascular origin as well; it is likely that the increased pulsation of meningeal vessels activates pain-sensitive structures within their walls or around the base of the brain. Certain systemic infectious agents, enumerated further on, seem to have a tendency to cause severe headache. The febrile headache may be generalized or predominate in the frontal or occipital regions and is much like histamine headache in being relieved on one side by carotid or superficial temporal artery compression and on both sides by jugular vein compression. It, like migraine, is increased by shaking the head.

A similar mechanism may be operative in the severe, bilateral, throbbing headaches associated with extreme rises in blood pressure, as occurs with pheochromocytoma, malignant hypertension, sexual activity, and in patients being treated with monoamine oxidase inhibitors. Mild to moderate degrees of hypertension, however, do not cause headaches despite a popular notion to the contrary. So-called cough and exertional headaches may also have their basis in the distention of intracranial vessels.

For many years, following the investigations of Harold Wolff, the headache of migraine was attributed to dilatation of the extracranial arteries. Now it appears that this is not a constant relationship and that the headache is of intracranial as much as extracranial origin, perhaps related to the sensitization of blood vessels and their surrounding structures. Activation of the trigeminovascular system (the trigeminal nerves and the blood vessels they supply), leading to “sterile inflammation,” has also been assigned a role in the genesis of migraine headache. These and other theories of causation are summarized by Cutrer and discussed further on in this chapter in the sections on migraine.

With regard to cerebrovascular diseases causing head pain, the extracranial temporal and occipital arteries, when involved in giant-cell arteritis (cranial or “temporal” arteritis), give rise to severe, persistent headache, at first localized on the scalp and then more diffuse. With occlusion or dissection of the vertebral artery, the pain is in the upper neck or postauricular; basilar artery thrombosis causes pain to be projected to the occiput and sometimes to the forehead. The ipsilateral eye and brow and the forehead above it are the most common sites of projected pain from dissection of the carotid and occlusion of the stem of the middle cerebral arteries. Expanding or ruptured intracranial aneurysms may cause pain projected from the posterior communicating artery to the eye.

Infection or blockage of paranasal sinuses is accompanied by pain over the affected maxillary or frontal sinuses. Usually it is associated with tenderness of the skin in the same distribution. Pain from the ethmoid and sphenoid sinuses is localized deep in the midline behind the root of the nose or occasionally at the vertex (especially with disease of the sphenoid sinus) or adjacent part of the cranium. The mechanism in these cases involves changes in pressure and irritation of pain-sensitive sinus walls. Sinus pain recurs and subsides periodically, depending on drainage from the sinus. With frontal and ethmoidal sinusitis, the pain tends to be worse on awakening and gradually subsides when the patient is upright; the opposite pertains with maxillary and sphenoidal sinusitis. These relationships are believed to disclose their mechanism; pain is ascribed to filling of the sinuses and its relief to their emptying, induced by the dependent position of the ostia. Bending over intensifies the pain by causing changes in pressure, as does blowing the nose; during air travel, both earache and sinus headache tend to occur on descent, when the relative pressure in the blocked viscous rises. Sympathomimetic drugs such as phenylephrine hydrochloride, which reduce swelling and congestion, tend to relieve the pain. However, the pain may persist after all purulent secretions have disappeared, probably because of blockage of the orifice by boggy membranes and absorption of air from the blocked sinus (*vacuum sinus headaches*). The condition is relieved when aeration is restored.

Headache of ocular origin, located as a rule in the orbit, forehead, or temple, is of the steady, aching type and tends to follow prolonged use of the eyes in close work. The main faults are hypermetropia and astigmatism (rarely myopia), which result in sustained contraction of extraocular as well as frontal, temporal, and even occipital muscles. Correction of the refractive error abolishes the headache. Traction on the extraocular muscles or the iris during eye surgery will evoke pain. Patients who develop diplopia from neurologic causes or are forced to use one eye because the other has been occluded by a patch often complain of frontal headache. Another mechanism is involved in *iritis* and in *acute glaucoma*, in which raised intraocular pressure causes steady, aching pain in the region of the eye, radiating to the forehead. As for headache in general, it is important that the eyes be refracted, but eyestrain is not as frequent a cause as one would expect from the wholesale dispensing of eyeglasses for its relief.

Headaches that accompany disease of ligaments, muscles, and apophysial joints in the upper part of the cervical spine are referred to the occiput and nape of the neck on the same side and sometimes to the temple and forehead. These headaches have been reproduced in part by the injection of hypertonic saline solution into the affected ligaments, muscles, and zygapophysial (facet) joints. Such pains are especially frequent in late life because of the prevalence of degenerative changes in the cervical spine and tend also to occur after whiplash injuries or other forms of sudden flexion, extension, or torsion of the head on the neck. If the pain is arthritic in origin, the first movements after the individual has been still for some hours are stiff and painful. The pain of fibromyalgia, a controversial entity, is evidenced by tender areas near the cranial insertion of cervical and other muscles. There are no pathologic data as to the nature of these vaguely palpable and tender lesions, and it is uncertain whether the pain actually arises in them. They may represent only the deep tenderness felt in the region of referred pain or the involuntary secondary protective spasm of muscles. Sleep disturbance is often associated, as is depression. Massage of muscles, heat, and injection of the tender spots with local anesthetic have

unpredictable effects but relieve the pain in some cases. Unilateral occipital headache is often misinterpreted as occipital neuralgia (see further on).

The headache of meningeal irritation (infection or hemorrhage) is acute in onset, usually severe, generalized, deep-seated, constant, and associated with stiffness of the neck, particularly on forward bending. It has been ascribed to increased intracranial pressure; indeed, the withdrawal of CSF may afford some relief. However, dilatation and inflammation of meningeal vessels and the chemical irritation of pain receptors in the large vessels and meninges by chemical agents, particularly serotonin and plasma kinins, are probably more important factors in the production of pain and spasm of the neck extensors. In the chemically induced meningitis from rupture of an epidermoid cyst, for example, the spinal fluid pressure is usually normal but the headache is severe.

A singular headache is produced by subarachnoid hemorrhage; it is very intense and paroxysmal in onset, as already mentioned, and is associated with vomiting and neck stiffness, the latter being a reflection of meningeal irritation. There may be transient loss of consciousness. The ocular examination assumes importance in that there may be subhyaloid hemorrhages. It is not uncommon for the rupture of an aneurysm that gives rise to subarachnoid hemorrhage to be precipitated by exertion, even of minor degree. Very few other headache syndromes simulate this disease (see page 716).

Lumbar puncture (LP) headache, as elaborated in Chap. 2, is characterized by a steady occipitonal and frontal pain coming on within a few minutes after arising from a recumbent position and is relieved within a minute or two by lying down. Its cause is a persistent leakage of CSF into the lumbar tissues through the needle track. The CSF pressure is low (often zero in the lateral decubitus position), and the injection of sterile isotonic saline solution intrathecally or the placing of an epidural “blood patch” relieves the headache. Usually this type of headache is increased by compression of the jugular veins but is unaffected by digital obliteration of one carotid artery. It seems probable that, in the upright position, a low intraspinal and negative intracranial pressure permits caudal displacement of the brain, with traction on dural attachments and dural sinuses. Pannullo and colleagues, with magnetic resonance imaging, have demonstrated this downward displacement of the cranial contents. Headache following cisternal puncture is less frequent. As soon as the leakage of CSF stops and CSF pressure is restored (usually within hours or a few days), the headache disappears. “Spontaneous” low-pressure headache may follow a sneeze, strain, or athletic injury, sometimes as a result of rupture of the arachnoid sleeve along a nerve root (page 542). Less frequently, lumbar puncture is complicated by severe stiffness of the neck and pain over the back of the neck and occiput (page 541); a second spinal tap in some instances discloses slight pleocytosis but no decrease in glucose—a sterile or chemical meningitis. This benign reaction must be distinguished from the rare occurrence of bacterial meningitis due to introduction of bacteria by the LP needle.

Headaches that are aggravated by lying down or lying on one side occur with acute and chronic subdural hematoma and some brain tumors, particularly those in the posterior fossa. The headache of subdural hematoma, when it occurs, is dull and unilateral, perceived over most of the affected side of the head. The headaches of pseudotumor cerebri are also generally worse in the supine position (Chap. 31). In all these states of raised intracranial pressure, headaches are typically worse in the early morning hours after a long period of recumbency.

Exertional headaches are usually benign but are sometimes related to pheochromocytoma, arteriovenous malformation, or other intracranial lesions. The same applies to headaches induced by stooping (see further on).

PRINCIPAL VARIETIES OF HEADACHE

There should be little difficulty in recognizing the acute headaches of migraine, glaucoma, purulent sinusitis, subarachnoid hemorrhage, and bacterial or viral meningitis and the subacute headache of brain tumor provided that these sources of headache are kept in mind. A fuller account of these types of headache may be found in later chapters of this book, where the underlying diseases are described. When the headache is chronic, recurrent, and unattended by other symptoms and signs of neurologic disease, the physician faces a more difficult diagnostic problem.

The following types of headaches should then be considered (Table 10-1). In general, the classification of these headaches and other types of craniofacial pain follow the plan outlined by the International Headache Society (see Olesen). One area of controversy in classification concerns the status (and indeed the existence) of tension headache. A currently held view, with which the authors do not entirely agree, is that there is a continuum between migraine and tension headache. This relationship is considered further on.

Migraine

Migraine is a ubiquitous familial disorder characterized by periodic, commonly unilateral, often pulsatile headaches that begin in childhood, adolescence, or early adult life and recur with diminishing frequency during advancing years.

Two closely related clinical syndromes have been identified, the first called *migraine with aura* and the second, *migraine without aura* (terminology of the International Headache Society). For many years the first syndrome was referred to as *classic or neurologic migraine* and the second as *common migraine*. The ratio of classic to common migraine is 1:5. Either type may be preceded by vague premonitory changes in mood and appetite (a prodrome). *Migraine with aura*, the term now used to denote classic migraine, is ushered in by an evident disturbance of nervous function, most often visual, followed in a few minutes by hemicranial or, in about one-third of cases, by bilateral headache, nausea, and sometimes vomiting, all of which last for hours or as long as a day or two. Migraine without aura is characterized by an unheralded onset over minutes or longer of hemicranial headache or, less often, by generalized headache with or without nausea and vomiting, which then follows the same temporal pattern as the migraine with aura. Sensitivity to light and noise attends both types, and intensification with movement of the head is common. If the pain is severe, the patient prefers to lie down in a quiet, darkened room and tries to sleep. The *hemicranial* and the *throbbing* (pulsating) aspects of migraine are its most characteristic features in comparison to other headache types; each patient displays a proclivity for the pain to affect one side or the other of the cranium, but not exclusively.

The genetic nature of classic migraine is apparent from its occurrence in several members of the family of the same and successive generations in 60 to 80 percent of cases; the familial frequency of common migraine is slightly lower. Twin and sibling studies have not revealed a consistent mendelian pattern in either the classic or common form; the inheritance in all likelihood is

Table 10-1
Common types of headache

TYPE	SITE	AGE AND SEX	CLINICAL CHARACTERISTICS	DIURNAL PATTERN	LIFE PROFILE	PROVOKING FACTORS	ASSOCIATED FEATURES	TREATMENT
Migraine without aura (common migraine)	Frontotemporal Uni- or bilateral	Adolescents, young to middle-aged adults, sometimes children, more common in women	Throbbing (pulsatile); worse behind one eye or ear Becomes dull ache and generalized Scalp sensitive	Upon awakening or later in day Duration: 4–24 h in most cases, sometimes longer	Irregular intervals, weeks to months Tends to decrease in middle age and during pregnancy	Bright light, noise, tension, alcohol Relieved by darkness and sleep	Nausea and vomiting in some cases	Ergotamine sumatriptan, nonsteroidal anti-inflammatory agents Propranolol or amitriptyline for prevention
Migraine with aura (neurologic migraine)	Same as above	Same as above Family history frequent	Same as above	Same as above	Same as above	Same as above	Scintillating lights, visual loss, and scotomas	Same as above
Cluster (histamine headache, migrainous neuralgia)	Orbitotemporal Unilateral	Adolescent and adult males (90%)	Intense, nonthrobbing	Usually nocturnal, 1–2 h after falling asleep Occasionally diurnal	Nightly or daily for several weeks to months Recurrence after many months or years	Alcohol in some	Unilateral paresthesias, weakness, dysphasia, vertigo, rarely confusion	Ergotamine before anticipated attack, O ₂ , sumatriptan Methysergide, corticosteroids, verapamil, valproate, and lithium in recalcitrant cases

Tension headaches	Generalized	Mainly adults, both sexes, more in women	Pressure (nonthrobbing), tightness, aching	Continuous, variable intensity, for days, weeks, or months	One or more periods of months to years	Fatigue and nervous strain	Depression, worry, anxiety	Antianxiety and antidepressant drugs
Meningeal irritation (meningitis, subarachnoid hemorrhage)	Generalized, or bioccipital or bifrontal	Any age, both sexes	Intense, steady deep pain, may be worse in neck	Rapid evolution — minutes to hours	Single episode	None	Neck stiff on forward bending Kernig and Brudzinski signs	For meningitis or bleeding (see text)
Brain tumor	Unilateral or generalized	Any age, both sexes	Variable intensity May awaken patient Steady pain	Lasts minutes to hours; worse in early A.M., increasing severity	Once in a lifetime: weeks to months	None Sometimes position	Papilledema Vomiting Impaired mentation Seizures	Corticosteroids Mannitol Treatment of tumor
Temporal arteritis	Unilateral or bilateral, usually temporal	Over 50 years, either sex	Throbbing, then persistent aching and burning, arteries thickened and tender	Intermittent, then continuous	Persists for weeks to months	None	Focal signs Loss of vision Polymyalgia rheumatica Fever, weight loss, increased sedimentation rate	Corticosteroids

polygenic. Certain rare forms of migraine, such as familial hemiplegic migraine, appear to be monogenic disorders, but the role of these genes, one of which codes for a calcium channel (see below), in classic and common migraine is speculative.

Migraine, with or without aura, is a remarkably common condition; its prevalence among Caucasians is in the range of 4 to 6 percent among men and 13 to 18 percent among women (see Stewart et al). The reported numbers are lower among Asians. Migraine may have its onset in childhood but usually begins in adolescence; in more than 80 percent of patients, the onset is before 30 years of age, and the physician should be cautious in attributing headaches that appear for the first time after this age to migraine.

In women, the headaches tend to occur during the premenstrual period; in about 15 percent of such migraineurs, the attacks are exclusively perimenstrual ("true menstrual migraine"), although estrogen and progesterone levels throughout the menstrual cycle are the same in normal and migrainous women. *Menstrual migraine*, discussed further on, is thought to be related to the withdrawal of estradiol rather than progesterone (based on the work of Somerville). It is now acknowledged that the influence of sex hormones on headache is more complex. The attacks cease during pregnancy in 75 to 80 percent of women, and in others they continue at a reduced frequency; less often, attacks of migraine or the associated neurologic symptoms first appear during pregnancy, usually in the first trimester.

Although migraine usually diminishes in severity and frequency with age, it may actually worsen in some postmenopausal women, and estrogen therapy may either increase or, paradoxically, diminish the incidence of headaches. The use of birth control pills has been associated with an increased frequency and severity of migraine and in rare instances has resulted in a permanent neurologic deficit.

Some patients link their attacks to certain dietary items—particularly chocolate, cheese, fatty foods, oranges, tomatoes, and onions—but these connections in most cases seem to us to be overrated. Some of these foods are rich in tyramine, which has been incriminated as a provocative factor in migraine. Alcohol, particularly red wine or port, regularly provokes an attack in some persons; in others, headaches are consistently induced by exposure to glare or other strong sensory stimuli, sudden jarring of the head ("footballer's migraine"), or by rapid changes in barometric pressure. Perhaps the most common ostensible trigger is excess caffeine intake or withdrawal of caffeine.

Migraine with aura frequently has its onset soon after awakening, but it may occur at any time of day. During the preceding day or so, there may have been mild changes in mood (sometimes a surge of energy or a feeling of well-being), hunger or anorexia, drowsiness, and frequent yawning. Then, abruptly, there is a disturbance of vision consisting usually of unformed flashes of white, or silver or, rarely, of multicolored lights (photopsia). This may be followed by an enlarging blind spot with a shimmering edge (*scintillating scotoma*), or formations of dazzling zigzag lines (arranged like the battlements of a castle, hence the term *fortification spectra* or *teichopsia*). Other patients complain instead of blurred or shimmering or cloudy vision, as though they were looking through thick or smoked glass or the wavy distortions produced by heat rising from asphalt. These luminous hallucinations move slowly across the visual field for several minutes and may leave an island of visual loss in their wake (scotomatous defects); the latter are usually bilateral and often homonymous (involving corresponding parts of the field of vision of each eye), pointing to their origin in

the visual cortex. Patients almost invariably attribute these visual symptoms to one eye rather than to parts of both fields. Ophthalmologic abnormalities of retinal and optic nerve vessels have been described in some cases but are not typical (see further on).

Other focal neurologic symptoms, much less common than visual ones, include numbness and tingling of the lips, face, and hand (on one or both sides); slight confusion of thinking; weakness of an arm or leg; mild aphasia or dysarthria, dizziness, and uncertainty of gait; or drowsiness. Only one or a few of these neurologic phenomena are present in any given patient, and they tend to occur in more or less the same combination in each attack. If weakness or paresthetic numbness spreads from one part of the body to another or if one neurologic symptom follows another, this occurs relatively slowly over a period of minutes (not over seconds, as in a seizure, or simultaneously in all affected parts as in a transient ischemic attack). These neurologic symptoms last for 1 to 15 min, sometimes longer; as they begin to recede, they are followed by a unilateral dull pain that progresses to a throbbing headache (usually but not always on the side of the cerebral disturbance), which slowly increases in intensity. At its peak, within minutes to an hour, the patient is forced to lie down and to shun light and noise. Light is irritating and may be painful to the globes, or it is perceived as overly bright (dazzle), and strong odors are disagreeable. Nausea and, less often, vomiting may occur. The headache lasts for hours and sometimes for a day or even longer and is always the most unpleasant feature of the illness. The temporal scalp vessels may be tender and the headache is worsened by strain or jarring of the body or rapid movement of the head. Pressure on the scalp vessels or carotid artery may momentarily reduce the pain.

Between attacks, the migrainous patient is normal. For a time, when psychosomatic medicine was much in vogue, there was insistence on a migrainous personality, characterized by tenseness, rigidity of attitudes and thinking, meticulousness, and perfectionism. Further analyses, however, have not established a particular personality type in the migraineur. Moreover, the fact that the headaches may begin in early childhood, when the personality is relatively amorphous, would argue against this idea. There is no clear relationship, despite many statements to the contrary, between migraine and neurosis. Some patients have noted that their attacks of migraine tend to occur during the "let-down period," after many days of hard work or nervous tension, but the temporal relations between headache and the day's or week's activities have not proved to be consistent. A relationship to epilepsy is also tenuous; however, the incidence of seizures is slightly higher in migrainous patients and their relatives than in the general population. Lance and Anthony find no mechanism common to migraine and epilepsy. There does seem to be in migraineurs an overrepresentation of motion sickness and of fainting.

Migraine Variants Much variation occurs. The headache may be exceptionally severe and abrupt in onset ("crash migraine" or "thunderclap headache"), raising the specter of subarachnoid hemorrhage. Careful questioning sometimes reveals that the headache did not attain its peak of severity rapidly but evolved over several minutes or half hour, but often the distinction from subarachnoid hemorrhage can be made only by examination of the CSF and imaging of the brain (see further on, under "Special Varieties of Headache").

The headache may at times precede or accompany rather than follow the neurologic abnormalities of migraine with aura. Though typically hemicranial (the French word *migraine* is said to be de-

rived from *megrism*, which in turn was derived from the Latin *hemicrania* and its corrupted forms *hemigranea* and *migranea*), the pain may be frontal, temporal, or quite often, generalized.

Milder forms of migraine, especially if partially controlled by medication, may not force the patient to withdraw from accustomed activities. Any one of the three principal components—neurologic abnormality, headache, and nausea and vomiting—may be absent. With advancing age, there is a tendency for the headache and nausea to become less severe, finally leaving only the neurologic abnormality (“aura without migraine”), which itself recurs with decreasing frequency. This is also subject to variation. Visual disturbances, by far the most common, differ in detail from patient to patient; numbness and tingling of the lips and the fingers of one hand are probably next in frequency, followed by transient aphasia or a thickness of speech and hemiparesis as mentioned earlier. Rarely, there is sudden but transient blindness or a hemianopia at the onset, accompanied by only a mild headache. All of these neurologic syndromes must be distinguished from transient ischemic attacks (TIA) and small strokes, which they resemble if the typical headache fails to follow the neurologic symptoms (see further on, under “Stroke and TIA with Migraine”).

Basilar Migraine A less common form of the migraine syndrome, with prominent brainstem symptoms, was described by Bickerstaff. The patients, usually young women with a family history of migraine, first develop visual phenomena like those of typical migraine except that they occupy the whole of both visual fields (temporary cortical blindness may occur). There may be associated vertigo, staggering, incoordination of the limbs, dysarthria, and tingling in both hands and feet and sometimes around both sides of the mouth. These symptoms last 10 to 30 min and are followed by headache, which is usually occipital. Some patients, at the stage when the headache is likely to begin, may faint, and others become confused or stuporous, a state that may persist for several hours or longer. Exceptionally there is an alarming period of coma or quadriplegia. The symptoms closely resemble those due to ischemia in the territory of the basilar-posterior cerebral arteries—hence the name *basilar artery* or *vertebrobasilar migraine*. Subsequent studies have indicated that basilar migraine, though more common in children and adolescents, affects men and women more or less equally over a wide age range, and that the condition is not always benign and transient (see further on, under “Complicated Migraine”).

Ophthalmoplegic and Retinal Migraine The former are recurrent unilateral headaches associated with weakness of extraocular muscles. A transient third-nerve palsy with ptosis, with or without involvement of the pupil, is the usual picture; rarely, the sixth nerve is affected. This disorder is more common in children. The paresis often outlasts the headache by days or weeks; after many attacks, a slight mydriasis and, rarely, ophthalmoparesis may remain as permanent defects.

Retinal and anterior optic nerve ischemia has also been documented. In some cases, the retinal arterioles are attenuated and sometimes there are retinal hemorrhages; in other cases, narrowing of retinal arteries or venules has been observed during an attack, as described in the cases reported by Berger and colleagues. In still other cases, monocular blindness is associated with disc edema and peripapillary hemorrhages, and vision recovers only partially after several months (Hupp et al). Such events are referred to as *retinal migraine*, or, more accurately, *ocular migraine*, since either the retinal or the ciliary circulation may be involved. It is well to remember that in adults the syndrome of headache, unilateral

ophthalmoparesis, and loss of vision may have more serious causes, including temporal (cranial) arteritis.

Migraine following Head Injury A particularly troublesome migraine variant occurs in a child or adolescent who, after a trivial head injury, may lose sight, suffer severe headache, or be plunged into a state of confusion, with belligerent and irrational behavior that lasts for hours or several days before clearing. In yet another variant there is an abrupt onset of either one-sided paralysis or aphasia after virtually every minor head injury (we have seen this condition several times in college athletes) but without visual symptoms and little or no headache. Although a family history of migraine is frequent in such cases, there has been no hemiplegia in other family members.

Migraine in Young Children This may present particular difficulties in diagnosis, since a young child’s capacity for accurate description is limited. Instead of complaining of headache, the child appears limp and pale and complains of abdominal pain; vomiting is more frequent than in the adult and there may be slight fever. Recurrent attacks are referred to by pediatricians as the “periodic syndrome.” Another variant in the child is episodic vertigo and staggering (paroxysmal disequilibrium) followed by headache (see Watson and Steele). Also, there are the puzzling patients with bouts of fever or transient disturbances in mood (psychic equivalents) and abdominal pain (*abdominal migraine*), dubious entities at best. We have also seen several infants and young children who have had attacks of hemiplegia (without headache), first on one side then the other, every few weeks. Recovery was complete, and arteriography in one child, after more than 70 attacks, was normal. The relationship of this condition to neurologic migraine remains uncertain. The only advantage of considering such attacks as migrainous is that it may protect some patients from unnecessary diagnostic procedures and surgical intervention; but, by the same token, it may delay appropriate investigation and treatment.

Hemiplegic Migraine In a related disorder, known as *hemiplegic migraine*, an infant, child, or adult has episodes of unilateral paralysis that may long outlast the headache. Several families have been described in which this condition was inherited as an autosomal dominant trait (*familial hemiplegic migraine*). Linkage-analysis studies of this disorder have localized the responsible gene to chromosome 19 in one-third of families (Joutel et al); in other families, the gene has localized to chromosome 1; in yet others, no linkage has been found. The gene on chromosome 19 codes for a voltage-gated calcium channel protein, which raises the provocative possibility that other forms of migraine are also due to an ion channel disorder. Instances of hemiplegic migraine may account for some of the inexplicable strokes in young women and older adults of both sexes. The situation is, however, more complex; Ducros and colleagues have found a variety of other neurologic features in these families, including persistent cerebellar ataxia and nystagmus in 20 percent; others had attacks of coma and hemiplegia, from which they recovered.

Complicating the situation is the undoubtedly existence of sporadic migraine with transient hemiplegia that has no familial trait. Neurologic symptoms lasting more than an hour or so should prompt investigation for alternative causes of headache, but none may be found.

Stroke and Transient Ischemic Attacks with Migraine (See also Chap. 34) Attacks of migraine, instead of beginning in childhood and recurring in stereotyped fashion every few weeks or months with diminishing frequency in middle and late adult years, may have their onset later in life or may suddenly increase in fre-

quency during menopause or in association with hypertension and vascular disease. Some of the transient aphasic, hemianesthetic, or hemiplegic attacks of later life may be of migrainous origin ("migrainous accompaniments"); Fisher has provided support for this hypothesis.

Rarely, neurologic symptoms, instead of being transitory, may leave a permanent deficit (e.g., a homonymous visual field defect), indicative of an ischemic stroke. This is called *complicated migraine* or *migrainous infarction*. Platelet aggregation, edema of the arterial wall, increased coagulability of the blood, and intense, prolonged spasms of vessels have all been implicated (on rather uncertain grounds) in the pathogenesis of arterial occlusion and strokes that complicate migraine (Rascol et al). The reported incidence of this complication has varied. At the Mayo Clinic, in a group of 4874 patients aged 50 years or younger with a diagnosis of migraine, migraine equivalent, or vascular headache, 20 patients had migraine-associated infarctions (Broderick and Swanson). The reports of Dorfman and coworkers, in which cerebral infarction was revealed by computed tomography (CT) in four young adults (16 to 32 years of age) with migraine, and of Caplan, who described seven patients in whom attacks of migraine were complicated by strokes in the vertebrobasilar territory, matches our experience and suggests that these complications may be more prevalent than is generally appreciated. There is a paucity of useful pathology by which to interpret the mechanism of migraine-associated stroke.

In children with the mitochondrial disease MELAS (page 844) and in adults with the rare vasculopathy CADASIL (page 707), migraine may be a prominent feature. These issues are addressed further in Chap. 34.

The special problem of focal cerebral disorders associated with segmental vasospasm that follows treatment with the "tripitan" group of drugs is discussed further on and a similar but spontaneous syndrome of severe headache and fluctuating focal neurologic symptoms due to vasospasm (Call-Fleming syndrome) is discussed on page 730.

Other Variations In some individuals, the migraine, for unaccountable reasons, may increase in frequency for several months. As many as three or four attacks may occur each week, leaving the scalp continuously tender. An even more difficult clinical problem that arises with some regularity on our services is posed by migraine that lapses into a condition of daily or virtually severe continuous headache (*status migrainosus*). The pain is initially unilateral, later more generalized, more or less throbbing, and disabling; vomiting or nausea are common at the outset but generally abate. Almost without exception, there is a preceding history compatible with migraine; the absence of prior headaches should raise concern about a more serious cause. Status migrainosus has sometimes followed a head injury or a viral infection, but most cases have no explanation. Relief is sought by increasing the intake of ergot preparations or even opiate medications, often to an alarming degree, but with only temporary relief. The mechanism of migraine being obscure, one can only surmise that the basic process has been greatly intensified. Treatment is considered further on.

Always to be considered in the diagnosis of such cases is the possibility that migraine has been combined with tension headache (migraine-tension or mixed-pattern headache) or transformed to so-called analgesia-rebound headache or ergotamine, or triptan-dependency headache, as described by Taimi and colleagues. Narcotic addiction is another consideration. It has been our practice to admit such patients to the hospital, discontinue all ergot and nar-

cotic medication, and administer corticosteroids, one of the triptan medications, or ergots intravenously in selected patients (see further on for details of treatment).

Migraine with CSF Pleocytosis A particularly intriguing problem arises in the patient with migraine who is found to have a lymphocytic pleocytosis in the spinal fluid. Most of these cases in our experience have turned out to be simply instances of aseptic meningitis that have precipitated migraine in susceptible individuals. In others cases, a few cells are found in the spinal fluid during an attack of migraine without obvious explanation; probably a minor cellular reaction can be ignored if there is no fever. But, under the title "Pseudomigraine with Temporary Neurological Symptoms and Lymphocytic Pleocytosis," Gomez-Aranda and colleagues have described what is possibly yet another migraine variant. Their series comprised 50 adolescents and young adults, predominantly males, who developed several episodes of transient (hours) neurologic deficits, accompanied by migraine-like headaches, sometimes with slight fever. One-quarter of this group had a history of migraine and a similar number had a viral-like illness within 3 weeks of the neurologic problem. The CSF contained from 10 to 760 lymphocytes per cubic millimeter and the total protein was elevated. Neurologic deficits were mainly sensorimotor and aphasic; only 6 patients had visual symptoms. The patients were asymptomatic between attacks and in none did the entire illness persist beyond 7 weeks. The causation and pathophysiology of this syndrome and its relation to migraine are entirely obscure, although one plausible explanation is an aseptic inflammation of the leptomeningeal vasculature of some type. We have observed three very similar cases, all in otherwise healthy middle-aged men, not related to the use of nonsteroidal medications, and we found corticosteroids to be helpful. The distinction between this syndrome and the recurrent aseptic meningitis of Mollaret and other chronic meningoencephalitic syndromes is sometimes difficult; the latter condition has been attributed to herpes infection in some instances (page 635).

Cause and Pathogenesis So far, it has not been possible to determine, from the many clinical observations and investigations, a unifying theory as to the cause and pathogenesis of migraine. Tension and other emotional states, which are claimed by some migraineurs to precede their attacks, are so inconsistent as to be no more than potential aggravating factors. Clearly, an underlying genetic factor is implicated, although it is expressed in a recognizable mendelian pattern (autosomal dominant) in a relatively small number of families (see above). The puzzle is how this genetic fault is translated periodically into a regional neurologic deficit, unilateral headache, or both. For many years, our thinking about the pathogenesis of migraine was dominated by the views of Harold Wolff and others—that the headache was due to the distention and excessive pulsation of branches of the external carotid artery. Certainly the throbbing, pulsating quality of the headache and its relief by compression of the common carotid artery supported this view, as did the early observation of Graham and Wolff that the headache and amplitude of pulsation of the extracranial arteries diminished after the intravenous administration of ergotamine tartrate.

The importance of vascular factors continues to be emphasized by more recent findings. In a group of 11 patients with classic migraine, Olsen and colleagues, using the xenon inhalation method, noted a regional reduction in cerebral circulation during the period when neurologic symptoms appear. They concluded that the reduction in blood flow was sufficient to cause both ischemia and

the neurologic deficits and that the latter had a vascular origin. In a subsequent study, Woods and colleagues described a patient who, during positron emission tomography (PET), fortuitously had an attack of common migraine. Highly sophisticated measurements showed a reduction in blood flow that started in the occipital cortex and spread slowly forward on both sides, in a manner much like that of the spreading depression of Leão (see below). Cutter and colleagues, using perfusion-weighted magnetic resonance imaging (MRI), corroborated the finding of diminished occipital cerebral blood flow during the aura in four patients. However, a study using single-photon emission computed tomography (SPECT) in 20 patients during and after attacks of migraine without aura disclosed no detectable focal changes of cerebral blood flow; also, no changes occurred after treatment of the attacks with 6 mg of subcutaneous sumatriptan (Ferrari et al). Iversen and associates, by means of ultrasound measurements, documented a dilatation of the superior temporal artery on the side of the migraine during the headache period. The same dilatation in the middle cerebral arteries has been inferred from observations with transcranial Doppler imaging. The well-established complication of cerebral infarction is also in keeping with a vascular hypothesis, but it involves only a tiny proportion of migraineurs. This vascular hypothesis must be regarded as uncertain, but clearly there is frequently a reduction in blood flow during auras. The original opinion expressed by Wolf that a vascular element is responsible for the cranial pain of migraine is also unconfirmed, but this view is still favored by many headache experts.

Several other relationships between the vascular changes and evolving neurologic symptoms of migraine are noteworthy. Lashley, who plotted his own visual aura, calculated that the cortical impairment progressed at a rate of 2 to 3 mm/min. Also, during the aura, there occurs a regional reduction in blood flow, as noted above. It begins in one occipital lobe and extends forward slowly (2.2 mm/min) as a wave of "spreading oligemia" that does not respect arterial boundaries (Lauritzen and Olesen). Both of these events are intriguingly similar to the above-mentioned phenomenon of "spreading cortical depression," first observed by Leão in experimental animals. He demonstrated that a noxious stimulus applied to the rat cortex was followed by vasoconstriction and slowly spreading waves of inhibition of the electrical activity of cortical neurons, moving at a rate of approximately 3 mm/min. Lauritzen and Olesen attribute both the aura and the spreading oligemia to the spreading cortical depression of Leão, and considerable work since then has corroborated this idea. These observations, however, apply only to the aura.

An alternative but not necessarily exclusive hypothesis linking the aura and the painful phase of migraine through a neural mechanism originating in the trigeminal nerve has been proposed by Moskowitz. This is based on the fact that the involved vessels, both extracranial and intracranial, are innervated by small unmyelinated fibers that are derived from the trigeminal nerve and subserve both pain and autonomic functions (the "trigeminovascular" complex). This model raises the possibility that the headache has a neurogenic basis in the trigeminal ganglion. Activation of these fibers also releases substance P, calcitonin gene-related peptide (CGRP), and other peptides into the vessel wall, which serves to dilate the cerebral vessels and increase their permeability. The throbbing headache is thus induced. Perhaps both neural and vascular mechanisms are operative. A pictorial representation of this theory is given in the review by Goadsby and colleagues. More recently, nitric oxide that is generated by endothelial cells has also

been implicated as the cause of the pain of migraine headache, but the reason for its release and the relationship to changes in blood flow is unclear.

Blau and Dexter and also Drummond and Lance are confident that the presence or absence of headache does not depend on extracranial vascular factors. These authors point to their findings that occlusion of blood flow through the scalp or common carotid circulation fails to alleviate the pain of migraine in one-third to one-half the patients. Alternatively, Lance has suggested that the trigeminal pathways are in a state of persistent hyperexcitability in the migraine patient and that they discharge periodically, perhaps in response to a hypothalamic stimulus. This is in keeping with current theories regarding the trigeminovascular complex discussed above as well as with evolving ideas on central sensitization to pain due to repeated noxious stimulation from one region. Also, there is a body of circumstantial evidence that serotonin acts as a humoral mediator in the neural and vascular components of the migraine headache. This evidence and the role of other factors in the pathogenesis of migraine have been reviewed in detail by Lance and Goadsby. The potential role of nitric oxide has been mentioned, and its importance in migraine is bolstered by the observation that drugs blocking its production ameliorate the headache.

The foregoing observations leave a number of questions unanswered. Is one to conclude that migraine with and without aura are different diseases, involving extracranial arteries in one instance and intracranial ones in another? Is the circulatory change the primary cause of headache, or is it a secondary or coincidental phenomenon? Is diminished neuronal activity (spreading depression) the primary cause of neurologic symptoms (it seems so) and headache (unclear), and is the diminished regional blood flow secondary to reduced metabolic demand? Why are the posterior portions of the brain (visual auras) so often implicated?

No final reconciliation of all these conflicting data is possible at this time and the mechanism of migraine remains incompletely explained. Several aspects seem clear, however. The authors continue to favor the unique mechanism of spreading depression as the best explanation of the neurologic deficit, as well as the view that a trigeminal vascular reflex, which releases vasogenic substances into the vessel walls, is the most plausible explanation of the headache. The neural mechanisms that underlie these changes and precisely what is altered by the genetic predisposition to migraine are unresolved. There are fairly consistent vascular changes during the aura (reduced regional flow, mainly in posterior regions of the cerebrum) and, at the same time, dilation of both basal brain and scalp vessels; but the connection of this change in caliber to pain, the traditional explanation for headache, is not certain. Perhaps emotion, fatigue, fasting, mild head injury, and so forth serve, in vulnerable individuals, to activate the neural mechanisms.

Diagnosis Neurologic migraine should occasion no difficulty in diagnosis if a good history is obtained. The difficulties come from a lack of awareness that (1) a progressively unfolding neurologic syndrome may be migrainous in origin, (2) the neurologic disorder may occur without headache, and (3) recurrent migraine headaches take many forms, some of which may prove difficult to distinguish from the other common types of headache. Some of these problems merit elaboration because of their practical importance.

The neurologic part of the migraine syndrome may resemble a transient ischemic attack, focal epilepsy, the clinical effects of a slowly evolving hemorrhage from an arteriovenous malformation

or aneurysm, or a thrombotic or embolic stroke. It is the pace of the neurologic symptoms of migraine, more than their character, that reliably distinguishes the condition from epilepsy.

Ophthalmoplegic migraine will suggest a carotid aneurysm, but in normotensive younger individuals, saccular aneurysm is a great rarity; in very few cases has carotid arteriography revealed such an abnormality. Transient monocular blindness from carotid stenosis is likewise a rarity in the age group affected most by migraine, but the antiphospholipid syndrome (page 735), which has some ill-defined relationship to migraine, does cause episodic unilateral visual loss in this group and should be sought as a unifying diagnosis. There have been many claims that the invariant occurrence of migraine on the same side of the head increases the likelihood of an underlying arteriovenous malformation (AVM). R. D. Adams, who studied more than 1200 patients with AVM, found that the headaches, which occurred in over 30 percent of these individuals, usually did not include the other features of either migraine or cluster headache. However, in about 5 percent of these patients, the headaches were indeed associated with visual aura, making them indistinguishable from neurologic migraine. In most, the AVM was in the occipital region, on the side of the headache; usually, there was an initial visual aura. Approximately half of the patients with AVM and migraine had a family history of migraine. Thus, AVM must be regarded as an acknowledged cause of recurrent headache, and the latter may be frequent and troublesome for years before the malformation is revealed by a hemorrhage or discovered by other manifestations.

A special but quite common problem relates to paroxysms of throbbing headache that are not hemicranial in distribution, not preceded by a neurologic aura, and not accounted for by other known causes. It is difficult to be certain whether these are examples of common (nonneurologic) migraine or of some other type of cephalgia. Unfortunately, since diagnosis depends on the interpretation of the patient's symptoms and since there is as yet no valid confirmatory laboratory test, the controversy as to where migraine begins and ends tends to become polemical. Favoring the diagnosis of migraine are onset in childhood or adolescence, lifelong history, positive family history, previous attacks or more typical hemicranial migraine, and response of the headache to ergotamine or triptan medication. The observation that pattern and flash visual stimulation induces fast waves of high amplitude in children with migraine may, if corroborated, prove to be helpful (Mortimer et al.).

Treatment of Migraine This topic may logically be subdivided into two parts—control of the individual acute attack and prevention. The time to initiate treatment of an attack is during the neurologic (visual) prodrome at the very onset of the headache (see below). If the headaches are mild, the patient may already have learned that acetalsalicylic acid, acetaminophen, or another nonsteroidal anti-inflammatory drug (NSAID—the most effective type of drug for mild and moderate cases in our experience) will suffice to control the pain. Insofar as a good response may be obtained from one type of NSAID and not another, it is advisable to try two or three preparations in several successive attacks of headache and to use moderately high doses if necessary. Some of our colleagues state that reliable patients can be given small amounts of codeine or oxycodone, usually combined with aspirin or acetaminophen, for limited periods. The combination of aspirin or acetaminophen, caffeine, and butalbital, though popular with some patients, is usually incompletely effective if the headache is severe and is also

capable of causing drug dependence; therefore we have prescribed it sparingly. Numerous other agents have proved to be effective and each has had a period of popularity among neurologists (the review by Schulman and Silberstein is recommended).

Overall, for severe attacks, sumatriptan or one of the newer “triptans” (e.g., zolmitriptan, rizatriptan, etc.) and the ergot alkaloids, ergotamine tartrate, and particularly dihydroergotamine (DHE), are probably the most effective forms of treatment and are best administered early in the attack.

A single 6-mg dose of sumatriptan or its equivalent [selective agonists of serotonin (5HT) receptors], given subcutaneously, is an effective and well-tolerated treatment for migraine attacks. An advantage of sumatriptan, and now of some others in this class, is the ease of self-administration using prepackaged injection kits, thus avoiding frequent and inconvenient visits to the emergency department. Sumatriptan can also be given orally in a 50- or 100-mg tablet, zolmitriptan in a 2.5- or 5-mg tablet, and rizatriptan in a 10-mg dose repeated, if needed, in 2 h (and other similar drugs in this class), but their latencies for headache relief are longer than that of the subcutaneous injection. A tabulated comparison of the triptan drugs is given in the review by Goadsby and colleagues; others in this class are sure to be developed and subtle differences between them undoubtedly will be touted, but these are usually negligible in practical terms. Sumatriptan is available as a nasal spray, which is particularly useful in patients with nausea and vomiting. The response rate after 2 h is similar to that of the orally administered drug, and the nasal spray acts more rapidly.

Ergotamine is an equally effective agent, but some safety issues and aggressive marketing of the triptans have reduced its use. This is an alpha-adrenergic agonist with strong 5HT receptor affinity and vasoconstrictive action. The drug is taken as an uncoated 1- to 2-mg tablet of ergotamine tartrate, held under the tongue until dissolved (or swallowed), and repeated every half hour until the headache is relieved or until a total of 8 mg is taken. A single oral dose of promethazine (Phenergan) 50 mg, or of metoclopramide (Reglan) 20 mg, given with the ergotamine, relaxes the patient and allays nausea and vomiting. Patients in whom vomiting prevents oral administration may be given ergotamine by rectal suppository or DHE by nasal spray or inhaler (one puff at onset and another at 30 min) or can learn to give themselves a subcutaneous injection of DHE (usual dosage, 1 mg). Caffeine, 100 mg, is thought, on slim evidence, to potentiate the effects of ergotamine and other medications for migraine. When ergotamine is administered early in the attack, the headache will be abolished or reduced in severity and duration in some 70 to 75 percent of patients.

For severely ill patients who arrive in the emergency department or physician's office, having failed to obtain relief with the usual medications, Raskin has found metoclopramide 10 mg IV, followed by DHE 0.5 to 1 mg IV every 8 h for 2 days, to be effective. We also use this approach in cases of status migrainosus. Intravenous and oral corticosteroids have also been useful in some refractory cases and as a means of terminating migraine status, but they should not be given continuously. The potential success of metoclopramide should not be dismissed, as we and others have occasionally found that the headache abates after this initial injection. The sympathomimetic drug isometheptene combined with a sedative and acetaminophen (Midrin) has been useful for some patients and probably acts in a similar way to ergotamine and sumatriptan. A wide array of other drugs has been recommended as adjunctive therapy, e.g., metoclopramide, prochlorperazine, chlorpromazine, ketorolac, and intranasal lidocaine. Even anticonvul-

sants may have a role if the headache persists for days. Each of these drugs, given alone, is effective in alleviating the headache in about half of these patients. This fact emphasizes the need for blinded placebo trials for any new drug that is introduced for the treatment of headache.

Because of the danger of prolonged arterial spasm in patients who have vascular (particularly coronary) disease or are pregnant, the use of ergotamine is not advised. Similarly, triptan medications should not be given to patients with uncontrolled hypertension or to those taking serotonergic and tricyclic antidepressants. Elderly patients should have electrocardiographic and blood pressure monitoring during and after administration of the drugs. Even in healthy individuals, more than 10 to 15 mg of ergotamine or 6 mg of DHE per week is not advised. Both worsening of angina and transmyocardial infarction have occurred. From time to time, cases of severe but reversible cerebral vasospasm are reported after the use of ergotamine (as they are occasionally after use of the triptan drugs). Sudden worsening of the headache and fluctuating signs of focal cerebral ischemia have occurred in the cases with which we are familiar. Diffuse cerebral vasoconstriction underlies many of these cases. Of particular danger is the often unnoticed, concurrent use of other sympathomimetic drugs such as phenylpropanolamine as in one of the cases described by Singhal and colleagues and by Meschia et al (see discussion of Call-Fleming syndrome, "Diffuse Vasoconstriction," page 730). Cerebral hemorrhage is another rare complication that relates possibly to hypertension induced by ergots or triptans.

If, in an individual attack, all of the foregoing measures fail, it is probably best to resort briefly to narcotics, which usually give the patient a restful, pain-free sleep. Halfway measures at this point are usually futile. However, the use of narcotics as the mainstay of acute or prophylactic therapy is to be avoided.

Most recently, based on the action of certain peptides in the trigeminovascular complex, novel antagonists of calcitonin gene-related peptide (CGRP) have been used with therapeutic success (Olesen et al). Drugs of this type work by a different mechanism than do the triptans and may be alternatives in the future.

Prophylactic Treatment In individuals with frequent migrainous attacks, efforts at prevention are worthwhile. The most effective agents have been beta blockers, certain anticonvulsants, and antidepressants. Considerable success has been obtained with propranolol (Inderal), beginning with 20 mg three times daily and increasing the dosage gradually to as much as 240 mg daily, probably best given as a long-acting preparation in the higher dosage ranges. Underdosing is a major reason for ineffectiveness. If propranolol is unsuccessful, one of the other beta blockers, specifically one that does not have agonist properties—atenolol (40 to 160 mg/day), timolol (20 to 40 mg/day), or metoprolol (100 to 200 mg/day)—may prove to be effective. In patients who do not respond to these drugs over a period of 4 to 6 weeks, valproic acid 250 mg taken three to four times daily or one of the tricyclic antidepressants (e.g., amitriptyline, 75 to 125 mg nightly) may be tried; it is not clear if the newer antidepressants are as effective. Calcium channel blockers (e.g., verapamil, 320 to 480 mg/day; nifedipine, 90 to 360 mg/day) are also reportedly effective in decreasing the frequency and severity of migraine attacks in some patients, but there is typically a lag of several weeks before benefit is attained and our success with them has been limited. Methysergide (Sansert), an ergot-like preparation that was more widely used in the past, in doses of 2 to 6 mg daily for several weeks or months is effective in the prevention of migraine. Retroperitoneal and pulmonary fibrosis are rare

but serious complications that can be avoided by discontinuing the medication for 3 to 4 weeks after every 5-month course of treatment. Clonidine, 0.05 mg three times daily; isometheptane (Midrin) as already mentioned; indomethacin, 150 to 200 mg/day; and cyproheptadine (Periactin), 4 to 16 mg/day are found to be helpful in some patients and may be particularly useful in preventing predictable attacks of perimenstrual migraine. A typical experience is for one of these medications to reduce the number and severity of headaches for several months and then to become less effective, whereupon an increase in the dosage, if tolerated, may help; or one of the many alternatives can be tried. The newest putative treatment for headaches, both migraine and tension, is the injection of botulinum toxin (Botox) into sensitive temporalis and other cranial muscles. Elimination of headaches for 2 to 4 months has been reported—a claim that justifies further study. Whether these injections are of value during an acute attack is uncertain.

A group of relatively uncommon migraine-type headaches respond very well to indomethacin, so much so that some authors have defined a category of *indomethacin-responsive headaches*. These include orgasmic migraine, chronic paroxysmal hemicrania (see further on), hemicrania continua, exertional headache, and some instances of premenstrual migraine.

Some patients allege that certain items of food induce attacks (chocolate, hot dogs, smoked meats, oranges, and red wine are the ones most commonly mentioned), and it is obvious enough that they should avoid these foods if possible. Limiting caffeinated beverages may be helpful. In certain cases the correction of a refractive error, an elimination diet, or behavioral modification is said to have reduced the frequency and severity of migraine and of tension headaches. However, the methods of study and the results have been so poorly controlled that it is difficult to evaluate them. All experienced physicians appreciate the importance of helping patients rearrange their schedules with a view to controlling tensions and hard-driving ways of living. There is no one way of accomplishing this. Psychotherapy has not been helpful, or at least one can say that there is no critical evidence of its value. The claims for sustained improvement of migraine with chiropractic manipulation are similarly unsubstantiated and do not accord with our experience. Meditation, acupuncture, and biofeedback techniques all have their advocates, but again the results, while not to be entirely discounted, are uninterpretable.

Cluster Headache

This type of headache has been described under a variety of names, including *paroxysmal nocturnal cephalgia* (Adams), *migrainous neuralgia* (Harris), *histamine cephalgia* (Horton), *red migraine*, *erythromelalgia of the head*, and others. Kunkle and colleagues, who were impressed with the characteristic "cluster pattern" of the attacks, later coined the term in current use—"cluster headache." This headache pattern occurs predominantly in young adult men (range 20 to 50 years; male-to-female ratio about 5:1) and is characterized by a consistent unilateral orbital localization. The pain is felt deep in and around the eye, is very intense and nonthrobbing as a rule, and often radiates into the forehead, temple, and cheek—less often to the ear, occiput, and neck. Its other characteristic feature is a nightly recurrence, between 1 and 2 h after the onset of sleep, or several times during the night; less often, it occurs during the day, unattended by aura or vomiting. The headache recurs with remarkable regularity each day for periods extending over 6 to 12 weeks, followed then by complete freedom for many months or

even years (hence the term *cluster*). However, in approximately 10 percent of patients, the headache has become chronic, persisting over years. There are several associated vasomotor phenomena by which cluster headache can be identified: a blocked nostril, rhinorrhea, injected conjunctivum, lacrimation, miosis, and a flush and edema of the cheek, all lasting on average for 45 min (range 15 to 180 min). Some of our patients, when alerted to the sign, also report a slight ptosis on the side of the orbital pain; in a few, the ptosis has become permanent after repeated attacks. The homolateral temporal artery may become prominent and tender during an attack, and the skin over the scalp and face may be hyperalgesic.

Most patients arise from bed during an attack and sit in a chair and rock or pace the floor, holding a hand to the side of the head. The pain of a given attack may leave as rapidly as it began or may fade away gradually. Almost always the same orbit is involved during a cluster of headaches as well as in recurring bouts. During the period of freedom from pain, alcohol, which commonly precipitates headaches during a cluster, no longer has the capacity to do so.

The picture of cluster headache is usually so characteristic that it cannot be confused with any other disease, though those unfamiliar with it may entertain a diagnosis of migraine, trigeminal neuralgia, carotid aneurysm, temporal arteritis, or pheochromocytoma. To be distinguished also are the *Tolosa-Hunt syndrome* of ocular pain and ocular motor paralysis (see further on) and the *paratrigeminal syndrome of Raeder*, which consists of paroxysms of pain somewhat like that of tic douloureux in the distribution of the ophthalmic and maxillary divisions of the fifth nerve, in association with ocular sympathetic paralysis (ptosis and miosis but with preservation of facial sweating). Loss of sensation in a trigeminal nerve distribution and weakness of muscles innervated by the fifth nerve are often added. We have seen instances of head pain, particularly in women, in which the features of both cluster headache and Raeder syndrome could be recognized; no lesion in or near the trigeminal ganglion was found.

Variants of Cluster Headache Cases of paroxysmal pain behind the eye or nose or in the upper jaw or temple—associated with blocking of the nostril or lacrimation and described under the titles of *sphenopalatine* (Sluder), *petrosal*, *vidian*, and *ciliary neuralgia* (Charlin or Harris, “lower half” headache)—probably represent variants of cluster headache. A similar head pain may occasionally be confined to the lower facial, postauricular, or occipital areas. Ekbom distinguished yet another “lower cluster headache” syndrome with infraorbital radiation of the pain, an ipsilateral partial Horner syndrome, and ipsilateral hyperhydrosis. There is no evidence to support the separation of these neuralgias as distinct entities.

Chronic paroxysmal hemicrania is the name given by Sjaastad and Dale to a unilateral form of headache that resembles cluster headache in some respects but has several distinctive features. Like cluster headaches, these are of short duration (2 to 45 min) and usually affect the temporo-orbital region of one side, accompanied by conjunctival hyperemia, rhinorrhea, and in some cases a partial Horner syndrome. The acronym SUNCT has been applied to the condition (short-lasting unilateral neuralgiform attacks with conjunctival injection and tearing). Unlike cluster headache, however, the paroxysms occur many times each day, recur daily for long periods (the patient of Price and Posner had an average of 16 attacks daily for more than 40 years), and, most importantly, respond dra-

matically to the administration of indomethacin, 25 to 50 mg tid. Unlike the usual form of cluster headache, chronic paroxysmal hemicrania is more common in women than in men, in a ratio of 3:1. Of note, this variant may be symptomatic of lesions near the cavernous sinus (mainly pituitary adenoma) or in the posterior fossa; most cases are idiopathic.

Also known is a recurrent nocturnal headache in elderly individuals (“hypnic headache”), as described further on.

The relationship of the cluster headache to migraine remains conjectural. No doubt the headaches in some persons have some of the characteristics of both, hence the terms *migrainous neuralgia* and *cluster migraine* (Kudrow). Lance and others, however, have pointed out differences that seem important to the present authors: flushing of the face on the side of a cluster headache and pallor in migraine; increased intraocular pressure in cluster headache, normal pressure in migraine; increased skin temperature over the forehead, temple, and cheek in cluster headache, decreased temperature in migraine; and notable distinctions in sex distribution, age of onset, rhythmicity, and other clinical features, as described above. Cluster may be triggered in sensitive patients by the use of nitroglycerin and, as mentioned, by alcohol; the same occurs rarely in migraine.

The cause and mechanism of the cluster headache syndrome are unknown. Gardner and coworkers originally postulated a paroxysmal parasympathetic discharge mediated through the greater superficial petrosal nerve and sphenopalatine ganglion. These authors obtained inconsistent results by cutting the nerve, but others (Kittrelle et al) have reported that application of cocaine or lidocaine to the region of the sphenopalatine fossa (via the nostril) consistently aborts attacks of cluster headache. Capsaicin, applied over the affected region of the forehead and scalp, may have the same effect. Stimulation of the ganglion is said to reproduce the syndrome. Kunkle, on the basis of a large personal experience, concluded that the pain arises from the internal carotid artery, in the canal through which it ascends in the petrous portion of the temporal bone. In the course of an arteriogram, during which a patient with cluster headaches fortuitously developed an attack, Ekbom and Greitz noted a narrowing of the ipsilateral internal carotid artery. This was interpreted as being due to swelling of the arterial wall, which in turn compromised the pericarotid sympathetic plexus and caused the Horner syndrome. On somewhat speculative grounds, the cyclic nature of the attacks has been linked to the hypothalamic mechanism that governs the circadian rhythm. At the onset of the headache, the region of the suprachiasmatic nucleus appears to be active on PET scanning (May et al).

The fact that cluster headaches could be reproduced by the intravenous injection of 0.1 mg histamine (an early experimental technique for studying the mechanism of headache) led to the notion, popular for many years, that this form of headache was caused by the spontaneous release of histamine and gave rise to a form of treatment that consisted of “desensitizing” the patient by slow intravenous injections of this drug given daily for several weeks. Experience has shown that this form of treatment accomplishes little. It should be pointed out that the intravenous injection of histamine induces or worsens many forms of focal or generalized headache (due to fever, trauma, brain tumor) that are dependent on activation of pain-sensitive tissue around the vessels derived from the internal carotid artery.

Treatment The usual nocturnal attacks of cluster headache can be treated with a single anticipatory dose of ergotamine at bedtime

(2 mg orally). Inhalation of 100% oxygen for 10 to 15 min at the onset of headache may also abort the attack, but this is not always practical. Intranasal lidocaine, or sumatriptan (or zolmitriptan as for migraine, see above) can also be used to abort an acute attack. In other patients, ergotamine given once or twice during the day, at times when an attack of pain is expected, has been helpful.

With regard to prevention during a cluster, if ergotamine and sumatriptan are not effective or become ineffective in subsequent bouts, most headache experts prefer to use verapamil, up to 480 mg per day. Ekbom introduced lithium therapy for cluster headache (600 mg, up to 900 mg daily) and Kudrow has confirmed its efficacy in chronic cases. Lithium and verapamil may be given together, but lithium toxicity is a frequent problem. Methysergide (2 to 8 mg daily) has also been successful as a prophylactic measure but has potential secondary effects that make it less appealing than the alternatives. A course of prednisone, beginning with 75 mg daily for 3 days and then reducing the dose at 3-day intervals, has been beneficial in many patients. Usually it can be decided within a week if any of these medications is effective. Indomethacin (Indocin, 75 to 200 mg/day) has reportedly been efficacious in the chronic form of cluster headache but was ineffective in several of our patients. Propranolol has been suggested as prophylaxis by some headache experts. In brief, no method is effective in all cases, but the best initial approach probably involves the use of one of the sumatriptan compounds. Rare cases of intractable cluster headache, in which the syndrome persists for weeks or longer without remission, have been treated by partial section of the trigeminal nerve, as described by Jarrar and colleagues.

Tension Headache

This, the most common variety of headache, is usually bilateral, with occipitonal, temporal, or frontal predominance or diffuse extension over the top of the cranium. The pain is usually described as dull and aching, but questioning often uncovers other sensations, such as fullness, tightness, or pressure (as though the head were surrounded by a band or clamped in a vise) or a feeling that the head is swollen and may burst. On these sensations, waves of aching pain are superimposed. These may be interpreted as paroxysmal or throbbing and, if the pain is more on one side, the headache may suggest a migraine without aura. However, absent in tension headache are the persistent throbbing quality, nausea, photophobia, and phonophobia of migraine. Nor do most tension headaches seriously interfere with daily activities, as migraine does. The onset is more gradual than that of migraine, and the headache, once established, may persist with only mild fluctuations for days, weeks, months, or even years. In fact, this is the only type of headache that exhibits the peculiarity of being present throughout the day, day after day, for long periods of time. The term *chronic tension-type headache* is used to signify this type of chronic daily headache, which is often associated with anxiety and depression, as noted below. Although sleep is usually undisturbed, the headache is present when the patient awakens, or it develops soon afterward, and the common analgesic remedies have little or no beneficial effect if the pain is of more than mild to moderate severity.

The incidence of tension headache is certainly greater than that of migraine. However, most patients treat tension headaches themselves and do not seek medical advice. Like migraine, tension headaches are more common in women than in men. Unlike migraine, they infrequently begin in childhood or adolescence but are more likely to occur in middle age and to coincide with anxiety,

fatigue, and depression in the trying times of life. In the large series of Lance and Curran, about one-third of patients with persistent tension headaches had readily recognized symptoms of depression. In our experience, chronic anxiety or depression of varying degrees of severity is present in the majority of patients with protracted headaches. Migraine and traumatic headaches may be complicated by tension headache, which, because of its persistence, often arouses fears of a brain tumor or other intracranial disease. However, as Patten points out, not more than one or two patients out of every thousand with tension headaches will be found to harbor an intracranial tumor, and in our experience, the discovery of a tumor has been most often accidental (see further on).

In a substantial group of patients, the headache, when severe, develops a pulsating quality, to which the term *tension-migraine* or *tension-vascular* headache has been applied (Lance and Curran). This is particularly the case in patients with protracted and chronic daily headaches. Observations such as these have tended to blur the sharp distinctions between migrainous and tension headaches in some cases.

For many years it was taught that tension headaches were due to excessive contraction of craniocervical muscles and an associated constriction of the scalp arteries. However, it is not clear that either of these mechanisms contributes to the genesis of tension headache, at least in its chronic form. Until recently it has been felt that in most patients with tension headache, the craniocervical muscles are quite relaxed (by palpation) and show no evidence of persistent contraction when measured by surface electromyographic (EMG) recordings. Anderson and Frank found no difference in the degree of muscle contraction between migraine and tension headache. However, using an ingenious laser device, Sakai et al have reported that the pericranial and trapezius muscles are hardened in patients with tension headaches. Recently, nitric oxide has been implicated in the genesis of tension-type headaches, specifically by creating a central sensitization to sensory stimulation from cranial structures. The strongest support for this concept comes from several reports that an inhibitor of nitric oxide reduces muscle hardness and pain in patients with chronic tension headache (Ashina et al). At present, these are interesting but speculative ideas.

Treatment of Tension Headache Simple analgesics, such as aspirin or acetaminophen or other NSAIDs, may be helpful, but only for brief periods. Tension headaches respond best to the cautious use of one of several drugs that relieve anxiety or depression, especially when these symptoms are present. Stronger analgesic medication should be avoided. Raskin reports success with calcium channel blockers, phenelzine, or cyproheptadine. Ergotamine and propranolol are not effective unless there are symptoms of both migraine and tension headache. Some patients respond to ancillary measures such as massage, meditation, and biofeedback techniques. Relaxation techniques may be helpful in teaching patients how to deal with underlying anxiety and stress (Lance).

Headaches in the Elderly

In several surveys of an elderly population, headache with onset in this age period was found to be a prominent symptom in as many as one of six persons and more often to have serious import than headache in a younger population. In one series of such patients reported by Pascual and Berciano, more than 40 percent were classified as having tension headaches (women more than men), and there was a wide variety of diseases in the others (posttraumatic

headaches, cerebrovascular disease, intracranial tumors, cranial arteritis, severe hypertension). Cough-induced headaches and cluster headaches were present in some of the men. New-onset migraine in this age group is a rarity.

Raskin has described a headache syndrome in older patients that shares with cluster headache a nocturnal occurrence (*hypnic headache*). It may occur with daytime naps as well. However, it differs in being bilateral and unaccompanied by lacrimation and rhinorrhea. Also, it differs from migraine. Raskin has successfully treated a number of his patients with 300 mg of lithium carbonate at bedtime. The nosologic position of this hypnic headache syndrome is undetermined.

Despite these considerations, the most treacherous and neglected cause of headache in the elderly is temporal (cranial) arteritis with or without polymyalgia rheumatica, as discussed further on.

Headache and Other Craniofacial Pain with Psychiatric Disease

As mentioned several times in the above discussions, in our clinics the most common cause of generalized persistent headache, both in adolescents and adults, is depression or anxiety in one of its several forms. The authors have also noted that many seriously ill psychiatric patients complain of frequent headaches that are not typically of the tension type. These patients report unilateral or generalized throbbing cephalic pain lasting for hours every day or two. The nature of these headaches, which in some instances resemble common migraine, is unsettled. Others have delusional symptoms involving physical distortion of cranial structures. As the psychiatric symptoms subside, the headaches usually disappear.

Odd cephalic pains, e.g., a sensation of having a nail driven into the head (*clavus hystericus*), may occur in hysteria and raise perplexing problems in diagnosis. The bizarre character of these pains, their persistence in the face of every known therapy, the absence of other signs of disease, and the presence of other manifestations of hysteria provide the basis for correct diagnosis. Older children and adolescents sometimes have peculiar behavioral reactions to headache: screaming, looking dazed, clutching the head with an agonized look. Usually, migraine is the underlying disorder, the additional manifestations responding to therapeutic support and suggestion.

Posttraumatic Headache

Severe, chronic, continuous, or intermittent headaches lasting several days or weeks appear as the cardinal symptom of several post-traumatic syndromes, separable in each instance from the headache that immediately follows head injury (i.e., scalp laceration and cerebral contusion with blood in the CSF and increased intracranial pressure).

The *headache of chronic subdural hematoma* is deep-seated, dull, steady, mainly unilateral, and may be accompanied or followed by drowsiness, confusion, and fluctuating hemiparesis. In more *acute hematomas*, we have been impressed with the positional worsening in some patients after lying down or leaning the head to one side. Tentorial hematomas produce the additional feature of pain in the eye. The head injury that gives rise to a subdural hematoma may have been minor, as described in Chap. 35, and forgotten by the patient and family. Typically the headache and other symptoms increase in frequency and severity over several weeks

or months. Patients who have received anticoagulation are particularly at risk. Diagnosis is established by CT and MRI.

Headache is a prominent feature of a complex syndrome comprising giddiness, fatigability, insomnia, nervousness, trembling, irritability, inability to concentrate, and tearfulness—a syndrome that we have called *posttraumatic nervous instability*. This type of headache and associated symptoms, which resemble the tension headache syndrome, are described fully in Chap. 35, “Craniocerebral Trauma.” The patient with posttraumatic nervous instability requires supportive therapy in the form of repeated reassurance and explanations of the benign nature of the symptoms, a program of increasing physical activity, and the use of drugs that allay anxiety and depression. The early settlement of litigation, which is often an issue, works to the patient’s advantage.

Tenderness and aching pain sharply localized to the scar of a scalp laceration represent in all probability a different problem and raise the question of a traumatic neuralgia. Tender scars from scalp lacerations may be treated by repeated subcutaneous injections of local anesthetics, such as 5 mL of 1% procaine, which also acts as a diagnostic test.

With *whiplash injuries* of the neck, there may be unilateral or bilateral retroauricular or occipital pain, probably due to stretching or tearing of ligaments and muscles at the occipitotonuchal junction or to a worsening of a pre-existent cervical arthropathy. Much less frequently, cervical intervertebral discs and nerve roots are involved.

Under the heading of *posttraumatic dysautonomic cephalgia*, Vijayan and Dreyfus have described a syndrome comprising severe, episodic, throbbing unilateral headaches sometimes accompanied by ipsilateral mydriasis and excessive sweating of the face, thus simulating migraine or cluster headache. Between bouts of headache, a few of the patients showed partial ptosis and miosis as well as pharmacologic evidence of partial sympathetic denervation. The condition followed injury to the soft tissues of the neck in the region of the carotid artery sheath. The headaches did not respond to treatment with ergotamine, but prompt relief was obtained in each case with the beta-adrenergic blocking agent, propranolol.

Headaches of Brain Tumor

Headache is said to be a significant symptom in about two-thirds of all patients with brain tumor, but it is infrequent in our experience, particularly as the heralding symptom of a tumor in an adult. The pain has no specific features; it tends to be deep-seated, usually nonthrobbing (occasionally throbbing), and is described as aching or bursting. Attacks of pain last a few minutes to an hour or more and occur once or many times during the day. Physical activity and changes in position of the head may provoke pain, whereas rest diminishes its frequency (see Rooke for a discussion of exertional headache). Nocturnal awakening because of pain occurs in only a small proportion of patients and is by no means diagnostic. Unexpected forceful (projectile) vomiting may punctuate the illness in its later stages. If unilateral, the headache is nearly always on the same side as the tumor. Pain from supratentorial tumors is felt anterior to the interauricular circumference of the skull; from posterior fossa tumors, it is felt behind this line. Bifrontal and bioccipital headaches coming on after unilateral headaches probably signify the development of increased intracranial pressure.

Having stated that headache is not to be equated with brain tumor, one cannot help but be impressed with its frequency as a manifestation of colloid cysts, and we have several times stumbled

on the correct diagnosis when an odd, unexplained headache led to brain imaging. The mechanism of headache in cases of colloid cyst is not simply one of blocking the flow of CSF at the foramina of Monro, since it is not predicated on the development of hydrocephalus. Additionally, Harris described headaches of paroxysmal type with intra- and periventricular brain tumors, and many others have commented on the same type of headache with parenchymal tumors. These are severe headaches that reach their peak intensity in a few seconds, last for several minutes or as long as an hour, and then subside quickly. When they are associated with vomiting, transient blindness, leg weakness with "drop attacks," and loss of consciousness, there is a high likelihood of brain tumor. With respect to its onset, this headache resembles that of subarachnoid hemorrhage, but the latter is far longer-lasting. In its entirety, this paroxysmal headache is most typical of the aforementioned colloid cyst of the third ventricle, but it can occur with other tumors as well, including craniopharyngiomas, pinealomas, and cerebellar masses.

Headaches of Temporal Arteritis (Giant-Cell Arteritis, Cranial Arteritis)

(See also Chap. 34)

This particular type of inflammatory disease of cranial arteries is an important cause of headache in elderly persons. All of our patients have been more than 55 years of age, most of them above age 65. From a state of normal health, the patient develops an increasingly intense throbbing or nonthrobbing headache, often with superimposed sharp, stabbing pains. In a few patients the headache has had an almost explosive onset. The pain is usually unilateral, sometimes bilateral, and often localized to the site of the affected arteries in the scalp. The pain persists to some degree throughout the day and is particularly severe at night. It lasts for many months if untreated (average duration, 1 year). The superficial temporal and other scalp arteries are frequently thickened and tender and without pulsation. Jaw claudication and ischemic nodules on the scalp, with ulceration of the overlying skin, have been described in severe cases.

Many of the patients feel generally unwell and have lost weight; some have a low-grade fever and anemia. Usually the sedimentation rate is greatly elevated (>50 mm/h and usually over 75 mm/h), and a few patients have a neutrophilic leukocytosis. As many as 50 percent of patients have generalized aching of proximal limb muscles, reflecting the presence of polymyalgia rheumatica (see page 189).

The importance of early diagnosis relates to the threat of blindness from thrombosis of the ophthalmic or posterior ciliary arteries. This may be preceded by several episodes of amaurosis fugax (transient monocular blindness, page 692). Ophthalmoplegia may also occur but is less frequent, and its cause, whether neural or muscular, is not settled. The large intracranial vessels are occasionally affected. Once vision is lost, it is seldom recoverable. For this reason the earliest suspicion of cranial arteritis should lead to biopsy of the appropriate scalp artery and the immediate administration of corticosteroids. Microscopic examination discloses an intense granulomatous or "giant-cell" arteritis. If biopsy on one side fails to clarify the situation and there are sound clinical reasons for suspecting the diagnosis, the other side should be sampled. Arteriography of the external carotid artery branches is probably the most sensitive test but is seldom used; ultrasound examination has recently been introduced to display a dark halo and irregularly thick-

ened vessel wall of the temporal arteries. This technique has not yet been incorporated into the routine evaluation because its sensitivity has not been established; our own experience suggests that it may miss a proportion of cases. It may find use in choosing the site for biopsy of the temporal artery.

Treatment The administration of prednisone, 45 to 60 mg/day in single or divided doses over a period of several weeks, is indicated in all cases, with gradual reduction to 10 to 20 mg/day and maintenance at this dosage for several months or years, if necessary, to prevent relapse. The headache can be expected to improve within a day or two of beginning treatment; failure to do so brings the diagnosis into question. When the sedimentation rate or C-reactive protein are elevated, their return to normal is a reliable index of therapeutic response.

Headaches of Pseudotumor Cerebri (Benign, or Idiopathic Intracranial Hypertension)

The headache of pseudotumor cerebri assumes a variety of forms. Typical is a feeling of occipital pressure that is greatly worsened by lying down, but many patients have—in addition or only—headaches of migraine or tension type. Indeed, some of them respond to medications such as propranolol or ergot compounds. None of the proposed mechanisms for pain in pseudotumor cerebri seems to be adequate as an explanation, particularly the idea that cerebral vessels are displaced or compressed, since neither has been demonstrated. It is worth noting that facial pain may also be a feature of the illness, albeit rare. A more complete description of the clinical features, pathophysiology, and treatment can be found in Chap. 30.

SPECIAL VARIETIES OF HEADACHE

Low-Pressure and Spinal Puncture Headache These are commonly known to neurologists, as noted earlier in this chapter, and the latter type is an unavoidable part of lumbar punctures in about 5 percent of the cases. The headache is associated with the greatly reduced pressure of the CSF compartment and probably caused by traction or cranial blood vessels. Assuming the supine position almost immediately relieves the cranial pain and eliminates vomiting, but a blood-patch procedure may be required in persistent cases. In a limited number of cases, success has been obtained by the use of intravenous caffeine injections. The condition and its treatment are discussed on pages 541 and 542.

Menstrual Migraine, Migraine of Pregnancy, and Other Headaches Linked to the Hormonal Cycle The relation of headache to a drop in estradiol levels during the late luteal phase has been mentioned on page 150. There it was also indicated that the mechanism is probably more complex than can be explained simply by a drop in hormone levels. In practice, factors such as sleep deprivation are at least as important in triggering perimenstrual headaches. Premenstrual headache, taking the form of migraine or a combined tension-migraine headache, usually responds to the administration of an NSAID begun 3 days before the anticipated onset of the menstrual period; oral sumatriptan (25 to 50 mg qid) and zolmitriptan (2.5 to 5 mg bid) are equally effective. Manipulation of the hormonal cycle with danazol (a testosterone derivative) or estradiol has also been effective but is rarely necessary.

The management of migraine during pregnancy poses special problems because one wants to restrict exposure of the fetus to medications. It can be stated that beta-adrenergic compounds and tricyclic antidepressants may be used safely in the small proportion of women whose headaches persist or intensify during pregnancy. From a limited registry of patients who were given sumatriptan during pregnancy and from several small trials summarized by Fox and colleagues, no teratogenic effects or adverse effects on pregnancy arose, but triptan drugs should perhaps be used advisedly until their safety is confirmed. For those women who use anticonvulsants as a means of headache prevention, it is recommended that the drugs be stopped prior to pregnancy or as soon as it is known that pregnancy has begun.

Cough and Exertional Headache A patient may complain of very severe, transient cranial pain on coughing, sneezing, laughing heartily, lifting heavy objects, stooping, and straining at stool. Pain is usually felt in the front of the head, sometimes occipitally, and may be unilateral or bilateral. As a rule, it follows the initiating action within a second or two and lasts a few seconds to a few minutes. The pain is often described as having a bursting quality and may be of such severity as to cause the patient to cradle his head in his hands, thereby simulating the headache of acute subarachnoid hemorrhage.

Most often this syndrome takes the form of a benign idiopathic state that recurs over a period of several months to a year or two and then disappears. In a report of 103 patients followed for 3 years or longer, Rooke found that additional symptoms of neurologic disease developed in only 10. Symonds emphasized the usual benignity of the condition. The cause and mechanism have not been determined. During the attack, the CSF pressure is normal. Bilateral jugular compression may induce an attack, possibly because of traction on the walls of large veins and dural sinuses. In a few instances, we have observed this type of headache after lumbar puncture or after a hemorrhage from an arteriovenous malformation.

Aside from a rare instance of subarachnoid hemorrhage, patients with cough or strain headache may occasionally be found to have serious intracranial disease; most often it has been traced to lesions of the posterior fossa and foramen magnum, arteriovenous malformation, Chiari malformation, platybasia, basilar impression, or tumor. It may be necessary, therefore, to supplement the neurologic examination by appropriate CT and MRI. Far more common, of course, are the temporal and maxillary pains that are due to dental or sinus disease, which may also be worsened by coughing.

A special variant of exertional headache is "weight-lifter's headache." It occurs either as a single event or repeatedly over a period of several months, but each episode of headache may last many hours or days, again raising the suspicion of subarachnoid hemorrhage. The pain begins immediately or within minutes of heavy lifting. If the pain resolves in an hour or less and there is no meningismus or sign of bleeding on the CT, we have foregone lumbar puncture and angiography but have suggested that weight lifting not be resumed for several weeks. Athletes and runners in general seem to suffer exertional headaches quite often in our experience, and the episodes usually have migrainous features.

Indomethacin may be quite effective in controlling exertional headaches; this has been confirmed in controlled trials. Useful alternatives are NSAIDs, ergot preparations, and phenelzine. In a few of our patients, lumbar puncture appeared to resolve the problem in some inexplicable way.

Headaches Related to Sexual Activity Lance has described 21 cases of this type of headache, 16 in males and 5 in females. The headache took one of two forms: one in which headache of the tension type developed as sexual excitement increased and another in which a severe, throbbing, "explosive" headache occurred at the time of orgasm and persisted for several minutes or hours. The latter headaches were of such abruptness and severity as to suggest a ruptured aneurysm, but the neurologic examination was negative in every instance, as was arteriography in 7 patients who were subjected to this procedure. In 18 patients who were followed for a period of 2 to 7 years, no other neurologic symptoms developed. Characteristically, the headache occurred on several consecutive occasions and then inexplicably disappeared. In cases of repeated coital headache, indomethacin has been effective. Of course, so-called orgasmic headache is not always benign; a hypertensive hemorrhage, rupture of an aneurysm or vascular malformation, or myocardial infarction may occur during the exertion of sexual intercourse.

Thunderclap Headache ("Crash Migraine") As has been stated several times, the headache of subarachnoid hemorrhage due to rupture of a berry aneurysm is among the most abrupt and dramatic of cranial pains (see Chap. 34). There are several reports regarding such pains as a "warning leak" of rupture and even reports suggesting that such headaches occur as a consequence of unruptured aneurysms (although subsequent studies suggest that this is highly unlikely); it was in relation to a case of this nature that the term "*thunderclap*" was introduced by Day and Raskin. Patients on our services have offered descriptions such as "being kicked in the back of the head."

A small number of such cases, as pointed out by Dodick, are due to pituitary apoplexy, cerebral venous thrombosis, cervical arterial dissection, hypertensive crisis, or intracranial hypotension. To this list we would add diffuse arterial spasm, which may be idiopathic (Call-Fleming syndrome; see page 730) or the result of the administration of sympathomimetic or serotonergic drugs, including cocaine and medications for the treatment of migraine. However, in a large proportion of patients with thunderclap headache, the pain is indistinguishable from that due to subarachnoid hemorrhage, even to the extent of being accompanied by vomiting and acute hypertension in a few cases. The diagnosis is clarified when, after lumbar puncture and various types of cerebral imaging to exclude bleeding and aneurysm, the pain resolves in hours or less and turns out to have no discernible cause.

That this is a benign condition has been confirmed by Wijdicks and colleagues, who followed 71 cases for over 3 years and found no serious cerebrovascular lesions. For this reason, these cases have been presumed to be a form of migraine ("crash migraine"), partly on the basis of preceding or subsequent headaches and migrainous episodes in affected individuals; in our experience, not all of such patients have had migraine in the past. Notable is a tendency for thunderclap headaches to recur.

Erythrocyanotic Headache On rare occasions, an intense, generalized, throbbing headache may occur in conjunction with flushing of the face and hands and numbness of the fingers (erythromelalgia). Episodes tend to be present on awakening from sound sleep. This condition has been reported in a number of unusual settings: (1) in mastocytosis (infiltration of tissues by mast cells, which elaborate histamine, heparin, and serotonin); (2) with carcinoid tumors; (3) with serotonin-secreting tumors; (4) with some tumors of the

pancreatic islets; and (5) with pheochromocytoma. Seventy-five percent of patients with pheochromocytoma reportedly have vascular-type headaches coincident with paroxysms of hypertension and release of catecholamines (Lance and Hinterberger).

Headache Related to Medical Diseases

Severe headache may occur with a number of infectious illnesses caused by banal viral upper respiratory infections, by organisms such as *Mycoplasma* or *Coxiella* (Q fever), and particularly by influenza. The suspicion of meningitis is raised, even subarachnoid hemorrhage, but almost invariably there is no reaction in the CSF.

About 50 percent of patients with hypertension complain of headache, but the relationship of one to the other is not clear. Minor elevations of blood pressure may be a result rather than the cause of tension headaches. Severe (malignant) hypertension, with diastolic pressures of more than 120 mmHg, is regularly associated with headache, and measures that reduce the blood pressure relieve it. Abrupt elevations of blood pressure, as occur in patients who take monoamine oxidase inhibitors and then ingest tyramine-containing food, can cause headaches that are abrupt and severe enough to simulate subarachnoid hemorrhage. However, it is the individual with moderately severe hypertension and frequent severe headaches who causes the most concern. In some of these patients the headaches are of the common migraineous or tension type, but in others they defy classification. According to Wolff, the mechanism of the hypertensive headache is similar to that of migraine, i.e., increased vascular pulsations. The headaches, however, bear no clear relation to modest peaks in blood pressure. Curiously, headaches that occur toward the end of renal dialysis or soon after its completion are associated with a fall in blood pressure (as well as a decrease in blood sodium levels and osmolality). The latter type of headache is bifrontal and throbbing and is sometimes accompanied by nausea and vomiting. The mechanism of occipital pain that may awaken the hypertensive patient and wear off during the day is not understood.

Headaches frequently follow a seizure, having been recorded in half of one large series of epileptic patients analyzed in a Great Britain study. In migraineurs, the postictal headache may reproduce a typical migraine attack. Rarely, in patients with a vascular malformation, a migraine-like attack precedes a seizure.

Experienced physicians are aware of many other conditions in which headache may be a dominant symptom. These include fevers of any cause, carbon monoxide exposure, chronic lung disease with hypercapnia (headaches often nocturnal), hypothyroidism, Cushing disease, withdrawal from corticosteroid medication, hypoglycemia, mountain sickness, chronic exposure to nitrates, occasionally adrenal insufficiency, aldosterone-producing adrenal tumors, use of "the pill," and development of acute anemia with hemoglobin below 10 g.

No attempt is made here to discuss the symptomatic treatment of headache that may accompany these many medical conditions. Obviously the guiding principle in management is to uncover and remove the underlying disease or functional disturbance.

Headache Related to Diseases of the Cervical Spine

Headaches that accompany diseases of the upper cervical spine are well recognized, but their mechanism is obscure. Recent writings have focused on a wide range of causative lesions, such as zygo-

apophysial arthropathy, C2 dorsal root entrapment, calcified ligamentum flavum, hypertrophied posterior longitudinal ligament, and rheumatoid arthritis of the atlantoaxial region. CT and MRI have divulged a number of these abnormalities. They are discussed below, under "Third Occipital Nerve Headache," and in Chap. 11.

OTHER CRANIOFACIAL PAINS

See Table 10-2 and Chap. 47.

Trigeminal Neuralgia (Tic Douloureux)

This is a common disorder of middle age and later life, consisting of paroxysms of intense, stabbing pain in the distribution of the mandibular and maxillary divisions (rarely the ophthalmic division) of the fifth cranial nerve. The pain seldom lasts more than a few seconds or a minute or two, but it may be so intense that the patient winces involuntarily; hence the term *tic*. It is uncertain whether the tic is reflexive or quasi-voluntary. The paroxysms recur frequently, both day and night, for several weeks at a time. Another characteristic feature is the initiation of a jab or a series of jabs of pain by stimulation of certain areas of the face, lips, or gums, as in shaving or brushing the teeth, or by movement of these parts in chewing, talking, or yawning, or even by a breeze—the so-called trigger zones. Sensory or motor loss in the distribution of the fifth nerve cannot be demonstrated, though there are minor exceptions to this rule. In addition to the paroxysmal pain, some patients complain of a more or less continuous discomfort, itching, or sensitivity of restricted areas of the face, features regarded as atypical even though not infrequent.

In studying the relationship between stimuli applied to the trigger zones and the paroxysms of pain, the latter are found to be induced by touch and possibly tickle rather than by a painful or thermal stimulus. Usually a spatial and temporal summation of impulses is necessary to trigger a paroxysm of pain, which is followed by a refractory period of up to 2 or 3 min. This suggests that the mechanism of the paroxysmal pain is in the nature of allodynia, a feature of other neuropathic pains.

The *diagnosis* of tic douloureux must rest on the strict clinical criteria enumerated above, and the condition must be distinguished from other forms of facial and cephalic neuralgia and pain arising from diseases of the jaw, teeth, or sinuses. Most cases of trigeminal neuralgia are without obvious assignable cause (idiopathic), in contrast to symptomatic trigeminal neuralgia, in which paroxysmal facial pain is due to involvement of the fifth nerve by some other disease: multiple sclerosis (may be bilateral), aneurysm of the basilar artery, or tumor (acoustic or trigeminal neuroma, meningioma, epidermoid) in the cerebellopontine angle. It has become apparent, however, that a proportion of ostensibly idiopathic cases are due to compression of the trigeminal roots by a tortuous blood vessel, as originally pointed out by Dandy. Jannetta has observed it in most of his patients and has relieved their pain by surgical decompression of the trigeminal root in the form of removing the offending small vessel from contact with the proximal portion of the nerve (see below). Others have declared a vascular compressive causation to be less frequent (Adams et al). Each of the forms of symptomatic trigeminal neuralgia may give rise only to pain in the distribution of the fifth nerve, or it may produce a loss of sensation as well. This and other disorders of the fifth nerve, some of which give rise to facial pain, are discussed in Chap. 47, "Diseases of the Cranial Nerves."

Table 10-2
Types of facial pain

TYPE	SITE	CLINICAL CHARACTERISTICS	AGGRAVATING/RELIEVING FACTORS	ASSOCIATED DISEASES	TREATMENT
Trigeminal neuralgia (tic douloureux)	Second and third divisions of trigeminal nerve, unilateral	Men/women = 1:3 Over 50 years Paroxysms (10–30 s) of stabbing, burning pain; persistent for weeks or longer Trigger points No sensory or motor paralysis	Touching trigger points, chewing, smiling, talking, blowing nose, yawning	Idiopathic If in young adults, multiple sclerosis Vascular anomaly Tumor of fifth cranial nerve	Carbamazepine, phenytoin, gabapentin, alcohol injection, coagulation, or surgical (vascular) decompression of root
Postzoster neuralgia	Unilateral Usually ophthalmic division of fifth nerve	History of zoster Aching, burning pain; jabs of pain Paresthesias, slight sensory loss Dermal scars	Contact, movement	Herpes zoster	Carbamazepine, antidepressants, and sedatives
Costen syndrome	Unilateral, behind or front of ear, temple, face	Severe aching pain, intensified by chewing Tenderness over temporo-mandibular joints Malocclusion, missing molars	Chewing, pressure over temporo-mandibular joints	Loss of teeth, rheumatoid arthritis	Correction of bite Surgery in some
Tolosa-Hunt syndrome	Unilateral, mainly retro-orbital	Intense sharp, aching pain, associated with ophthalmoplegias and sensory loss over forehead; pupil usually spared	None	Granulomatous lesion of cavernous sinus or superior orbital fissure	Corticosteroids
Raeder paratrigeminal syndrome	Unilateral, frontotemporal and maxilla	Intense sharp or aching pain, ptosis, miosis, preserved sweating	None	Parasellar tumors, granulomatous lesions, trauma, idiopathic	Depends on type of lesion
“Migrainous neuralgia”	Orbitofrontal, temple, upper jaw, angle of nose and cheek	See cluster headache, Table 10-1	Alcohol in some		Ergotamine before anticipated attack
Carotidynia, lower-half headache, sphenopalatine neuralgia, etc.	Unilateral face, ear, jaws, teeth, upper neck	Both sexes, constant dull ache 2–4 h	Compression of common carotid at or below bifurcation reproduces pain in some	Occasionally with cranial arteritis, carotid tumor, migraine and cluster headache	Ergotamine acutely; methysergide for prevention Lithium Ca blockers
Atypical facial neuralgia (facial pain of indeterminate cause)	Unilateral or bilateral; cheek or angle of cheek and nose; deep in nose	Predominantly female 30–50 years Continuous intolerable pain Mainly maxillary areas	None	Depressive and anxiety states Hysteria Idiopathic	Antidepressant and antianxiety medication

Treatment Anticonvulsant drugs such as phenytoin (300 to 400 mg/day), valproic acid (800 to 1200 mg/day), clonazepam (2 to 6 mg/day), gabapentin (300 to 900 mg/day), and particularly carbamazepine (600 to 1200 mg/day), alone or in combination, suppress or shorten the duration and severity of the attacks. Carbamazepine is effective in 70 to 80 percent of patients, but half become tolerant over a period of several years. Baclofen may be useful in patients who cannot tolerate carbamazepine or gabapentin, but it is most effective as an adjunct to one of the anticonvulsant drugs. Capsaicin applied locally to the trigger zones or the topical instillation in the eye of an anesthetic (proparacaine 0.5%) has been helpful in some patients. By temporizing and using these drugs, one may permit a spontaneous remission to occur in perhaps one in five patients.

Most of the patients with intractable pain come to surgery or an equivalent form of root destruction. The commonly used procedures are (1) stereotactically controlled thermocoagulation of the trigeminal roots using a radiofrequency generator (Sweet and Wepsic) or similarly applied focused gamma radiation and (2) the procedure of vascular decompression, popularized by Jannetta, which requires a posterior fossa craniotomy but leaves no sensory loss. Barker and colleagues have reported that 70 percent of 1185 patients were relieved of pain by repositioning a small branch of the basilar artery that was found to compress the fifth nerve, and this benefit persisted, with an annual recurrence rate of less than 1 percent per year for 10 years. It is not clear if arteriography is useful in identifying an aberrant blood vessel prior to surgery, but we have generally not advised it. The therapeutic efficacy of the two surgical approaches is roughly equivalent; in recent years there has been a preference for microvascular decompression on the basis of its sparing of sensation, especially late in the course of the illness (Fields). Gamma knife radiation is emerging as a less intrusive alternative, but its full effect is not evident for many months. In practice, an anticonvulsant is often required for some period of time even after any of these procedures, and it must be reinstated when symptoms reoccur, as they often do in our experience.

Glossopharyngeal Neuralgia

This syndrome is much less common than trigeminal neuralgia but resembles the latter in many respects. The pain is intense and paroxysmal; it originates in the throat, approximately in the tonsillar fossa, and is provoked most commonly by swallowing but also by talking, chewing, yawning, laughing, etc. The pain may be localized in the ear or radiate from the throat to the ear, implicating the auricular branch of the vagus nerve. For this reason, White and Sweet suggested the term *vagoglossopharyngeal neuralgia*. This is the only craniofacial neuralgia that may be accompanied by bradycardia and even by syncope, presumably because of the triggering of cardioinhibitory reflexes by afferent pain impulses. There is no demonstrable sensory or motor deficit. Rarely, carcinoma or epithelioma of the oropharyngeal-infracranial region or peritonsillar abscess may give rise to pain that is clinically indistinguishable from glossopharyngeal neuralgia. For idiopathic glossopharyngeal neuralgia, a trial of carbamazepine, gabapentin, or baclofen may be useful. If these are unsuccessful, the conventional surgical procedure has been to interrupt the glossopharyngeal nerve and upper rootlets of the vagus nerve near the medulla. Recent observations suggest that a vascular decompression procedure similar to the one

used for tic but directed to a small vascular loop under the ninth nerve relieves the pain in a proportion of patients.

Acute Zoster and Postherpetic Neuralgia

Neuralgia associated with a vesicular eruption due to the herpes zoster virus may affect cranial as well as peripheral nerves. In the region of the cranial nerves, two syndromes are frequent: herpes zoster auricularis and herpes zoster ophthalmicus. Both may be exceedingly painful in the acute phase of the infection. In the former, herpes of the external auditory meatus and pinna and sometimes of the palate and occipital region—with or without deafness, tinnitus, and vertigo—is combined with facial paralysis. This syndrome, since its original description by Ramsay Hunt, has been known as geniculate herpes, supported only by the postmortem study of Denny-Brown and RD Adams (see Chap. 47). Pain and herpetic eruption due to herpes zoster infection of the gasserian ganglion and the peripheral and central pathways of the trigeminal nerve are practically always limited to the first division (herpes zoster ophthalmicus). Ordinarily, the eruption will appear within 4 to 5 days after the onset of the pain; if it does not, some cause other than herpes zoster will almost invariably declare itself. Nevertheless, a few cases have been reported in which the characteristic localization of pain to a dermatome, with serologic evidence of herpes zoster infection, was not accompanied by skin lesions.

The acute discomfort associated with the herpetic eruption usually subsides after several days or weeks, or it may linger for several months. Treatment with acyclovir, along the lines indicated in Chap. 33, will shorten the period of eruption and pain, but the drug does not prevent its persistence as a chronic pain. It is mostly in the elderly that the pain becomes chronic and intractable. Usually it is described as a constant burning, with superimposed waves of stabbing pain, and the skin in the territory of the preceding eruption is exquisitely sensitive to the slightest tactile stimuli, even though the threshold of pain and thermal perception is elevated. Allodynia is frequent. This unremitting *postherpetic neuralgia* of long duration represents one of the most difficult pain problems with which the physician has to deal. Some relief may be provided by application of capsaicin cream, use of a mechanical or electrical stimulator, or administration of phenytoin, gabapentin, or carbamazepine. Antidepressants such as amitriptyline and fluoxetine are helpful in some patients, and Bowsher has suggested, on the basis of a small placebo-controlled trial, that treatment with amitriptyline during the acute phase may prevent persistent pain. The addition of a phenothiazine to an antidepressant (e.g., amitriptyline 75 mg at bedtime and fluphenazine 1 mg tid) has proved to be a useful measure, but the long-term use of phenothiazines carries with it all the well-known risks, including that of inducing a movement disorder. Probably equivalent results are obtained by a combination of valproic acid and an antidepressant, as reported by Raftery. King has reported that two (5-grain) aspirin tablets crushed and mixed with cold cream or chloroform (15 mL) and spread over the painful zone on the face or trunk relieved the pain for several hours in most patients with postzoster neuralgia. Ketamine cream has been suggested as an alternative. The authors have limited experience with these topical treatments. Extensive trigeminal rhizotomy or other destructive procedures should be avoided, since these surgical measures are not universally successful and may superimpose a diffuse refractory dysesthetic component on the neuralgia (anesthesia dolorosa).

Trochlear Headache

Under the heading of “primary trochlear headache,” Yanguela and colleagues have described a periorbital pain that emanates from the superomedial orbit in the region of the trochlea (the pulley of the superior oblique muscle). Most of their patients were women. The pain was worsened by adduction and elevation of the globe on the affected side, in the direction of action of the superior oblique muscle. The authors describe a diagnostic method of examination that begins by having the patient look downward so that the trochlea can be palpated and compressed; the patient then looks upward, eliciting or exaggerating the pain while the examiner continues compression. Injection of the trochlea with corticosteroids relieved the pain in almost all of these patients. There is no limitation of a ocular movement or autonomic change and imaging of the orbit is normal. This syndrome, with which we have no experience, brings to mind the entity of Brown syndrome of trochlear entrapment with diplopia and pain (Chap. 13). The above authors have also described a “trochleitis” with similar characteristics and are also of the opinion that the trochlea may be a trigger point for migraine.

Otalgia

Pain localized in and around one ear is occasionally a primary complaint. This can have a number of different causes and mechanisms. During neurosurgical operations in awake patients, stimulation of cranial nerves V, VII, IX, and X causes ear pain, yet interruption of these nerves usually causes no demonstrable loss of sensation in the ear canal or the ear itself (superficial sensation in this region is supplied by the great auricular nerve, which is derived from the C2 and C3 roots). The neurosurgical literature cites examples of otalgia that were relieved by section of the nervus intermedius (sensory part of VII) or nerves IX and X. In otalgic cases, one is prompted to search for a nasopharyngeal tumor or vertebral artery aneurysm. Formerly, lateral sinus thrombosis was a common cause in children. But when this possibility is eliminated by appropriate studies, there will always remain examples of primary idiopathic otalgia, lower cluster headache, and glossopharyngeal neuralgia. Some patients with common migraine have pain centered in the ear region and occiput, but we have never observed a trigeminal neuralgia in which the ear was the predominant site of pain.

Occipital Neuralgia

Paroxysmal pain may occasionally occur in the distribution of the greater or lesser occipital nerves (suboccipital, occipital, and posterior parietal areas). While tenderness may be localized to the region where these nerves cross the superior nuchal line, there is only questionable evidence of an occipital nerve lesion at this site. Carbamazepine may provide some relief. Blocking the nerves with lidocaine may abolish the pain and encourage attempts to section one or more occipital nerves or the second or third cervical dorsal root, but the results have rarely been successful, and several such patients who had these procedures were later referred to us with disabling anesthesia dolorosa. We have advised repeated injections of local anesthetic agents and the use of steroids, traction, local heat, and analgesic and anti-inflammatory drugs. The pain at times may be difficult to distinguish from that arising in the upper three cervical apophysial joints, one type of which is discussed below.

“Third Occipital Nerve” Headache

This condition, a unilateral occipital and suboccipital ache, may be a prominent symptom in patients with neck pain, particularly after whiplash injuries (a prevalence of 27 percent, according to Lord et al). Bogduk and Marsland attribute this type of pain to a degenerative or traumatic arthropathy involving the C2 and C3 apophysial joints with impingement on the “third occipital nerve” (a branch of the C3 dorsal ramus that crosses the dorsolateral aspect of the apophysial joint). Ablation of the neck pain and headache by percutaneous blocking of the third occipital nerve under fluoroscopic control is diagnostic and temporarily therapeutic. More sustained relief (weeks to months) has been obtained by radiofrequency coagulation of the nerve or steroid injections of the joint. NSAIDs also provide some relief.

Carotidynia

This term was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries of patients with *atypical facial neuralgia*, or the so-called lower-half headache of Sluder. Compression of the artery in these patients, or mild electrical stimulation at or near the bifurcation, produced a dull ache that was referred to the ipsilateral face, ear, jaws, and teeth or down the neck. This type of carotid sensitivity occurs rarely as part of cranial (giant-cell) arteritis and of the rare condition known as Takayasu arteritis (Chap. 34) and during attacks of migraine or cluster headache. It has also been described with displacement of the carotid artery by tumor and dissecting aneurysm of its wall; among these causes, the last is of greatest concern. The idiopathic variety may have to do with a swelling or inflammation of the tissue surrounding the carotid bifurcation, a change that has been demonstrated on MRI by Burton and colleagues.

A variant of carotidynia, with a predilection for young adults, has been described by Roseman. This syndrome takes the form of recurrent, self-limited attacks of pain in the aforementioned distribution and tenderness at the carotid bifurcation lasting a week or two. During the attack, aggravation of the pain by head movement, chewing, and swallowing is characteristic. This condition is treated with simple analgesics. Yet another variety of carotidynia appears at any stage of adult life and recurs in attacks lasting minutes to hours in association with throbbing headaches indistinguishable from common migraine (Raskin and Prusiner). This form responds favorably to the administration of ergotamine, methysergide, and other drugs that are effective in the treatment of migraine.

Temporomandibular Joint Pain (Costen Syndrome)

This is a form of craniofacial pain consequent on dysfunction of one temporomandibular joint. Malocclusion due to ill-fitting dentures or loss of molar teeth on one side, with alteration of the normal bite, may lead to distortion of and ultimately degenerative changes in the joint and to pain in front of the ear, with radiation to the temple and over the face. The diagnosis is supported by the findings of tenderness over the joint, crepitus on opening the mouth, and limitation of jaw opening. The favored diagnostic maneuver involves palpating the joint from its posterior aspect by placing a finger in the external auditory meatus and pressing forward. The diagnosis can be made with some confidence only if this entirely reproduces the patient’s pain. CT and plain films are rarely

helpful, but effusions have been shown in the joints by MRI. Management consists of careful adjustment of the bite by a dental specialist and should be undertaken only when the patient meets the strict diagnostic criteria for this condition. In our experience, most of the putative diagnoses of Costen syndrome that reach the neurologist have been erroneous and the number of headaches and facial pains that are attributed to “temporomandibular joint dysfunction” is excessive, especially if judged by the response to treatment. The temporomandibular joint may also be the source of pain when involved by rheumatoid arthritis and other connective tissue diseases.

Facial Pain of Dental or Sinus Origin

Maxillary and mandibular discomfort are common effects of nerve irritation from deep caries, dental pulp degeneration, or periodontal abscess. The pain of dental nerve origin is most severe at night, slightly pulsating, and often associated with local tenderness at the root of the tooth in response to heat, cold, or pressure. It is usually eradicated by infiltrating the base of the tooth with lidocaine.

Trigeminal neuritis following dental extractions or oral surgery is another vexing problem. There may be sensory loss in the tongue or lower lip and weakness of the masseter or pterygoid muscle.

Sometimes the onset of “atypical facial pain” (see below) can be dated to a dental procedure such as tooth extraction, and, as usually happens, neither the dentist nor the neurologist is able to find a source for the pain or any malfunction of the trigeminal nerve. Roberts and coworkers as well as Ratner and associates have pointed out that residual microabscesses and subacute bone infection account for some of these cases. They isolated the affected region by local anesthetic blocks, curetted the bone, and administered antibiotics, following which the pain resolved. The removed bone fragments showed vascular and inflammatory changes and infection with oral bacterial flora.

Facial Pain of Uncertain Origin (“Atypical” Facial Pain)

There remains—after all the aforementioned pain syndromes and all the possible intracranial and local sources of pain from throat, mouth, sinuses, orbit, and carotid vessels have been excluded—a fair number of patients with pain in the face for which no cause can be found. These patients are most often young women, who describe the pain as constant and unbearably severe, deep in the face, or at the angle of cheek and nose and unresponsive to all varieties of analgesic medication. Because of the failure to identify an organic basis for the pain, one is tempted to attribute it to psychologic or emotional factors or to abnormal personality traits. Only a small proportion of the patients satisfy the diagnostic cri-

teria for hysteria, but depression of varying severity is found in nearly half. Many such patients, with or without depression, respond to tricyclic antidepressants and monoamine oxidase inhibitors. Always to be differentiated from this group is the condition of trigeminal neuropathy, described in Chap. 47. Facial pain of the “atypical type,” like other chronic pain of indeterminate cause, requires close observation of the patient, looking for lesions such as nasopharyngeal carcinoma to declare themselves. The pain should be managed by the conservative methods outlined in the preceding chapter and not by destructive surgery. Antidepressants may be helpful, especially if the patient displays obsessive characteristics in relation to the pain; some European neurologists favor clomipramine for various facial and scalp pains.

Other Rare Types of Facial Pain These include ciliary, nasociliary, supraorbital, and Sluder neuralgia. These are vague entities at best; some merely represent different descriptive terms given to pains localized around the eye and nose (see “Cluster Headache” above; also Table 10-2). The Tolosa-Hunt syndrome of pain behind the eye and granulomatous involvement of some combination of cranial nerves III, IV, VI, and ophthalmic V, responsive to steroids, are discussed in Chap. 47.

A kind of *reflex sympathetic dystrophy of the face* is postulated as another rare form of persistent facial pain that may follow dental surgery or penetrating injuries to the face. It is characterized by severe burning pain and hyperpathia in response to all types of stimuli. Sudomotor, vasomotor, and trophic changes are lacking, unlike causalgia that affects the limbs. Nevertheless, this form of facial pain responds to repeated blockade or resection of the stellate ganglion.

Under the title of *neck-tongue syndrome*, Lance and Anthony have described the occurrence of a sharp pain and tingling in the upper neck or occiput on sudden rotation of the neck associated with numbness of the ipsilateral half of the tongue. They attribute the syndrome to stretching of the C2 ventral ramus, which contains proprioceptive fibers from the tongue; these fibers run from the lingual nerve to the hypoglossal nerve and thence to the second cervical root.

The vexing problem that has gone by the self-evident name *burning mouth syndrome (stomatodynia)* occurs mainly in middle-aged and older women as commented in Chap. 12. The tongue or other oral sites may be most affected or the entire oral mucosa may burn. A few patients are found to have diabetes or vitamin B₁₂ deficiency as possible causes. The oral mucosa is normal when inspected and no one treatment has been consistently effective, but gabapentin combined with antidepressants should be tried (see the review by Grushka and colleagues). One of our patients with a limited form of this condition, which affected only the upper palate and gums, benefited from dental nerve blocks with lidocaine. Clonazepam may be helpful.

CHAPTER 11

PAIN IN THE BACK, NECK, AND EXTREMITIES

The diagnosis of pain in these parts of the body often requires the assistance of a neurologist. The task is largely to determine whether a disease of the spine has implicated the spinal cord or the spinal roots and to identify an injury of a peripheral nerve. To do this effectively, a clear understanding of the structures involved and some knowledge of orthopedics and rheumatology is necessary. We include a chapter on this subject in recognition of the fact that back pain is among the most frequent of medical complaints. Up to 80 percent of adults have low back pain at some time in their lives, and—according to Kelsey and White—an even larger percentage will be found at autopsy to have degenerative disc disease. Similar changes are disclosed by imaging studies of the lower spine. Our purpose in this chapter is to focus on the neurologic implications of back and neck pain and to help the clinician develop a systematic approach to patients with such complaints.

Since pains in the lower part of the spine and legs are caused by rather different types of disease than those in the neck, shoulder, and arms, they are considered separately.

PAIN IN THE LOWER BACK AND LIMBS

The lower parts of the spine and pelvis, with their massive muscular attachments, are relatively inaccessible to palpation and inspection. Although some physical signs and radiographs are helpful, diagnosis often depends on the patient's description of the pain and his behavior during the execution of certain maneuvers. Seasoned clinicians, for these reasons, have come to appreciate the need for a systematic inquiry and method of examination, the descriptions of which are preceded here by a brief consideration of the anatomy and physiology of the spine.

Anatomy and Physiology of the Lower Part of the Back

The bony spine is a complex structure, roughly divisible into an anterior and a posterior part. The former consists of a series of cylindric vertebral bodies, articulated by the intervertebral discs and held together by the anterior and posterior longitudinal ligaments. The posterior elements are more delicate and extend from the bodies as pedicles and laminae, which form the *spinal canal* by joining with the posterior aspects of the vertebral bodies and ligaments. Stout transverse and spinous processes project laterally and posteriorly, respectively, and serve as the origins and insertions of the muscles that support and protect the spinal column. The bony processes are also held together by sturdy ligaments, the most important being the ligamentum flavum. The posterior parts of the vertebrae articulate with one another at the diarthrodial *facet joints* (also called apophysial or zygapophysial joints), each of which is composed of the inferior facet of the vertebra above and the superior facet of the one below. These anatomic features are illustrated in Figs. 11-1 and 11-2. The facet and sacroiliac joints—covered by synovia, the compressible intervertebral discs, and the

collagenous and elastic ligaments—permit a limited degree of flexion, extension, rotation, and lateral motion of the spine.

The stability of the spine depends on the integrity of the vertebral bodies and intervertebral discs and on two types of supporting structures, ligamentous (passive) and muscular (active). Although the ligamentous structures are quite strong, neither they nor the vertebral body–disc complexes have sufficient integral strength to resist the enormous forces that may act on the spinal column; the stability of the lower back is therefore largely dependent on the voluntary and reflex activity of the sacrospinalis, abdominal, gluteus maximus, and hamstring muscles.

The vertebral and paravertebral structures derive their innervation from the meningeal branches of the spinal nerves (also known as recurrent meningeal or sinuvertebral nerves). These meningeal branches spring from the posterior divisions of the spinal nerves just distal to the dorsal root ganglia, re-enter the spinal canal through the intervertebral foramina, and supply pain fibers to the intraspinal ligaments, periosteum of bone, outer layers of the annulus fibrosus (which enclose the disc), and capsule of the articular facets. Copes and associates have found A- δ and C pain fibers extending into the inner layers of the annulus and even the nucleus pulposus. Although the spinal cord itself is insensitive, many of the conditions that affect it produce pain by involving these adjacent structures. For example, the sensory fibers from the lumbosacral and sacroiliac joints enter the spinal cord via the fifth lumbar and first sacral roots. Motor fibers exit through the corresponding anterior roots and form the efferent limb of segmental reflexes. The sympathetic nerves contribute only to the innervation of blood vessels. The spinal roots in the lumbar region, after exiting from the spinal cord, course downward in the spinal canal and are gradually displaced laterally until they angulate and exit at the intervertebral foramina. Prior to entering the short foraminal canal, the spinal root lies in a shallow furrow along the inner surface of the pedicle called the *lateral recess*. This is a common site of root entrapment by disc fragments and bony overgrowth.

The parts of the back that possess the greatest freedom of movement and hence are most frequently subject to injury are the lumbar, lumbosacral, and cervical. In addition to bending, twisting, and other voluntary movements, many actions of the spine are reflexive in nature and are the basis of posture.

Aging Changes in Spinal Structures Changes in the intervertebral discs and ligaments as a consequence of aging and perhaps a succession of minor traumas begin to occur as early as the first part of the third decade. Deposition of collagen and elastin and alterations of glycosaminoglycans combine to decrease the water content of the nucleus pulposus; concomitantly, the cartilaginous end plate becomes less vascular (Hassler). The dehydrated disc thins out and becomes more fragile. Similar changes occur in the annulus of the disc, which frays to an increasing degree with the passage of time, permitting the nucleus pulposus to bulge and, sometimes with injury, to extrude. This process can be observed by magnetic resonance imaging (MRI), which shows a gradual re-

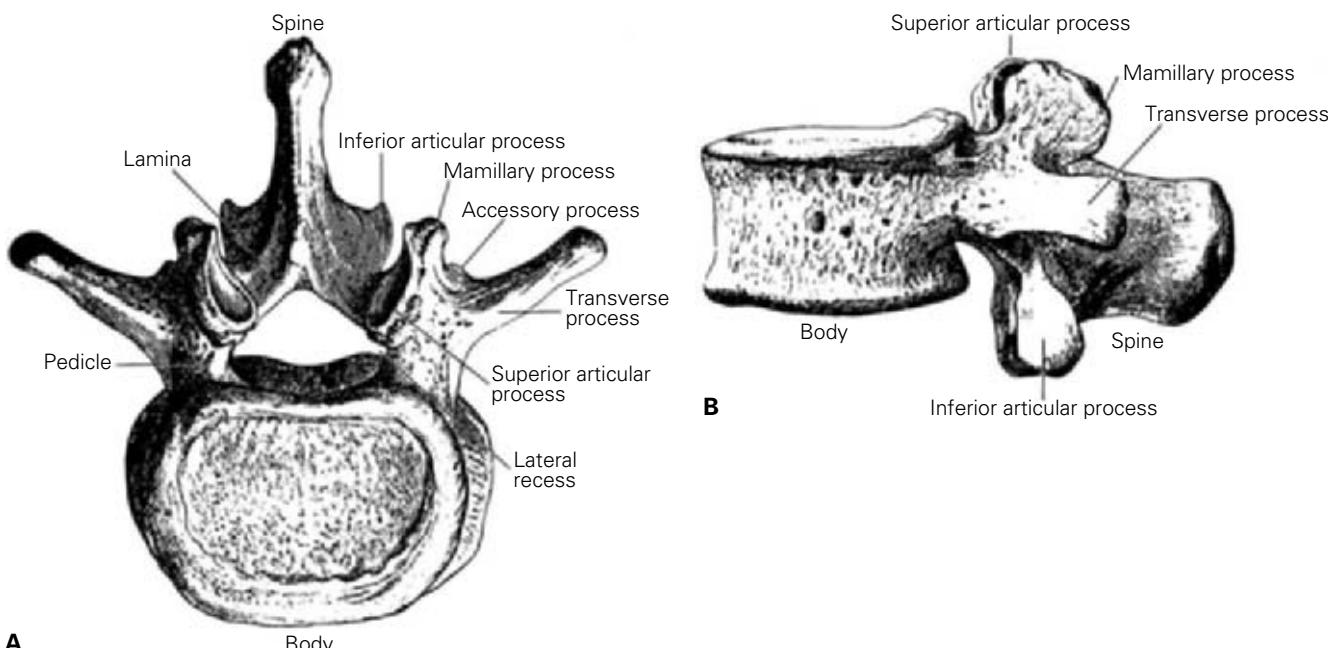

Figure 11-1. The fifth lumbar vertebra viewed from above (A) and from the side (B).

duction in the high signal of the nucleus pulposus with the passage of time. In women who had MRI for gynecologic reasons, Powell and coworkers found an increasing frequency of lumbar disc degeneration and bulging, approaching 70 percent by the fiftieth year of life. Similar abnormalities in asymptomatic men and women have been recorded by Jensen and colleagues. The shrinkage of the disc alters the alignment of the articular facets and vertebral bodies, leading sometimes to facet arthropathy and bony spur formation. The latter changes may contribute to stenosis of the spinal canal and also compromise the lateral recesses of the canal and the intervertebral foramina, where they impinge on nerve roots. Osteoporosis, especially in older women, is an important cause of vertebral flattening or collapse, additionally narrowing the spinal canal.

General Clinical Features of Low Back Pain

Types of Low Back Pain Of the several symptoms of spinal disease (pain, stiffness, limitation of movement, and deformity), pain is of foremost importance. Four types of pain may be distinguished: local, referred, radicular, and that arising from secondary (protective) muscular spasm. These several types of pain can often be discerned from the patient's description; reliance is placed mainly on the character of the pain, its location, and conditions that modify it.

Local pain is caused by any pathologic process that impinges on structures containing sensory endings. Involvement of the periosteum of the vertebral body, capsule of apophysial joints, muscles, annulus fibrosus, and ligaments is often exquisitely painful, whereas destruction of the nucleus pulposus alone produces little or no pain. Local pain is most often described as steady and aching, but it may be intermittent and sharp and, though not well circumscribed, is always felt in or near the affected part of the spine. Usually there is reflexive protective splinting at the corresponding spinal segments by intense contraction of the paravertebral mus-

cles, and certain movements or postures that counteract the spasm and alter the position of the injured tissues tend to aggravate the pain. Also, the superficial structures in the involved region are tender and direct pressure on them evokes pain. Muscles that are continually in reflex spasm may also become tender and sensitive to deep pressure.

Referred pain is of two types, one that is projected from the spine to viscera and other structures lying within the territory of the lumbar and upper sacral dermatomes and another that is projected from pelvic and abdominal viscera to the spine. Pain due to disease of the upper part of the lumbar spine is often referred to the flank, lateral hip, groin, and anterior thigh. This has been attributed to irritation of the superior cluneal nerves, which are derived from the posterior divisions of the first three lumbar spinal nerves and innervate the superior portions of the buttocks. Pain from the lower part of the lumbar spine is usually referred to the lower buttocks and posterior thighs and is due to irritation of lower spinal nerves, which activate the same pool of intraspinal neurons as the nerves that innervate the posterior thighs. Pain of this type is usually rather diffuse and has a deep, aching quality, but it tends at times to be more superficially projected. McCall and colleagues and Kellgren have verified these areas of reference by the injection of hypertonic saline into the apophysial joints. But, as Sinclair and coworkers have pointed out, the sites of reference are inexact and cannot be relied on for the precise anatomic localization of lesions. In general, the intensity of the referred pain parallels that of the local pain. In other words, maneuvers that alter local pain have a similar effect on referred pain, though lacking the precision and immediacy of so-called root pain.

Pain from visceral diseases is usually felt within the abdomen, flanks, or lumbar region and may be modified by the state of activity of the viscera and sometimes by assuming an upright or supine posture. Its character and temporal relationships have little relationship to movement of the back.

Radicular or "root" pain has some of the characteristics of referred pain but differs in its greater intensity, distal radiation,

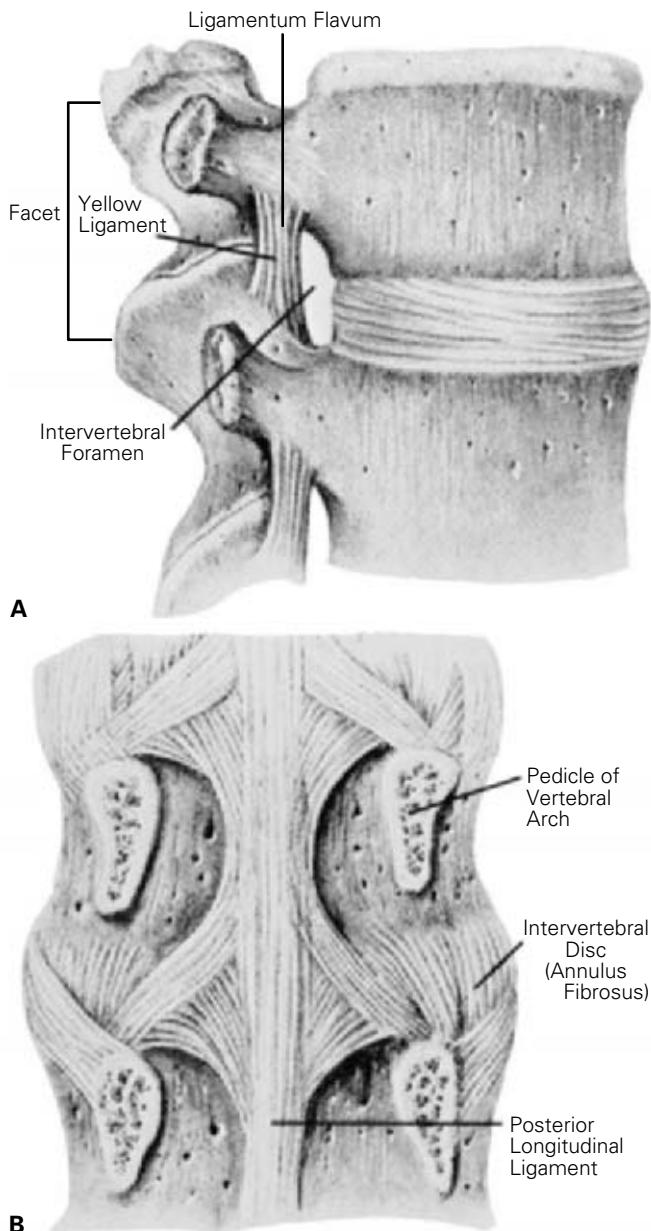

Figure 11-2. The main ligamentous structures of the spine. *A.* Buckling of the yellow ligament (*ligamentum flavum*) may compress the nerve root or the spinal nerve at its origin in the intervertebral foramen, particularly if the foramen is narrowed by osteophytic overgrowth. *B.* Posterior aspect of the vertebral bodies. Fibers of the posterior longitudinal ligament merge with the posteromedial portion of the annulus fibrosus, leaving the posterolateral portion of the annulus relatively unsupported. (Reproduced by permission from Finneson.)

circumscription to the territory of a root, and factors that excite it. The mechanism is stretching, irritation, or compression of a spinal root within or central to the intervertebral foramen. The pain is sharp, often intense, and usually superimposed on the dull ache of referred pain; it nearly always radiates from a paracentral position near the spine to some part of the lower limb. Coughing, sneezing, and straining characteristically evoke this sharp radiating pain, although each of these actions may also jar or move the spine and enhance local pain; jugular vein compression, which raises intra-

spinal pressure and may cause a shift in position of the root, has a similar effect. In fact, any maneuver that stretches the nerve root—e.g., “straight-leg raising” in cases of sciatica—evokes radicular pain. The patterns of radicular pain due to involvement of particular roots are described in the sections on prolapsed discs further on in the chapter, and the distribution of cutaneous innervation of the spinal roots is shown in Figs. 9-2 and 9-3. The most common pattern is *sciatica*, *pain that originates in the buttock and is projected along the posterior or posterolateral thigh*. It results from irritation of the L5 or S1 nerve root. Paresthesias or superficial sensory loss, soreness of the skin, and tenderness in certain circumscribed regions along the nerve usually accompany radicular pain. If the anterior roots are involved as well, there may be reflex loss, weakness, atrophy, and fascicular twitching.

In patients with severe circumferential constriction of the cauda equina due to spondylosis (*lumbar stenosis*), sensorimotor impairment and sometimes referred pain are elicited by standing and walking. The neurologic symptoms involve the calves and the backs of the thighs, thereby simulating the exercise-induced symptoms due to vascular insufficiency—hence the term *spinal claudication* (see page 179).

Of importance is the observation that referred pain from structures of the lower back (sometimes called *pseudoradicular*) does not, as a rule, project below the knees and is not accompanied by neurologic changes other than a vague numbness without demonstrable sensory impairment. The subcutaneous tissues within the area of referred pain may be tender. Of course, local, referred, and radicular pain may occur together.

Pain resulting from muscular spasm usually occurs in relation to local pain. The spasm may be thought of as a nociceptive reflex for the protection of the diseased parts against injurious motion. Muscle spasm is associated with many disorders of the low back and can distort normal posture. Chronic muscular contraction may give rise to a dull, sometimes cramping ache. One can feel the tautness of the sacrospinalis and gluteal muscles and demonstrate by palpation that the pain is localized to them. However, except for the most severe degrees of spasm in acute injury of the back, the contribution of this component to back pain is relatively small.

Other pains, often of undetermined origin, are sometimes described by patients with chronic disease of the lower part of the back: drawing and pulling in the legs; cramping sensation (without involuntary muscle spasm); tearing, throbbing, or jabbing pains; and feelings of burning or coldness. These sensations, like paresthesias and numbness, should suggest the possibility of nerve or root disease.

In addition to assessing the character and location of the pain, one should determine the factors that aggravate and relieve it, its constancy, and its relationship to activity and rest, posture, forward bending, and cough, sneeze, and strain. Frequently, the most important lead comes from knowledge of the mode of onset and the circumstances that initiated the pain. Inasmuch as many painful conditions of the back are the result of injuries incurred during work or in automobile accidents, the possibility of exaggeration or prolongation of pain for purposes of compensation must always be kept in mind.

Examination of the Lower Back

The main goals of the examination of the back by the neurologist are to differentiate pain that is due to nerve root compression from

musculoskeletal strains, metastatic spinal tumor, infectious and inflammatory diseases of the spine, and hip disease.

Some information may be gained by inspection of the back, buttocks, and lower limbs in various positions. The normal spine shows a thoracic kyphosis and lumbar lordosis in the sagittal plane, which in some individuals may be exaggerated (swayback). In the coronal plane, the spine is normally straight or shows a slight curvature, particularly in women. One should observe the spine closely for excessive curvature, a list, flattening of the normal lumbar lordosis, presence of a gibbus (a sharp, kyphotic angulation usually indicative of a fracture), pelvic tilt or obliquity (Trendelenburg sign), and asymmetry of the paravertebral or gluteal musculature. A sagging gluteal fold suggests involvement of the S1 root. In sciatica one may observe a flexed posture of the affected leg, presumably to reduce tension on the irritated nerve. Or, patients in whom a free fragment of lumbar disc material has migrated posterolaterally may be unable to lie down and extend the spine.

The next step in the examination is *observation of the spine, hips, and legs during certain motions*. It is well to remember that no advantage accrues from determining how much pain the patient can tolerate. More important is to determine when and under what conditions the pain begins or worsens. Observation of the patient's gait when he or she is unaware of being watched may disclose a subtle limp, a pelvic tilt, a shortening of step, or a stiffness of bearing—indicative of a disinclination to bear weight on a painful leg. One looks for limitation of motion while the patient is standing, sitting, and reclining. When standing, the motion of forward bending normally produces flattening and reversal of the lumbar lordotic curve and exaggeration of the thoracic curve. With lesions of the lumbosacral region that involve the posterior ligaments, articular facets, or sacrospinalis muscles and with ruptured lumbar discs, protective reflexes prevent flexion, which stretches these structures. As a consequence, the sacrospinalis muscles remain taut and prevent motion in the lumbar part of the spine. Forward bending then occurs at the hips and at the thoracolumbar junction; also, the patient bends in such a way as to avoid tensing the hamstring muscles and putting undue leverage on the pelvis. In the presence of degenerative disc disease, straightening up from a flexed position is performed with difficulty and is aided to some extent by flexing the knees.

Lateral bending is usually less instructive than forward bending, but in unilateral ligamentous or muscular strain, bending to the opposite side aggravates the pain by stretching the damaged tissues. With unilateral sciatica, the patient lists to one side and strongly resists bending to the opposite side, and the preferred posture in standing is with the leg slightly flexed at the hip and knee. When the herniated disc lies lateral to the nerve root and displaces it medially, tension on the root is reduced and pain is relieved by bending the trunk to the side opposite the lesion; with herniation medial to the root, tension is reduced by inclining the trunk to the side of the lesion.

In the *sitting position*, flexion of the spine can be performed more easily, even to the point of bringing the knees in contact with the chest. The reason for this is that knee flexion relaxes tightened hamstring muscles and relieves the stretch on the sciatic nerve. Asking the seated patient to extend the leg so that the sole of the foot can be inspected is a way of checking for a feigned Lasègue sign (see below).

Examination with the patient in the *reclining position* yields much the same information as in the standing and sitting positions. With lumbosacral disc lesions and sciatica, passive lumbar flexion

causes little pain and is not limited as long as the hamstrings are relaxed and there is no stretching of the sciatic nerve. Thus, with the knees flexed to 90 degrees, sitting up from the reclining position is unimpeded and not painful; with knees extended, there is pain and limited motion (Kraus-Weber test). With vertebral disease (e.g., arthritis), passive flexion of the hips is free, whereas flexion of the lumbar spine may be impeded and painful.

With the patient supine, passive *straight-leg raising* (possible up to 90 degrees in normal individuals) places the sciatic nerve and its roots under tension, thereby producing radicular radiating pain. This maneuver is the usual way in which compression of the L5 or S1 nerve root is detected (see further on); however, it may also cause an anterior rotation of the pelvis around a transverse axis, increasing stress on the lumbosacral joint and causing pain if this joint is arthritic or otherwise diseased. Consequently, in diseases of the lumbosacral joints and roots, passive straight-leg raising evokes pain and is restricted on the affected side (Lasègue sign). *Straight raising of the opposite leg* may also cause pain on the affected side and is believed by some to be an even more reliable sign of prolapsed disc than a Lasègue sign. It is important to remember that the evoked pain is always referred to the diseased side, no matter which leg is elevated. While the patient is in the supine position, leg length (anterosuperior iliac spine to medial malleolus) and the circumference of the thigh and calf may be measured. *Hyperextension* of the lumbar spine may be performed with the patient standing or lying prone. If the condition causing back pain is acute, it may be difficult to extend the spine in the standing position. A patient with lumbosacral strain or disc disease (except in the acute phase or if the disc fragment has migrated laterally) can usually extend or hyperextend the spine with little or no aggravation of pain. If there is an active inflammatory process or fracture of the vertebral body or posterior elements, hyperextension may be markedly limited. In disease of the upper lumbar roots, hyperextension is the motion that is most limited and reproduces pain; however, in some cases of lower lumbar disc disease with thickening of the ligamentum flavum, this movement is also painful. In patients with narrowing of the spinal canal (spondylosis, spondylolisthesis), upright stance and extension may produce neurologic symptoms (see further on).

Maneuvers in the *lateral decubitus position* yield less information as a rule. In cases of sacroiliac joint disease, abduction of the upside leg against resistance reproduces pain in the sacroiliac region, with radiation of the pain to the buttock, posterior thigh, and symphysis pubis. Hyperextension of the upside leg with the downside leg flexed is another test for sacroiliac disease. Rotation and abduction of the leg evoke pain in a diseased hip joint and with *trochanteric bursitis*. Another helpful indicator of *hip disease* is the Patrick test: with the patient supine, the heel of the offending leg is placed on the opposite knee and pain is evoked by depressing the flexed leg and externally rotating the hip.

Gentle palpation and percussion of the spine are the last steps in the examination. It is preferable to first palpate the regions that are the least likely to evoke pain. At all times the examiner should know what structures are being palpated (Fig. 11-3). Localized tenderness is seldom pronounced in disease of the spine because the involved structures are so deep. Nevertheless, tenderness over a spinous process or jarring by gentle percussion may indicate the presence of inflammation (as in disc space infection), pathologic fracture, a spinal metastasis, or a disc lesion at the site deep to it.

Tenderness over the interspinous ligaments or over the region of the articular facets between the fifth lumbar and first sacral ver-

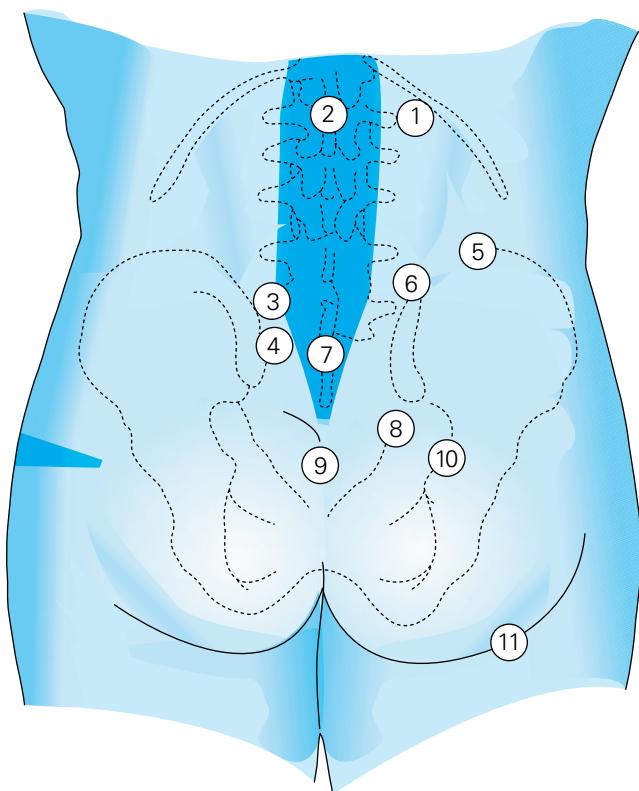

Figure 11-3. (1) Costovertebral angle. (2) Spinous process and interspinous ligament. (3) Region of articular facet (fifth lumbar to first sacral). (4) Dorsum of sacrum. (5) Region of iliac crest. (6) Iliolumbar angle. (7) Spinous processes of fifth lumbar and first sacral vertebrae (tenderness = faulty posture or occasionally spina bifida occulta). (8) Region between posterior superior and posteroinferior spines. Sacroiliac ligaments (tenderness = sacroiliac sprain, often tender, with fifth lumbar or first sacral disc). (9) Sacrococcygeal junction (tenderness = sacrococcygeal injury; i.e., sprain or fracture). (10) Region of sacrosciatic notch (tenderness = fourth or fifth lumbar disc rupture and sacroiliac sprain). (11) Sciatic nerve trunk (tenderness = ruptured lumbar disc or sciatic nerve lesion).

tebrae is consistent with lumbosacral disc disease [Fig. 11-3, (2) and (3)]. Tenderness in this region and in the sacroiliac joints is also a frequent manifestation of ankylosing spondylitis. Arthritic changes at a facet may cause the same tenderness. Tenderness over the costovertebral angle often indicates genitourinary disease, adrenal disease, or an injury to the transverse process of the first or second lumbar vertebra [Fig. 11-3, (1)]. Tenderness on palpation of the paraspinal muscles may signify a strain of muscle attachments or injury to the underlying transverse processes of the lumbar vertebrae. Focal pain in the same parasagittal line along the thoracic spine points to inflammation of the costotransverse articulation between spine and rib (*costotransversitis*).

In palpating the spinous processes, it is important to note any deviation in the lateral plane (this may be indicative of fracture or arthritis) or in the anteroposterior plane. A “step-off” forward displacement of the spinous process and exaggerated lordosis are important clues to the presence of *spondylolisthesis* (see further on).

Abdominal, rectal, and pelvic examinations are essential elements in the study of the patient with low back symptoms that fail to be clarified by the aforementioned spinal maneuvers. Neoplastic, inflammatory, or degenerative disorders may produce symptoms referred to the lower part of the spine.

On completion of the examination of the back and legs, one turns to a search for motor, reflex, and sensory changes in the lower extremities (see “Protrusion of Lumbar Intervertebral Discs,” further on in this chapter).

Ancillary Diagnostic Procedures

Depending on the circumstances, these may include a blood count and erythrocyte sedimentation rate (especially helpful in screening for infection or myeloma); calcium, phosphorus, uric acid, alkaline phosphatase, acid phosphatase, and prostate-specific antigen (if one suspects metastatic carcinoma of the prostate); a serum protein electrophoresis (myeloma proteins); in special cases, a tuberculin test or serologic test for *Brucella*; a test for rheumatoid factor; and HLA typing (for ankylosing spondylitis).

Radiographs of the lumbar spine (preferably with the patient standing) in the anteroposterior, lateral, and oblique planes are still useful in the routine evaluation of low back pain and sciatica. Readily demonstrable in plain films are narrowing of the intervertebral disc spaces, bony facetal or vertebral overgrowth, displacement of vertebral bodies (spondylolisthesis), and an unsuspected infiltration of bone by cancer. In cases of suspected disc herniation or tumor infiltration of the spinal canal, one generally proceeds directly to MRI. Although these imaging procedures have largely replaced conventional myelography, the latter examination, when combined with computed tomography (CT), provides detailed information about the dural sleeves that surround the spinal roots, at times disclosing subtle truncations caused by laterally situated disc herniations and at times revealing surface abnormalities of the spinal cord, such as arteriovenous malformations. Administration of gadolinium at the time of MRI enhances regions of inflammation and tumor.

Injection of contrast medium directly into the intervertebral disc (discogram) is practiced in very few institutions and is more difficult to interpret than CT myelography and MRI; it carries the risk of damage to nerve roots or the introduction of infection. Discography is indicated only in special circumstances and should be undertaken only by those who are specialized in its performance. Isotope bone scans may disclose tumors and inflammatory processes such as osteomyelitis, but these are also evident on CT and MRI.

Nerve conduction studies and electromyography (EMG) are particularly helpful in suspected root and nerve diseases, as indicated further on, in the discussion of protruded lumbar discs. However, as for all the aforementioned tests, they must be interpreted in the context of the history and clinical examination; otherwise they are subject to overuse and overinterpretation.

Principal Conditions Giving Rise to Pain in the Lower Back

Congenital Anomalies of the Lumbar Spine Anatomic variations of the spine are frequent, and though rarely of themselves the source of pain and functional derangement, they may predispose an individual to discogenic and spondylotic complications by virtue of altering the mechanics and alignment of the vertebrae or size of the spinal canal.

The most common anomaly is a lack of fusion of the laminae of one or several of the lumbar vertebrae or of the sacrum (spina bifida). Occasionally, a subcutaneous mass, hypertrichosis, or hyperpigmentation in the sacral area betrays the condition, but in most patients it remains occult until it is disclosed radiologically. The

anomaly may be accompanied by malformation of vertebral joints and usually induces pain only when aggravated by injury. The neurologic aspects of defective fusion of the spine (dysraphism) are discussed in Chap. 38.

Many other congenital anomalies affect the lower lumbar vertebrae: asymmetrical facet joints, abnormalities of the transverse processes, "sacralization" of the fifth lumbar vertebra (in which L5 appears to be fixed to the sacrum), or "lumbarization" of the first sacral vertebra (in which S1 looks like a sixth lumbar vertebra) are seen occasionally in patients with low back symptoms, but apparently with no greater frequency than in asymptomatic individuals. The role of these anomalies in the genesis of low back derangement is unclear, but in the authors' opinion they are rarely the cause of specific symptoms.

Spondylolysis consists of a bony defect in the pars interarticularis (the segment at the junction of pedicle and lamina) of the lower lumbar vertebrae. The defect is remarkably common; it is mainly a disease of children (peak incidence between 5 and 7 years of age) that affects approximately 5 percent of the North American population and is probably genetic. The defect assumes great importance in that it predisposes to subtle fracture at this location, sometimes precipitated by slight trauma but often in the absence of injury. Radiographically, the pars interarticularis defect is best visualized on oblique projections. In some persons it is unilateral and may cause unilateral aching back pain that is accentuated by hyperextension and twisting. It is not uncommon in athletes. In the usual bilateral form, small fractures at the pars interarticularis allow the vertebral body, pedicles, and superior articular facets to move anteriorly, leaving the posterior elements behind. This leads to an anterior displacement of one vertebral body in relation to the adjacent ones known as *spondylolisthesis* (the main cause of spondylolisthesis in adults is degenerative arthritic disease of the spine). It may cause little difficulty at first but eventually becomes symptomatic. The patient complains of limitation of motion and pain in the low back, radiating into the thighs. Examination discloses tenderness near the segment that has "slipped" (most often L5, occasionally L4), a palpable "step" of the spinous process forward from the segment below, hamstring spasm, and, in severe cases (*spondyloptosis*), shortening of the trunk and protrusion of the lower abdomen (both of which result from the abnormal forward shift of L5 on S1) as well as compression of spinal roots by the displaced vertebrae resulting in paresthesias and sensory loss, muscle weakness, and reflex impairment. These neurologic symptoms and signs tend not to be severe.

Sometimes, the fourth lumbar vertebra may slip forward on the fifth, narrowing the spinal canal, without the presence of a defect in the pars interarticularis. This is termed *intact arch spondylolisthesis* and occurs most often in middle-aged or elderly women. This form of spondylolisthesis is probably due to degenerative disease of the inferior and superior facets. It causes severe low back pain, made worse by standing or walking and relieved by bed rest. Symptoms of root compression are common, as indicated in the review by Alexander and colleagues.

Patients with progressive vertebral displacement and neurologic deficits require surgery, usually posterolateral fusion and excision of the posterior elements. Reduction of displaced vertebral bodies before fusion and direct repair of pars defects are possible in special cases.

Traumatic Disorders of the Low Back Traumatic disorders constitute the most frequent cause of low back pain. In severe acute

injuries the examiner must be careful to avoid further damage. All movements must be kept to a minimum until an approximate diagnosis has been made and adequate measures have been instituted for the proper care of the patient. If the patient complains of pain in the back and cannot move the legs, the spine may have been fractured and the cord or cauda equina compressed or crushed. The neck should not be manipulated, and the patient should not be allowed to sit up. (See Chap. 44 for further discussion of spinal cord injury.)

Acute Sprains and Strains The terms *lumbosacral strain*, *sprain*, and *derangement* are used loosely by most physicians, and it is probably not possible to differentiate them. What was formerly referred to as "sacroiliac strain" or "sprain" is now known to be due, in many instances, to disc disease. The term *acute low back strain* is preferable for minor, self-limited injuries that are usually associated with lifting heavy loads when the back is in a mechanically disadvantaged position, or there may have been a fall, prolonged uncomfortable postures such as air travel or car rides, or sudden unexpected motion, as may occur in an auto accident.

The discomfort of acute low back strain is often severe, and the patient may assume unusual postures related to spasm of the lower lumbar and sacrospinalis muscles. The pain is usually confined to the lower part of the back, in the midline or just to one side or other of the spine. The diagnosis of lumbosacral strain depends on the description of the injury or activity that precipitated the pain; the localization of the pain; the finding of localized tenderness; the augmentation of pain by postural changes—e.g., bending forward, twisting, or standing up from a sitting position; and the absence of signs of radicular involvement. In more than 80 percent of cases of acute low back strain of this type, the pain resolves in a matter of several days or a week even with no specific treatment.

Sacroiliac joint and ligamentous strain is the most likely diagnosis when there is tenderness over the sacroiliac joint and pain radiating to the buttock and posterior thigh, but this always needs to be distinguished from the sciatica of a ruptured intervertebral disc (see further on). Strain is characteristically worsened by abduction of the thigh against resistance and is also felt in the symphysis pubis or groin. It, too, responds within days or a week or two to conservative management.

Treatment of Acute Low Back Strain The pain of muscular and ligamentous strains is usually self-limited, responding to simple measures in a relatively short period of time. The basic principle of therapy in both disorders is to avoid reinjury and reduce the discomfort of painful muscles. Rest, in a recumbent position, for one or several days has been the traditional treatment, but several clinical trials over the years have questioned this dictum (see Vroom and colleagues). Nonetheless, lying on the side with knees and hips flexed or supine with a pillow under the knees are the favored positions for relief of pain. With strains of the sacrospinalis muscles and sacroiliac ligaments, the optimal position is hyperextension, which is effected by having the patient lie with a small pillow under the lumbar portion of the spine or by lying face down. Physical measures—such as application of ice in the acute phase and, later, heat diathermy and massage—can be tried, but these are of limited value beyond several days. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be given liberally during the first few days. Muscle relaxants are of little use, serving mainly to make bed rest more tolerable. The same can be said of traction, formerly a popular treatment. When weight bearing is resumed, discomfort

may be diminished by a light lumbosacral support, but many orthopedists refrain from prescribing this aid. As a result of several studies that have failed to demonstrate a benefit of bed rest, recent practice has been to mobilize patients as soon as they are able and to prescribe corrective exercises designed to stretch and strengthen trunk (especially abdominal) muscles, overcome faulty posture, and increase the mobility of the spinal joints. Despite this modern approach, the authors can affirm from personal experience that some injuries produce such discomfort that arising from a bed or chair is simply not possible in the early days after injury.

The use of spinal manipulation—practiced by chiropractors, osteopaths, and others—has always been a contentious matter in the United States, partly because of unrealistic therapeutic claims made in treating diseases other than low back derangements. By contrast, in certain parts of Europe, orthopedists often incorporate manipulative procedures into conventional practice. A type of slow muscle stretching and joint distraction (axial traction on a joint) administered by physiatrists and physical therapists is quite similar. It must be recognized that many patients seek chiropractic manipulation on their own, often before seeing a physician, and may not disclose this information to the physician. When the supporting elements of the spine (pedicles, facets, and ligaments) are not disrupted, chiropractic manipulation of the lumbar spine has provided acute relief to a considerable number of our patients with low back strain or facet pain; at issue is the durability of the effect, even with repeated so-called spinal adjustments. A randomized British trial has shown manipulation to be superior to analgesics and bed rest in returning patients to work after minor back injury (Meade et al.). Some other trials have corroborated this finding (Hadler et al.), while others have not, or, most often, the results have been ambiguous. In the study by Cherkin and colleagues comparing chiropractic, physical therapy (McKenzie method), and simple instruction to the patient from a booklet, manipulation yielded a slightly better outcome at the end of a month. Despite several hypotheses offered by practitioners of spinal manipulation, the mechanism of pain relief is not known. The sound created by rapid and forceful distraction of the facet joints, similar to cracking the knuckles, seems not to be necessary for pain relief. Whether all forms of low back pain represent minor subluxations, as claimed by chiropractors, is undocumented and seems unlikely. Chronic low back pain has, in the authors' experience, been less successfully treated by manipulative procedures, but there are some patients who testify to improvement in their clinical state, and admittedly the medical profession has little to offer many of these patients. The results with another popular approach, acupuncture, have been even more uncertain for acute or chronic back pain, most studies showing it to be no more effective than a sham treatment (Tudler et al.). It should be added, however, that the commitment of patients to a regimen of NSAIDs for many months or to narcotic analgesics is a hazard always to be avoided.

The Degenerative Low Back Syndrome Often the symptoms of low back strain are recurrent and more chronic in nature, being regularly exacerbated by bending or lifting, suggesting that postural, muscular, and arthritic factors play a role. This is the most common syndrome seen in orthopedic clinics, more in men than in women.

After some unusual activity, raising the question of trauma, especially if it happens in the workplace, the patient develops deep aching pain in the low back, increased by certain movements and attended by stiffness. The pain may additionally have a restricted radiation into the buttocks and posterior thigh, thereby simulating

root compression. There are no motor, sensory, or reflex abnormalities. Plain films and imaging procedures reveal some combination of osteoarthropathy, changes in vertebral discs, osteoarthritic changes in apophysial joints, and sometimes osteoporosis or slight spondylosis. Treatment with short-duration bed rest, analgesics, and physiotherapy, as outlined for acute strains, helps to relieve the symptoms, and the majority of patients recover within a few weeks, only to have a recurrence of similar pains in the future. Recurrent attacks are typical of degenerative spine disease that affects the vertebrae and facet joints. Chiropractic manipulation has the same uncertain effect as for acute low back symptoms. Usually the origin of the pain cannot be determined and special diagnostic procedures are not helpful. Only if the pain persists for longer than a month or so is MRI indicated. Quite often, changing the stiffness of the mattress (in either direction) is helpful. Newer foam bedding configurations reportedly have aided a number of our patients. Workers' compensation problems add to the disability, especially in older individuals.

Vertebral Fractures Fractures of lumbar vertebral bodies are usually the result of flexion injuries. Such trauma may occur in a fall or jump from a height (if the patient lands on his or her feet, the calcanei may also be fractured) or as a result of an auto accident or other violent injury. If the injury is severe, it may cause a fracture dislocation, a "burst" fracture of one or more vertebral bodies, or an asymmetrical fracture of a pedicle, lamina, or spinous process; most often, however, there is asymmetrical loss of height of a vertebral body (*compression fracture*), which may be extremely painful at the onset. When compression or other fractures occur with minimal trauma (or spontaneously), the bone has presumably been weakened by some pathologic process. Most of the time, particularly in older individuals, osteoporosis is the cause of such an event, but there are many other causes, including osteomalacia, hyperparathyroidism, prolonged use of corticosteroids, ankylosing spondylitis, myeloma, metastatic carcinoma, and a number of other local conditions. Spasm of the lower lumbar muscles, limitation of all movements of the lumbar section of the spine, and the radiographic appearance of the damaged lumbar portion (with or without neurologic abnormalities) are the basis of clinical diagnosis. The pain is usually immediate, though occasionally it may be delayed for days.

A fractured transverse process, which is almost always associated with tearing of the paravertebral muscles and a local hematoma, causes deep tenderness at the site of the injury, local muscle spasm, and limitation of all movements that stretch the lumbar muscles. The radiologic findings, particularly MRI, confirm the diagnosis. In some circumstances, tears of the paravertebral musculature may be associated with extensive bleeding into the retroperitoneal space; this produces paraspinal or groin pain and proximal leg weakness with loss of the patellar reflex on the affected side.

Herniation of Lumbar Intervertebral Discs (Table 11-1) This condition is a major cause of severe and chronic or recurrent low back and leg pain. It occurs mainly during the third and fourth decades of life, when the nucleus pulposus is still gelatinous. The disc between the fifth lumbar and first sacral vertebrae (L5-S1) is the one most often involved, and, with decreasing frequency, that between the fourth and fifth (L4-L5), third and fourth (L3-L4), second and third (L2-L3), and—quite infrequently—the first and second (L1-L2) lumbar vertebrae. Relatively rare but well described in the thoracic portion of the spine, disc disease is again

Table 11-1Features of the main root-compressive syndromes due to cervical and lumbar disc herniation^a

INTER-VERTEBRAL DISC SPACE	ROOT	PAIN REFERRAL	WEAKNESS	REFLEX CHANGE	ADDITIONAL FEATURES
C4-C5	C5	Shoulder, trapezius	Supra- and infraspinatus deltoid, slight biceps weakness	Slightly diminished biceps jerk	
C5-C6	C6	Trapezius ridge and tip of shoulder, radiation to anterior upper arm, thumb, and index finger	Biceps, brachioradialis, extensor carpi radialis	Diminished biceps and supinator jerk	Tenderness over spine of scapula and suprascapular region; paresthesias in thumb and index finger
C6-C7	C7	Shoulder, axilla, posterolateral arm, elbow, and middle finger	Triceps, wrist extensors	Diminished or absent triceps jerk	Tenderness over medial scapula and supraclavicular region or triceps. May complain of paresthesias in most of the fingers
C7-T1	C8	Medial forearm	Intrinsic hand muscles	Slight or no decrease in triceps jerk	Mimics ulnar palsy
L2-L3	L3	Anterior thigh, over knee	Thigh adductor, quadriceps	Absent or diminished knee jerk	
L3-L4	L4	Anterolateral thigh, medial foreleg	Anterior tibial, sometimes with partial foot drop		
L4-L5	L5	Posterolateral gluteal sciatica; lateral thigh, anterolateral foreleg, dorsal foot, lateral malleolus and great or second and third toe	Extensor hallucis longus and extensor digitorum brevis; some weakness of anterior tibialis, sometimes with foot drop	Unaffected (except posterior tibial)	Pain with straight-leg raising and variant tests; tenderness over fourth lumbar lateral process and lateral gluteal region
L5-S1	S1	Midgluteal sciatica; posterior thigh, posterolateral leg, lateral foot, heel, or lateral toes	Plantar-flexor and hamstring weakness	Absent or diminished ankle jerk	Pain with straight-leg raising and variant tests; tenderness over lumbosacral (L5-S1) joint and sciatic notch; discomfort walking on heels

^aFor pattern of sensory loss, see dermatomal diagram in Figs. 9-2 and 9-3.

frequent at the fifth and sixth and the sixth and seventh cervical vertebrae (see further on).

The ostensible cause of a herniated lumbar disc is a flexion injury, but a considerable proportion of patients do not recall a traumatic episode. Degeneration of the nucleus pulposus, the posterior longitudinal ligaments, and the annulus fibrosus may have taken place silently or have been manifest by mild, recurrent lumbar ache. A sneeze, lurch, or other trivial movement may then cause the nucleus pulposus to prolapse, pushing the frayed and weakened annulus posteriorly. Fragments of the nucleus pulposus protrude through rents in the annulus, usually to one side or the other (sometimes in the midline), where they impinge on a root or roots. In more severe cases of disc disease, the nucleus may be entirely extruded and lie epidurally, as a "free fragment." Large protrusions may compress the adjacent root against the articular apophysis or lamina. The protruded material may be resorbed to some extent and

become reduced in size, but often this does not occur, causing chronic irritation of the root or a discarthrosis with posterior osteophyte formation.

The Clinical Syndrome The fully developed syndrome of the common prolapsed intervertebral lower lumbar disc consists of (1) pain in the sacroiliac region, radiating into the buttock, thigh, and sometimes the calf and foot, a symptom broadly termed *sciatica*; (2) a stiff or unnatural spinal posture; and often (3) some combination of paresthesias, weakness, and reflex impairment.

The pain of herniated intervertebral disc varies in severity from a mild aching discomfort to the most severe knife-like stabs that radiate the length of the leg and are superimposed on a constant intense ache. Abortive forms of sciatica may produce aching discomfort only in the lower buttock and thigh and occasionally only in the lower hamstring or upper calf. With the most severe pain, the patient is forced to stay in bed, avoiding the slightest move-

ment; a cough, sneeze, or strain is intolerable. The patient is usually most comfortable lying on his or her back with legs flexed at the knees and hips and the shoulders raised on pillows to obliterate the lumbar lordosis. For some patients, a lateral decubitus position is more comfortable. Free fragments of disc that find their way to a lateral and posterior position in the spinal canal may produce the opposite situation, one whereby the patient is unable to extend the spine and lie supine. When the condition is less severe, walking is possible, though fatigue sets in quickly, with a feeling of heaviness and drawing pain. Sitting and standing up from a sitting position are particularly painful. The pain is usually located deep in the buttock, just lateral to and below the sacroiliac joint, and in the posterolateral region of the thigh, with radiation to the calf and infrequently to the heel and other parts of the foot. Radiation of pain into the foot should at least raise the suspicion of an alternative cause of nerve damage. It is noteworthy and surprising to patients that a lumbar disc protrusion sometimes causes little back pain, although in these circumstances there is often deep tenderness over the lateral process or facet joint adjacent to the protrusion. Pain is also characteristically provoked by pressure along the course of the sciatic nerve at the classic points of Valleix (sciatic notch, retrotrochanteric gutter, posterior surface of thigh, head of fibula). Pressure at one point may cause radiation of pain and tingling down the leg.

Elongation of the nerve root by straight-leg raising or by flexing the leg at the hip and extending it at the knee (Lasègue maneuver) is the most consistent of all pain-provoking signs, as discussed earlier. When sciatica is severe, straight-leg raising is restricted to 20 to 30 degrees of elevation; when the condition is less severe or with improvement, the angle formed by the leg and bed widens, finally to almost 90 degrees, in patients with flexible backs and limbs. During straight-leg raising, the patient can distinguish between the discomfort of ordinary tautness of the hamstring and the sharper, less familiar root pain, particularly when asked to compare the experience with that on the normal side. Many variations of the Lasègue maneuver have been described (with numerous eponyms), the most useful of which is accentuation of the pain by dorsiflexion of the foot (Bragard sign) or of the great toe (Sicard sign). The Lasègue maneuver with the healthy leg may evoke pain, but usually of lesser degree and always on the side of the spontaneous pain (Fajersztajn sign). The presence of this crossed straight-leg-raising sign is strongly indicative of a ruptured disc as the cause of sciatica (56 of 58 cases in the series of Hudgkins). With the patient standing, forward bending of the trunk will cause flexion of the knee on the affected side (Neri sign); the degree of limitation of forward bending approximates that of straight-leg raising. Sciatica may be provoked by forced flexion of the head and neck, coughing, or pressure on both jugular veins, all of which increase the intraspinal pressure (Naffziger sign). Marked inconsistencies in response to these tests raise the suspicion of psychologic factors.

With the patient in the upright position, the posture of the body is altered by the pain. He or she stands with the affected leg slightly flexed at the knee and hip, so that only the ball of the foot rests on the floor. The trunk tends to tilt forward and to one side or the other, depending on the relationship of the protruded disc material to the root (see above). This antalgic posture is referred to as *sciatic scoliosis* and is maintained by reflex contraction of the paraspinal muscles, which can be both seen and palpated. In walking, the knee is slightly flexed, and weight bearing on the painful leg is brief and cautious, giving a limp. It is particularly painful for the patient to go up and down stairs.

The signs of more severe spinal root compression are impairment of sensation, loss or diminution of tendon reflexes, and muscle weakness, as summarized in Table 11-1. Generally, disc herniation compresses the root on one side, at the level just below the herniation (see below). Hypotonia is evident on inspection and palpation of the buttock and calf, and the Achilles tendon tends to be less salient. Paresthesias (rarely hyperesthesia or hypoesthesia) are reported by one-third of patients; usually they are felt in the foot, sometimes in the leg. Often there is a diminution of pain perception corresponding to the appropriate dermatome; the location of sensory symptoms conforms to the dermatomal supply of the sensory root (Figs. 9-1 and 9-3). Muscle weakness occurs, but less frequently. In only a few patients is a foot drop (L5 root) or weakness of plantar flexion (S1 root) the main feature of disc protrusion, but it is notable that some of these patients will have little associated pain. The ankle or knee jerk is usually diminished or lost on the side of the lesion. The reflex changes have little relationship to the severity of the pain or sensory loss. Furthermore, compression of the fourth or fifth lumbar root may occur without any change in the tendon reflexes. Bilaterality of symptoms and signs is rare, as is sphincteric paralysis, but they may occur with large central protrusions that compress the cauda equina. The cerebrospinal fluid (CSF) protein is then predictably elevated, usually in the range of 55 to 85 mg/dL, sometimes higher.

As indicated above, herniations of the intervertebral lumbar discs occur most often between the fifth lumbar and first sacral vertebrae (compressing the S1 root) (Fig. 11-4) and between the fourth and fifth lumbar vertebrae (compressing the L5 root). It is important, therefore, to recognize the clinical characteristics of root compression at these two sites, as summarized in Table 11-1. *Lesions of the fifth lumbar root* produce pain in the region of the hip and posterolateral thigh (i.e., sciatica) and, in more than half such cases, lateral calf (to the external malleolus), dorsal surface of the foot, and the first or second and third toes. Pain is elicited by the straight-leg raising test or one of its variants, and protective nociceptive reflexes come into play that limit further elevation of the leg. Paresthesias may be felt in the entire territory or only in its distal parts. The tenderness is in the lateral gluteal region and near the head of the femur. Weakness, if present, involves the extensors of the big toe and of the foot. The ankle jerk may be diminished (more often it is normal), but the knee jerk is hardly ever altered. Walking on the heels may be more difficult and uncomfortable than walking on the toes because of weakness of dorsiflexion.

With *lesions of the first sacral root*, the pain is felt in the midgluteal region, posterior part of the thigh, posterior region of the calf to the heel, outer plantar surface of the foot, and fourth and fifth toes. Tenderness is most pronounced over the midgluteal region (in the region of the sacroiliac joint), posterior thigh areas (sciatica), and calf, and the straight-leg raising tests exaggerate or bring this out. Paresthesias and sensory loss are mainly in the lower part of the leg and outer toes, and weakness, if present, involves the flexor muscles of the foot and toes, abductors of the toes, and hamstring muscles. The Achilles reflex is diminished or absent in the majority of cases. In fact, loss of the Achilles reflex may be the only objective sign. Walking on the toes is more difficult and uncomfortable than walking on the heels because of weakness of the plantar flexors.

The less frequent lesions of the *third and fourth lumbar roots* give rise to pain in the anterior part of the thigh and knee and anteromedial part of the leg (fourth lumbar), with corresponding sensory impairment. The knee jerk is diminished or abolished. L3

motor root lesions may weaken the quadriceps, thigh adductor, and iliopsoas; L4 root lesions weaken the anterior tibial innervated muscles. L1 root pain is projected to the groin and L2 to the lateral hip. Motion of the spine and certain positions are most evocative of root pain; if the pain is constant in all positions, root irritation is seldom the cause.

Much has been made of a distinctive syndrome associated with extreme lateral disc protrusions, particularly those situated within the proximal portion of the intervertebral spinal foramina. Unremitting radicular pain without back pain and a tendency to worsen with extension of the back and torsion toward the side of the herniation are said to be characteristic. Also, in rare instances of lumbar *intradural* disc rupture, there may not be sciatic pain because the free fragment does not impinge on the roots of the cauda equina. Both of these configurations may confound clinical and radiologic diagnosis and make surgery more difficult.

Rarer still are protrusions of *thoracic intervertebral discs* (0.5 percent of all surgically verified disc protrusions, according to Love and Schorn). The four lowermost thoracic interspaces are the most frequently involved. Trauma, particularly hard falls on the heels or buttocks, is an important causative factor. Deep boring spine pain; root pain circling the body or projected to the abdomen or thorax (sometimes simulating visceral disease); paresthesias below the level of the lesion; loss of sensation; both deep and superficial; and paraparesis or paraplegia are the usual clinical manifestations.

A herniated lumbar disc at one interspace may compress more than one root (Fig. 11-4), and it follows that the symptoms will then reflect this involvement. Furthermore, the above descriptions of single root compression refer mainly to signs and symptoms of atypical posterolateral disc protrusion. Very large *central disc protrusions* may compress the entire cauda equina with a dramatic syndrome that includes intense low back and bilateral sciatic pain, incomplete paraparesis, loss of both ankle jerks, and most characteristic, varying degrees of urinary retention and incontinence. This demands immediate surgical attention.

Anomalies of the lumbosacral roots may lead to errors in localization (see descriptions by Postaccini et al). The combined rupture of two or more discs occurs occasionally and further complicates the clinical picture. When both the L5 and S1 roots are compressed by a large herniated disc, the signs of the S1 lesion usually predominate.

Herniation may occur into the adjacent vertebral body, giving rise to a so-called Schmorl nodule. In such cases there are no signs of nerve root involvement, although back pain may be present, sometimes recurrent and referred to the thigh. Most often, these circular densities adjacent to the endplate of the vertebral body are found incidentally on CT or MRI.

Diagnosis When all components of the syndrome are present, diagnosis is easy; but most neurologists prefer to corroborate their clinical impression by MRI of the spine from L3 to S1 or, with less efficacy, by CT. MRI is favored because of the advantages of the sagittal image and the clarity of the anatomic relationships between discs and nerve roots; however, the differences are modest except when the extruded fragment is molded into the adjacent bone (as it is prone to be with laterally extruded fragments) and

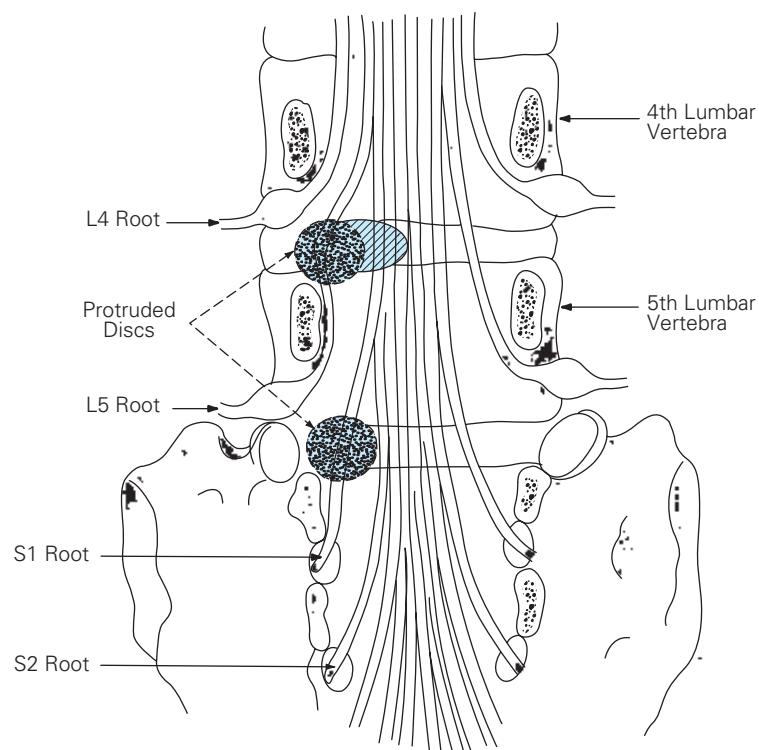

Figure 11-4. Mechanisms of compression of the fifth lumbar and first sacral roots. A lateral disc protrusion at the L4-L5 level usually involves the fifth lumbar root and spares the fourth; a protrusion at L5-S1 involves the first sacral root and spares the fifth lumbar root. Note that a more medially placed disc protrusion at the L4-L5 level (cross-hatched) may involve the fifth lumbar root as well as the first (or second and third) sacral root.

becomes evident on CT. As indicated earlier, we turn to CT-myelography for a refined definition of the root sleeves and may use the EMG to corroborate subtle findings. Usually MRI will demonstrate the extruded disc at the suspected site and will also exclude herniations at other sites or an unsuspected tumor (Fig. 11-5). At the lumbosacral junction there is a wide gap between the posterior margins of the vertebrae and the dural sac, so that a lateral or central protrusion of the L5-S1 disc may fail to distort the dural margin as seen on myelography.

We find, as do Leyshon and coworkers, that the needle EMG study is abnormal, showing fibrillation potentials in denervated muscles after 1 or 2 weeks in over 90 percent of cases. Loss or marked asymmetry of the H reflex is another useful indication of S1 radiculopathy and corroborates the loss of an Achilles reflex. The finding of denervation potentials in the paraspinal muscles (indicating root rather than peripheral nerve lesions) and in muscles that conform to a root distribution is also helpful provided that at least 2 or 3 weeks have elapsed from the onset of root pain. But we would emphasize that, while useful information is sometimes to be gained from EMG, it is needed in only a fraction of cases and often provides only corroborating data.

It is most important to keep in mind that a number of disc abnormalities, frequently observed on MRI and loosely referred to as "herniation," may be incidental findings, unrelated to the patient's symptoms. Jensen and colleagues, in an MRI study of the lumbar spine in 98 asymptomatic adults, found that in more than half there was a symmetrical extension of a disc (or discs) beyond the margins of the interspace (*bulging*). In 27 percent, there was a

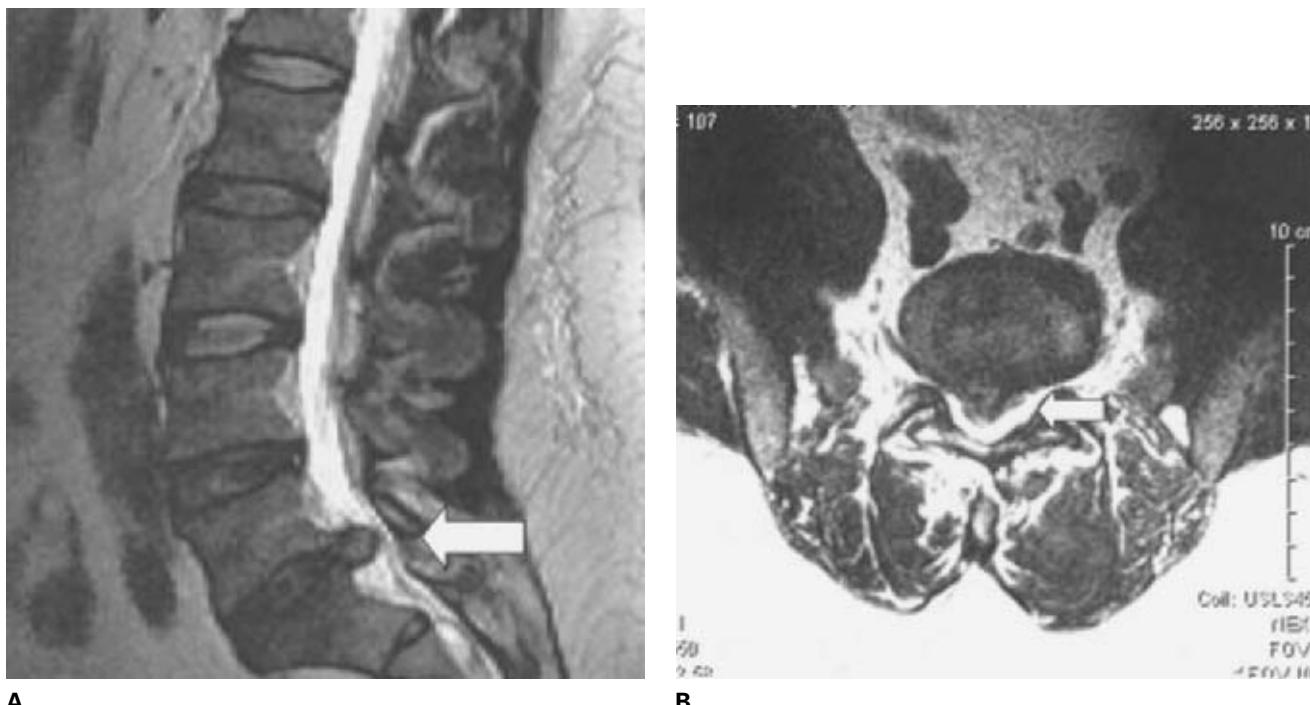

**A**

Figure 11-5. Lumbar disc herniation on T1-weighted MRI. *A*. Sagittal view of large L5-S1 herniated nucleus pulposus (arrow). The extruded material has the same signal characteristics as the normal adjacent disc. *B*. Axial view of same disc (arrow) showing the paracentral mass that obliterates the epidural fat signal and compresses the S1 nerve root.

focal or asymmetrical extension of the disc beyond the interspace (*protrusion*), and in only 1 percent was there more extreme extension of the disc (*extrusion*). These findings emphasize the importance of using precise terms in describing the MRI abnormalities and always evaluating these abnormalities in the light of the patient's symptoms.

Management of Ruptured Lumbar Disc In the treatment of an *acute or chronic rupture of a lumbar disc*, complete bed rest is usually advised and appears to be helpful, although even this time-honored tenet has been questioned by the results of several randomized studies (Vroomen et al). Nonetheless, we still adhere to this form of treatment, and it is associated with marked improvement in the majority of patients. Analgesic medications, either NSAIDs or narcotics, may be required for a few days. In a few but not all patients with severe sciatica, we have been impressed with the temporary relief afforded by administration of oral dexamethasone for several days, 4 mg every 8 h, although this has not been studied systematically. The only indication for emergency surgery is an acute compression of the cauda equina by massive disc extrusion, causing bilateral sensorimotor loss and sphincteric paralysis or severe unilateral motor loss. Although not necessarily the recommended course, it should be pointed out that there are instances where even a dramatic syndrome of cauda equina compression has cleared up after several weeks of bed rest. Traction is of little value in lumbar disc disease, and it is best to permit the patient to find the most comfortable position. After a brief period at rest, the patient can be allowed to resume activities gradually, sometimes with the protection of a brace or light spinal support. The patient may suffer minor recurrence of the pain but should be able to continue his or her usual activities, and most will eventually recover. The more routine measures for man-

aging back pain, as mentioned in an earlier section, may also be helpful.

If the pain and neurologic findings do not subside in response to this type of conservative management or the patient suffers frequent disabling acute episodes, surgical treatment must be considered. Most of the patients requiring surgery because of intractable pain within days after a brief trial of bed rest will be found to have a large extruded disc fragment. This should be preceded by MRI to localize the lesion (and exclude intra- or extradural tumors); if no lesion is found, CT myelography and EMG may be helpful in detecting lateral recess stenosis and other causes of sciatica (see further on). The surgical procedure most often indicated for lumbar disc disease is a hemilaminectomy, with excision of the disc fragment. In cases with sciatic pain due to L4-L5 or L5-S1 disc ruptures, 85 to 90 percent are relieved by operation. Rerupture occurs in approximately 5 percent (Shannon and Paul). Arthrodesis (spinal fusion) of the involved segments is indicated only in cases in which there is extraordinary instability, usually related to extensive surgery or to an anatomic abnormality (such as spondylolisthesis).

In our experience and that of our colleagues, the features that are predictive of better outcome from decompressive surgery are younger age, a clear precipitating event for the back and sciatic pain, clinical features that are restricted to compression of a single nerve root, and the absence of chronic or frequently recurrent back pain. Issues regarding the use of microscopic surgery and various special techniques are best left to surgical colleagues, but the results are comparable for most techniques.

The treatment of nerve root compression with repeated epidural injections of methylprednisolone enjoyed a period of popularity, but controlled studies of this procedure have failed to confirm its sustained efficacy (White et al; Cuckler et al), and the procedure is not without complications. Carette et al have found

only short-term improvement with facet injection, but the ultimate need for surgery was not altered (see further on). Nevertheless, many neurologists have not discarded this form of treatment in view of notable success in selected patients. Chemonucleolysis had been used for the management of lumbar disc lesions; however, as experience with this procedure increased, so did the number of failures and adverse effects, and the procedure has been abandoned. The same is true for the intradural injection of methylprednisolone.

Other Causes of Sciatica and Low Back Pain

An increasing experience with lumbar back pain, gluteal neuralgia, and sciatica has impressed the authors with the large number of such cases that are unsolvable. At one time all these cases were classified as sciatic neuritis or "sacroiliac strain." After Mixter and Barr popularized the concept of prolapsed disc, all sciatica and lumbar pains were ascribed to this condition. Operations became widely practiced, not only for frank disc protrusion but also for "hard discs" (unruptured) and related pathologies of the spine. The surgical results became less and less satisfactory until recently, in large referral centers, as many patients were being seen with unrelieved postlaminectomy pain as with unoperated ruptured discs.

To explain these cases of chronic pain, a number of new pathologic entities, a few of uncertain status, have been described. Entrapment of lumbar roots may be the consequence not only of disc rupture but also of spondylotic spurs with *stenosis of the lateral recess*, cysts of the synovium derived from the facet joint, hypertrophy of facets, compression of the nerve by the pyriformis muscle (one of the questionable syndromes in our view), and rarely, arachnoiditis. Lateral recess stenosis in particular may be a cause of sciatica not relieved by disc surgery (see below, under "Lumbar Stenosis"). Synovial cysts arising from a facet joint are not uncommon, and even very small ones may be situated in the proximal portion of the foramen, thereby causing sciatica. If pain is intractable, surgical removal of the cyst is indicated. Another surprising finding in the course of imaging the spinal canal is a cyst-like dilatation of the perineurial sheath (Tarlov cysts). One or more sacral roots may be involved at points where they penetrate the dura and may be associated with radicular symptoms. There are reports of relief from opening the cysts and freeing the roots, but the results seem more uncertain to us. Sciatica that is temporally linked to the premenstrual period is almost always due to endometriosis involving the nerve at the sciatic notch. We have also observed cases of sciatica that occurred with each pregnancy.

These are but a few of the large number of spinal abnormalities disclosed by newer radiologic techniques. Images of these abnormalities—congenital and developmental stenoses, Paget disease, various apophysial joint abnormalities including the synovial cysts mentioned above, unilateral spondylolisthesis, trochanteric and ischiogluteal bursitis—are presented in the symposium on CT of the lumbar spine, which is perhaps dated in terms of the type of imaging used but still relevant (see References, under "Symposium").

Compression of the cauda equina by epidural tumor, as described further on, most often begins with back pain or sciatica, as a result of deposits of prostatic or breast cancer or myeloma. The sciatic nerve or the plexus from which it originates may be implicated in tumor growths (lymphoma, neurofibrosarcoma). Several inflammatory diseases of the cauda equina produce back pain and bilateral sciatica and may be mistaken for the more usual types of

cauda equina compression; cytomegalovirus infection in AIDS patients, Lyme disease, herpetic infection, and neoplastic meningitis at times behave in this fashion. In all of these, the CSF shows an intense pleocytosis. The Guillain-Barré syndrome may also produce misleading back and radicular pain before weakness is apparent. The caudal roots in these diseases enhance with gadolinium on MRI. A problem not easily classified but having a distinctive clinical profile that should be known to neurologists is that of an osteoid osteoma. These benign tumors characteristically cause severe nocturnal pain located in one region of the parasagittal spine that awakens the patient from a peaceful sleep; also typical is complete relief after aspirin or small doses of other NSAIDs. MRI or CT is required to detect the lesion, since it may not be evident on plain x-rays of the spine.

One must not overlook the possible occurrence of a *lumbosacral plexus neuritis*, a unilateral (occasionally bilateral) disorder akin to brachial neuritis, and acute or subacute sciatic or femoral neuropathy due to diabetes, herpes zoster, or a retroperitoneal mass, any of which may produce a syndrome similar to that of ruptured disc (see Chap. 46).

Finally, it must again be emphasized that, if one sees enough of these cases, the cause of a number of them, particularly those with bilateral vague burning along the sciatic nerve, cannot be settled.

Lumbar Stenosis and Spondylotic Caudal Radiculopathy

In the lumbar region, osteoarthritic or spondylotic changes may lead to compression of one or more caudal roots. The problem is more likely to occur if there is a congenitally narrow lumbar canal. The roots are caught between the posterior surface of the vertebral body and the ligamentum flavum posterolaterally. Lateral recess stenosis, which is a common feature of the spondylotic change (as mentioned above), also contributes to root compression and may be the main problem in some patients. Upon standing or walking (downhill walking is especially difficult), there is in many cases a gradual onset of numbness and weakness of the legs, usually with asymmetrical sciatic, calf, or buttock discomfort that forces the patient to sit down. When this condition is more severe, the patient gains relief by squatting or lying down with the legs flexed at the hips and knees. Usually the numbness begins in one leg, spreads to the other, and ascends as standing or walking continues. Tendon reflexes may disappear, only to return on flexing the spine. Pain in the low back and glutei is variable. Disturbances of micturition and impotence are infrequent unless there has been an additional more acute disc herniation. In some patients with lumbar stenosis, neurologic symptoms persist without relation to body position.

The clinical picture, with its intermittency, corresponds to the so-called intermittent claudication of the cauda equina described by van Gelderen in 1948. Soon thereafter, it was shown by Verbiest to be due not to ischemia but to encroachment on the cauda by hypertrophied apophysial joints, thickened ligaments, and small protrusions or simple bulging of disc material engrafted on a canal that is developmentally shallow in the anteroposterior diameter. Sometimes a slight subluxation at L3-L4 or at L4-L5 is also present. Later it became evident that the canal in these cases is also narrow from side to side (reduced interpedicular distance seen radiographically).

Many patients have acquired, as a result of destabilization of the spinal column, a small degree of *spondylolisthesis* that exag-

gerates the narrowing of the canal. It is when this slippage is unstable that new symptoms are likely to appear abruptly; a new foot drop or urinary retention or overflow incontinence are the ones most common in our experience. This instability is evidenced on conventional x-rays by a change in the diameter of the spinal canal as the patient moves between the flexed and extended position of the back.

Decompression of the spinal canal relieves the symptoms in a considerable proportion of the cases, but the results are quite inconsistent and a thorough discussion of surgical treatment cannot be undertaken here. It will only be remarked that patients must be chosen carefully and success is likely if the clinical features conform to the typical syndrome and there is definite evidence of root compression.

Spondylotic lumbar radiculopathy is the caudal equivalent of spondylotic cervical myelopathy and radiculopathy. Insofar as the former is a cauda equina syndrome, its differential diagnosis is also discussed in Chap. 44, "Diseases of the Spinal Cord."

Osteoarthritis or Osteoarthropathy This, the most frequent cause of mundane back pain, usually occurs in later life and may involve all or any part of the spine. However, it is most prevalent in the cervical and lumbar regions, where it is sometimes confused with discogenic syndromes. The pain is centered in the affected part of the spine, is increased by movement, and is associated with stiffness and limitation of motion. There is a notable absence of systemic symptoms such as fatigue, malaise, and fever, and the pain can usually be relieved by rest; more importantly, however, *there are no signs of radicular compression*. Some patients complain of vague and intermittent pains in the upper or posterior legs, but sciatica is not a feature and the straight-leg raising tests do not elicit it. A slightly flexed posture is preferred. The sitting position is usually comfortable, although stiffness and discomfort are accentuated when the erect posture is resumed.

The severity of the symptoms often bears little relation to the radiologic findings; pain may be present despite minimal radiographic findings; conversely, marked osteophytic overgrowth with spur formation, ridging, bridging of vertebrae, narrowing of disc spaces, subluxation of posterior joints on flexion, and air in the disc spaces can be seen in both symptomatic and asymptomatic persons.

Facet Syndrome The nature of this syndrome has been somewhat clarified in recent years, but its definition is still imprecise. It appears that two distinct painful states can be related to disease of the facet joint and the adjacent lateral recess. In one type, facet hypertrophy gives rise to a lumbar monoradiculopathy indistinguishable from that due to a ruptured disc. Reynolds et al have documented 22 such cases. Of these patients, 16 had an L5 radiculopathy, 3 an S1 radiculopathy, and 3 an L4 radiculopathy; in 15 of the patients there was coexisting back pain. At operation, the spinal root was compressed against the floor of the intervertebral canal by overgrowth of an inferior or superior facet. Foraminotomy and facetectomy, after exploration of the root from the dural sac to the pedicle, relieved the pain in 12 of the 15 operated cases.

In a second more common type, facet hypertrophy gives rise to a focal lumbar back pain, typically parasagittal, sometimes in the midline, with variable tenderness over the joint but without signs of root compression; it is relieved for a variable period by injection of the joint with lidocaine or its derivatives. Often one is uncertain whether it was the analgesic effect on the joint or the infiltration of the region around the nerve root that relieved the

pain. Two controlled studies have provided evidence of the ineffectiveness of another popular treatment for this type of low back pain, namely, corticosteroid injections into the facet joints (Carette et al; Lilius et al). Notwithstanding these studies, we have found the injection of analgesics and steroids in and around the facet to be a useful temporizing measure in some patients. In any case, this group of patients does not require operation. Some patients have discovered that they may obtain temporary relief from facet pain by forcefully twisting or stretching the back and creating an audible pop at the affected joint, comparable to chiropractic manipulation. Over time, they acquire a laxity of the supporting structures of the joint, which may actually perpetuate the problem.

Lumbar Adhesive Arachnoiditis This also is a somewhat vague entity in which the arachnoid membrane is thickened and opaque in the vicinity of the cauda equina. The term is also applied to thickening of the arachnoidal sheaths around roots (normal roots have essentially no epineurium). According to a British review, lumbar arachnoiditis is rare, having been seen in only 80 of 7600 myelograms. Judging by American writings, it is much more frequent (see "Symposium," in the References). The usual clinical features are intractable low-back and leg pain and paresthesias, all positionally sensitive, in combination with neurologic abnormalities referable to lumbar spinal roots. In our patients, multiple myelograms, disc rupture, operative procedures, infections, and subarachnoid bleeding have been causally involved. Some cases have followed spinal anesthesia and even epidural anesthesia by a period of months or years. The presumption is that the dura had been breached and often there were clinical signs of an aseptic meningitis soon after the procedure.

The MRI shows eccentrically thickened meninges in the spinal canal with arachnoid adhesions and collections of CSF that displace nerve roots (Fig. 11-6). Abnormalities are even more striking on CT myelographic studies in which the contrast is broken up and fails to outline the roots. Treatment is unsatisfactory. Lysis of adhesions and administration of intrathecal steroids have been of little value, although some experienced surgeons claim otherwise. Epidural injection of steroids is occasionally helpful, according to some orthopedists.

Ankylosing Spondylitis This disorder, referred to in the past as *rheumatoid spondylitis* and as *von Bechterew* or *Marie-Strumpell arthritis*, affects young adult males predominantly. Its prevalence in the general population has been variously estimated at 1 to 3 per 1000. Approximately 95 percent of patients with ankylosing spondylitis are marked by the histocompatibility antigen HLA-B27 (which is present in only 7 percent of nonaffected persons). Pain, usually centered in the low back, is the main complaint, at least in the initial stages of the disease. Often it radiates to the back of the thighs and groin. At first the symptoms are vague (tired back, "catches" up and down the back, sore back), and the diagnosis may be overlooked for many years. Although the pain is recurrent, limitation of movement is constant and progressive; over time, it dominates the clinical picture. Early in the course of disease there is only "morning stiffness" or an increase in stiffness after periods of inactivity; these findings may be present long before radiologic changes become manifest. Rarely, a cauda equina compression syndrome may complicate ankylosing spondylitis, the result apparently of an inflammatory reaction and later a proliferation of connective tissue in the caudal canal (Matthews). Limitation of chest expansion, tenderness over the sternum, decreased motion and ten-

Figure 11-6. Severe lumbar arachnoiditis causing back pain, sciatica, and paresthesias years after spinal analgesia. Lumbar MRI performed with infusion of gadolinium showing thickened arachnoid and displacement of cauda equina roots by acquired arachnoid cysts.

dency to progressive flexion of the hips, and the characteristic immobility and flexion deformity of the spine (“poker spine”) may be present early in the course of the disease.

The radiologic hallmarks are, at first, destruction and subsequently obliteration of the sacroiliac joints, followed by bony bridging of the vertebral bodies to produce the characteristic “bamboo spine.” When this occurs, the pain usually subsides, but the patient has by then little motion of the back and neck. An unusual additional feature, almost unique to this condition, is an extreme dilatation of the lumbar thecal sac. Ankylosing spondylitis may also be accompanied by the Reiter syndrome, psoriasis, and inflammatory diseases of the intestine (see also Chap. 44). The great risk in this disease is fracture dislocation of the spine from relatively minor trauma, particularly flexion-extension injuries.

Occasionally ankylosing spondylitis is complicated by destructive vertebral lesions. This complication should be suspected whenever the pain returns after a period of quiescence or becomes localized. The cause of these lesions is not known, but they may represent a response to nonunion of fractures, taking the form of an excessive production of fibrous inflammatory tissue. When it is severe, ankylosing spondylitis may involve both hips, greatly accentuating the back deformity and disability.

When it affects the spine, rheumatoid arthritis may be confined to the cervical region; it is considered further on in this chapter.

Neoplastic and Infectious Diseases of the Spine (See Also Chap. 44) *Metastatic carcinoma* (breast, bronchus, prostate, thyroid, kidney, stomach, uterus), multiple myeloma, and lymphoma are the common malignant tumors that involve the spine. The primary lesion may be small and asymptomatic, and the first manifestation of the tumor may be pain in the back due to metastatic deposits. The pain is described as constant and dull; it is often unrelieved by rest and is generally worse at night, often interrupting sleep. Radicular pain may be added, as described earlier in this chapter. At the time of onset of the back pain, there may be no radiographic changes; when such changes do appear, they usually take the form of destructive lesions in one or several vertebral bodies with little or no involvement of the disc space, even in the face of a compression fracture. Before such destructive changes become evident, a CT or radioactive isotope scan may be helpful in detecting areas of osteoblastic activity due to neoplastic or inflammatory disease and characteristic changes are also evident on MRI.

Infection of the vertebral column, *osteomyelitis*, is usually caused by staphylococci and less often by coliforms and mycobacteria. The patient complains of pain in the back, of subacute or chronic nature, which is exacerbated by movement but not materially relieved by rest. Motion becomes limited, and there is percussion-induced tenderness over the spine in the involved segments and pain with jarring of the spine, as occurs when the heels strike the floor. Often these patients are afebrile and do not have a leukocytosis. The erythrocyte sedimentation rate is elevated as a rule. Highly characteristic is the demonstration by CT scanning and MRI of involvement of both the vertebral body and the adjacent intervertebral disc—the finding of a breached disc space is one of the features that differentiates infectious from neoplastic diseases of the spine. A paravertebral mass is often found, indicating an abscess, which may, in the case of tuberculosis, drain spontaneously at sites quite remote from the vertebral column. We have also encountered a number of patients with subacute bacterial endocarditis who complained of severe midline thoracic and lumbar back pain but had no evident infection of the spine. Tuberculous spinal infection and the resultant kyphotic deformity (Pott disease) represent a special condition that is common in developing countries (see pages 611 and 1061).

Special mention should be made of *spinal epidural abscess*, which necessitates urgent surgical treatment. Indeed, in some series, failure to properly identify this lesion has led to cases of paraplegia or death from sepsis. Most often this is due to staphylococcal infection, which is carried in the bloodstream from a septic focus (e.g., furuncle) or is introduced into the epidural space from an osteomyelitic lesion. Another important avenue of infection is the intravenous self-administration of adulterated drugs and use of contaminated needles. Rarely the infection is introduced in the course of a lumbar puncture, epidural injection, or laminectomy for disc excision. In some instances the source of the epidural infection cannot be ascertained. The main symptoms are fever, leukocytosis, and persistent and severe localized pain, intensified by percussion and pressure over the vertebral spines; additionally the pain may acquire a radicular radiation. These symptoms mandate immediate investigation by MRI or CT myelography and surgical intervention, preferably before the signs of paraplegia, sphincter dysfunction, and sensory loss become manifest. Exceptionally small abscesses can be treated successfully with antibiotics alone. This process is discussed further on page 1060. A noninflammatory form of acute epidural compression may be due to hemorrhage (anticoagulant therapy, vascular malformation) and, in the cervical region, to rheumatoid arthritis (see further on).

Intraspinal Hemorrhage Sudden, excruciating midline back pain (*le coup de poignard* or “the strike of the dagger”—often with rapidly evolving paraparesis, urinary retention, and numbness of the legs)—may announce the occurrence of subarachnoid, subdural, or epidural bleeding. The most common causes of such an event are a coagulopathy (mainly from warfarin) and a spinal arteriovenous malformation (AVM), as discussed on pages 1070 and 1072. Spinal arterial aneurysms are much less common underlying lesions. It should be mentioned that back pain of comparable intensity may mark the onset of acute myelitis, spinal cord infarction, compression fracture, and occasionally, Guillain-Barré syndrome.

Pain from Visceral Disease Peptic ulcer disease and carcinoma of the stomach most typically induce pain in the epigastrium. However, if the posterior stomach wall is involved, particularly if there is retroperitoneal extension, the pain may be felt in the thoracic spine, centrally or to one side, or in both locations. If intense, it may seem to encircle the body. The back pain tends to reflect the characteristics of the pain from the affected organ; e.g., if due to peptic ulceration, it appears about 2 h after a meal and is relieved by food and antacids.

Diseases of the pancreas are apt to cause pain in the back, being more to the right of the spine if the head of the pancreas is involved and to the left if the body and tail are implicated. Retroperitoneal neoplasms—e.g., lymphomas, renal cell tumors, sarcomas, and other carcinomas—may evoke pain in the thoracic or lumbar spine with a tendency to radiate to the lower part of the abdomen, groins, anterior thighs, or flank. A tumor in the iliopsoas region often produces a unilateral lumbar ache with radiation toward the groin and labia or testicle; there may also be signs of involvement of the upper lumbar spinal roots. An aneurysm of the abdominal aorta may induce pain localized to an analogous region of the spine. The sudden appearance of lumbar pain in a patient receiving anticoagulants should arouse suspicion of retroperitoneal bleeding. This pain may also be referred to the groin.

Inflammatory diseases and neoplasms of the colon cause pain that may be felt in the lower abdomen, the midlumbar region, or both. As with intense pain higher in the spine, it may have a belt-like distribution. Pain from a lesion in the transverse colon or first part of the descending colon may be central or left-sided; its level of reference is to the second and third lumbar vertebrae. If the sigmoid colon is implicated, the pain is lower, in the upper sacral spine and anteriorly in the suprapubic region or left lower quadrant of the abdomen. Retroperitoneal appendicitis may have an odd referral of pain to the low flank and back.

Gynecologic disorders often manifest themselves by back pain, but their diagnosis is seldom difficult. Thorough abdominal palpation as well as vaginal and rectal examination by an experienced physician, supplemented by ultrasound and CT scanning or MRI, usually discloses the source of pain. The uterosacral ligaments are the most important pelvic source of chronic back pain. Endometriosis or carcinoma of the uterus (body or cervix) may invade these structures, causing pain localized to the sacrum either centrally or more to one side. In endometriosis, the pain begins premenstrually and often merges with menstrual pain, which also may be felt in the sacral region. Rarely, cyclic engorgement of ectopic endometrial tissue may give rise to sciatica and other radicular pain. Malposition of the uterus (retroversion, uterus descended, and prolapse) characteristically gives rise to sacral pain, especially after the patient has been standing for several hours. Changes in posture may also evoke pain here when a fibroma of

the uterus pulls on the uterosacral ligaments. Low back pain with radiation into one or both thighs is a common phenomenon during the last weeks of pregnancy.

Pain due to carcinomatous infiltration of pelvic nerve plexuses is continuous and becomes progressively more severe; it tends to be more intense at night and may have a burning quality. The primary lesion can be inconspicuous and may be overlooked on pelvic examination.

Coccydynia This is the name applied to pain localized to the “tail piece,” the three or four small vestigial bones at the lowermost part of the sacrum. The trauma of childbirth, a fall on the buttocks, avascular necrosis, a glomus tumor, or one of a variety of other rare tumors and anal disorders can sometimes be established as the cause of pain in this region. Far more often, the source remains obscure. In the past, patients in this latter group were indiscriminately subjected to coccygectomy, but more recent studies have demonstrated that most cases respond favorably to injections of local anesthetic and methylprednisolone or to manipulation of the coccyx under anesthesia (Wray et al).

Obscure Types of Low Back Pain and the Question of Psychiatric Disease It is a safe clinical rule that most patients who complain of low back pain have some type of primary or secondary disease of the spine and its supporting structures or of the abdominal or pelvic viscera. However, even after careful examination, there remains a sizable group of patients in whom no pathologic basis for the back pain can be found. Two categories can be recognized: one with postural back pain and another with aggravating psychiatric illness, but there are always cases where the diagnosis remains obscure.

Postural Back Pain Many slender, asthenic individuals and some fat, middle-aged ones have chronic discomfort in the back, and the pain interferes with effective work. The physical examination is unrevealing except for slack musculature and poor posture. The pain is diffuse in the middle or lower region of the back; characteristically, it is relieved by bed rest and induced by the maintenance of a particular posture over a period of time. Spinal manipulation is said to have helped a number of these patients. Pain in the neck and between the shoulder blades is a common complaint among thin, tense, active women and seems to be related to taut trapezius muscles.

Adolescent girls and boys are subject to a form of epiphysial disease of the spinal vertebrae (Scheuermann disease), which, over a period of 2 to 3 years, may cause low back pain upon exercise. Some of these individuals are predisposed to kyphoscoliosis. Also in this age group, spondylolysis, described earlier in this chapter, should be excluded as a cause of persistent back pain.

Psychiatric Illness Low back pain may be a major symptom in patients with hysteria, malingering, anxiety neurosis, depression, and hypochondriasis as well as in many nervous persons whose symptoms do not conform to any of these psychiatric illnesses. Again, it is good practice to assume that pain in the back in such patients may signify disease of the spine or adjacent structures, and this should always be carefully sought. However, even when some organic factors are found, the pain may be exaggerated, prolonged, or woven into a pattern of invalidism because of coexistent primary or secondary psychologic factors. This is especially true when there is the possibility of secondary gain (notably workers’ compensation or settlement of personal injury claims). Patients seeking compensation for protracted low back pain without obvious structural dis-

ease tend, after a time, to become suspicious, uncooperative, and hostile toward their physicians or anyone who might question the authenticity of their illness. One notes in them a tendency to describe their pain vaguely and a preference to discuss the degree of their disability and their mistreatment at the hands of the medical profession. The description of the pain may vary considerably from one examination to another. Often also, the region(s) in which pain is experienced and its radiation are nonphysiologic, and the condition fails to respond to rest and inactivity. These features and a negative examination of the back should lead one to suspect a psychologic factor. A few patients, usually frank malingerers, adopt the most bizarre gaits and attitudes, such as walking with the trunk flexed at almost a right angle (camptocormia), and are unable to straighten up. Or the patient may be unable to bend forward even a few degrees, despite the absence of muscle spasm, and may wince at the slightest pressure, even over the sacrum, which is seldom a site of tenderness unless there is pelvic disease.

The depressed and anxious patient with back pain represents a troublesome problem. A common error is to minimize the importance of anxiety and depression or to ascribe them to worry over the illness and its social effects. In these circumstances, common and minor back ailments—e.g., those due to osteoarthritis and postural ache—are enhanced and rendered intolerable. Such patients are still subjected to unnecessary surgical procedures. The disability seems excessive for the degree of spinal malfunction; misery, irritability, and despair are the prevailing features of the syndrome. One of the most reliable diagnostic features is the response to drugs or other measures that alleviate the depression (see Chap. 57).

Failed Back Syndrome

Surely the most difficult patients to manage are those with chronic low back pain who have already had one or more laminectomies and sometimes a fusion without substantial relief. In one large series of patients operated on for proven disc prolapse, 25 percent were left with troublesome symptoms and 10 percent required further surgery (Weir and Jacobs). In such patients our practice has been to repeat the MRI or CT myelography. In a small number of the patients, it will be found that the disc has reruptured, or that there is a lateral recess stenosis, or that a disc has ruptured at another level. It may happen that the surgeon did not remove all the herniated disc tissue, in which case another operation to remove the remainder will be successful. Electromyography and nerve conduction studies, searching for evidence of a radiculopathy, are helpful. If there is evidence of a radiculopathy but no disc material, or only scar tissue is seen on MRI, one cannot know whether the pain is due to injury from the initial rupture or was the aftermath of surgery. Various explanations are then invoked—radiculitis, lateral recess syndrome, facet syndrome, unstable spine, and lumbar arachnoiditis, described earlier in this chapter (see reviews by Quiles et al and by Long as well as the “Symposium” listed in the References).

One would suppose that these patients with chronic pain could be subdivided into a group with continued radicular pain and another with referred pain from disease of the spine. However, once the pain becomes chronic, the separation is not easy. Pressure over the spine, buttock, or thigh may cause pain to be projected into the leg. Lidocaine blocks of nerve roots have yielded inconsistent results. Occupational injuries, in which workers' compensation or litigation is a factor, make the patient's report of therapeutic effects

almost worthless. Transcutaneous stimulators, posterior column stimulators, intrathecal injections of analgesics, and epidural steroid injections have seldom helped for long in our experience. At present the best that can be offered the patient is weight reduction (in appropriate individuals), stretching and progressive exercise to strengthen abdominal and back muscles, as well as NSAIDs and antidepressant drugs. A trial of massage and other types of physiotherapy or a limited course of spinal chiropractic manipulation is reasonable.

Preventive Aspects of Lower Back Pain

Without doubt these are important. There would be many fewer back problems if adults kept their trunk muscles in optimal condition by regular slow stretching and exercise such as swimming, walking briskly, running, and calisthenic programs. Morning is the ideal time for exercising, since the back of the older adult tends to be stiffest following a night of inactivity. Experimenting with mattresses of various stiffness may be helpful. Sleeping with the back hyperextended and sitting for long periods in an overstuffed chair or a badly designed car seat are particularly likely to aggravate backache. It is estimated that intradiscal pressures are increased 200 percent by changing from a recumbent to a standing position and 400 percent when slumped in an easy chair. Correct sitting posture lessens this pressure. Long trips in a car or plane without change in position put maximal strain on discal and ligamentous structures in the spine. Lifting from a position in which the back is flexed, as in removing a heavy suitcase from the trunk of a car, is risky (one should always lift with the object close to the body). Also, sudden strenuous activity without conditioning and warmup is likely to injure discs and their ligamentous envelopes. Certain families seem disposed to disc rupture and other injuries.

PAIN IN THE NECK, SHOULDER, AND ARM

General Considerations

In this connection, it is useful to distinguish three major categories of painful disease—that originating in the *cervical spine*, in the *brachial plexus*, and in the *shoulder*. Although the distribution of pain from each of these sources may overlap, the patient can usually indicate its site of origin.

Pain arising from the *cervical part of the spine* is felt in the neck and back of the head and may be projected to the shoulder and upper arm; it is evoked or enhanced by certain movements or positions of the neck and is accompanied by limitation of motion of the neck and by tenderness to palpation over the cervical spine.

Pain of brachial plexus origin is experienced in the supraclavicular region, or in the axilla and around the shoulder; it may be worsened by certain maneuvers and positions of the arm and neck (extreme rotation) and is sometimes associated with tenderness of structures above the clavicle. A palpable abnormality above the clavicle may disclose the cause of the plexopathy (aneurysm of the subclavian artery, tumor, cervical rib). The combination of circulatory abnormalities and signs referable to the medial cord of the brachial plexus is characteristic of the *thoracic outlet syndrome*, described further on.

Pain localized to the shoulder region, worsened by motion, and associated with tenderness and limitation of movement, especially internal and external rotation and abduction, points to a ten-

donitis, subacromial bursitis, or tear of the rotator cuff, which is made up of the tendons of the muscles surrounding the shoulder joint. The term *bursitis* is often used loosely to designate these disorders. Shoulder pain, like spine and plexus pain, may radiate into the arm and rarely into the hand, but sensorimotor and reflex changes—which always indicate disease of nerve roots, plexus, or nerves—are absent. Shoulder pain of this type is very common in middle and late adult life. It may arise spontaneously or after unusual or vigorous use of the arm. Local tenderness over the greater tuberosity of the humerus is characteristic. Plain x-rays of the shoulder may be normal or show a calcium deposit in the supraspinatus tendon or subacromial bursa; MRI is able to demonstrate more subtle abnormalities, such as muscle and tendon tears of the rotator cuff or a labral tear of the joint capsule. In most patients the pain subsides gradually with immobilization and analgesics, followed by a program of increasing shoulder mobilization. If it does not, the injection of small amounts of corticosteroids into the bursa, or the site of major pain indicated by passive shoulder movement in the case of rotator cuff injuries, is often temporarily effective and allows the patient to mobilize the shoulder.

Osteoarthritis and osteophytic spur formation of the cervical spine may cause pain that radiates into the back of the head, shoulders, and arm on one or both sides. Coincident compression of nerve roots is manifest by paresthesias, sensory loss, weakness and atrophy, and tendon reflex changes in the arms and hands. Pain in the neck may project into and cause numbness or burning of one half the tongue (the “neck-tongue syndrome”; see page 165). Should bony ridges form in the spinal canal, as described in detail in Chap. 44, the spinal cord may be compressed, with resulting spastic weakness, ataxia, and loss of vibratory and position sense in the legs (*cervical spondylosis*). The bony changes are evident on plain films but are better seen by CT. There may be difficulty in distinguishing cervical spondylosis with root and spinal cord compression from a primary neurologic disease (syringomyelia, amyotrophic lateral sclerosis, or tumor) with an unrelated cervical osteoarthritis, particularly at the C5-C6 and C6-C7 levels. Here the CT-myelogram and MRI are of particular value in revealing compression of the spinal cord, generally with narrowing of the spinal canal to less than 10 to 11 mm in the anteroposterior diameter (see also pages 1073–1076).

A combination of osteoarthritis of the cervical spine with injury to ligaments and muscles when the neck has been forcibly extended and flexed (e.g., the acceleration or “whiplash injury” in rear-end automobile collisions) can create a number of difficult clinical problems. The injury ranges from a minor sprain of muscles and ligaments to severe tearing of these structures, to avulsion of muscle and tendon from vertebral body, and even to vertebral and intervertebral disc damage. The latter lesions can be seen with MRI and, if severe, can result in root or spinal cord compression or, occasionally, in cartilaginous embolization of the spinal cord (see page 1072). Milder degrees of whiplash injury are often complicated by psychologic and compensation factors (see LaRocca for a review of this subject).

Spinal rheumatoid arthritis may be restricted to the cervical apophysial (facet) joints and the atlantoaxial articulation. The usual manifestations are pain, stiffness, and limitation of motion in the neck and pain in the back of the head. In contrast to ankylosing spondylitis, rheumatoid arthritis is rarely confined to the spine. Because of major affection of other joints, the diagnosis is relatively easy to make, but significant involvement of the cervical spine may be overlooked in patients with diffuse disease. In the advanced

stages of the disease, one or several of the vertebrae may become displaced anteriorly, or a synovitis of the atlantoaxial joint may damage the transverse ligament of the atlas, resulting in forward displacement of the atlas on the axis, i.e., atlantoaxial subluxation. In either instance, serious and even life-threatening compression of the spinal cord may occur gradually or suddenly. Cautiously performed lateral radiographs in flexion and extension are useful in visualizing atlantoaxial dislocation or subluxation of the lower segments. Occipital headache and neck pain related to degenerative changes in the upper cervical facets is discussed with other cranial pains on page 164 (so-called third occipital nerve pain).

Cervical Disc Herniation (Table 11-1)

A common cause of neck, shoulder, and arm pain is disc herniation in the lower cervical region; the process is comparable to disc herniation in the lumbar region but gives rise, of course, to a different set of symptoms (Table 11-1). It appears most often without a clear and immediate cause, but it may develop after trauma, which may be major or minor (from sudden hyperextension of the neck, falls, diving accidents, forceful manipulations). The roots most commonly involved are the seventh (in 70 percent of cases) and the sixth (20 percent); fifth- and eighth-root involvement makes up the remaining 10 percent (Yoss et al.).

When the protruded disc lies between the sixth and seventh vertebrae, there is involvement of the *seventh cervical root* as outlined in Table 11-1. The pain is in the region of the shoulder blade, pectoral region and medial axilla, posterolateral upper arm, elbow and dorsal forearm, index and middle fingers, or all the fingers. Tenderness is most pronounced over the medial aspect of the shoulder blade opposite the third to fourth thoracic spinous processes and in the supraclavicular area and triceps region. Paresthesias and sensory loss are most evident in the second and third fingers or may be experienced in the tips of all the fingers. Weakness involves the extensors of the forearm and sometimes of the wrist; occasionally the hand grip is weak as well; the triceps may be weak and the triceps reflex is diminished or absent; the biceps and supinator reflexes are preserved.

With a laterally situated disc protrusion between the fifth and sixth cervical vertebrae, the symptoms and signs are referred to the *sixth cervical root*. The full syndrome is characterized by pain at the trapezius ridge and tip of the shoulder, with radiation into the anterior-upper part of the arm, radial forearm, often the thumb, and sometimes the lateral aspect of the index finger as well. There may also be paresthesias and sensory impairment in the same regions; tenderness in the area above the spine of the scapula and in the supraclavicular and biceps regions; weakness in flexion of the forearm (biceps) and in contraction of the deltoid when sustaining arm abduction; and diminished to absent biceps and supinator reflexes (the triceps reflex is retained or exaggerated in our experience, but some texts record it as slightly diminished in some patients).

The *fifth cervical root* syndrome, produced by disc herniation between the fourth and fifth vertebral bodies, is characterized by pain in the shoulder and trapezius region and by supra- and infraspinatus weakness, manifest by an inability to abduct the arm and rotate it externally with the shoulder adducted (weakness of the supra- and infraspinatus muscles). There may be a slight degree of weakness of the biceps and a corresponding reduction in the reflex, but these are inconsistent findings.

Compression of the *eighth cervical root* at C7-T1 may mimic an ulnar palsy. The pain is along the medial side of the forearm

and the sensory loss is in the distribution of the medial cutaneous nerve of the forearm and of the ulnar nerve in the hand. The weakness largely involves the muscles supplied by the ulnar nerve, namely the intrinsic hand muscles (page 1168). The reflexes are unaffected.

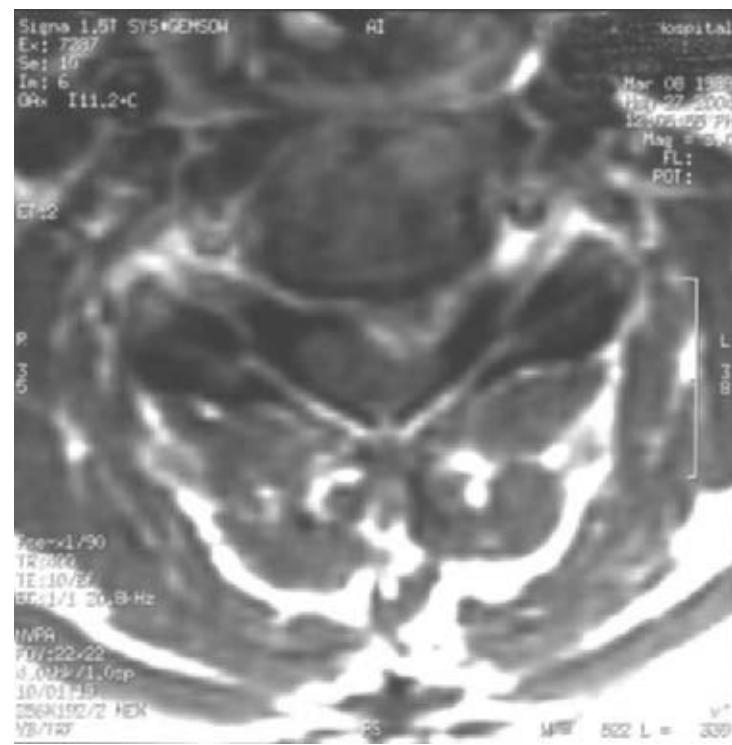

These syndromes are usually incomplete in that only one or several of the typical findings are present. Particularly noteworthy is the occurrence, in laterally placed cervical disc rupture, of isolated weakness without pain, especially with discs at the fifth and sixth levels. Friis and coworkers have described the distribution of pain in 250 cases of herniated disc or spondylotic nerve root compression in the cervical region. Virtually every patient, irrespective of the particular root(s) involved, showed a *limitation in the range of motion of the neck and aggravation of pain with movement (particularly hyperextension)*. Coughing, sneezing, and downward pressure on the head in the hyperextended position usually exacerbated the pain, and traction (even manual) tended to relieve it. Nerve conduction studies, F responses, and EMG are extremely helpful in confirming the level of root compression and distinguishing pain of radicular origin from that originating in the brachial plexus or in individual nerves of the brachium (see page 1165).

As already mentioned, in many of the cervical radicular syndromes, the onset is acute and no traumatic incident can be documented. It is difficult to relate the syndrome to osseous changes that must have been present for years. Even more difficult to explain is the tendency to recovery within a few weeks when movement of the neck is limited by traction or a collar, as discussed below.

Unlike herniated lumbar discs, cervical ones, if large and centrally situated, result in compression of the spinal cord (central disc causing compression of all of the cord; paracentral disc, asymmetrical but bilateral parts of the cord) (Fig. 11-7). The centrally situated disc is often painless, and the cord syndrome may simulate a degenerative neurologic disease (e.g., amyotrophic lateral sclerosis).

A

B

rosis, combined system disease). Bilateral hand numbness, paresthesias, or similar altered sensation is common. Failure to consider a protruded cervical disc in patients with obscure symptoms in the legs, including stiffness and falling, is a common error. A vague sensory change can often be detected several dermatomes below the level of compression. The diagnosis and the level of disc protrusion should be confirmed by CT myelography or by MRI (Fig. 11-7).

Management of Herniated Cervical Disc

Conservative measures should be instituted before turning to surgical removal of the disc unless there are signs of a rapidly or subacutely progressing myelopathy (i.e., leg and arm weakness, hyperreflexia in the legs, gait ataxia, sphincteric dysfunction). In the case of cervical disc with radicular pain, a close-fitting foam collar is quite beneficial. The collar should be fitted so that little flexion and extension of the neck are permitted, but it must remain comfortable enough to encourage consistent use; we have found it helpful to have the patient bring the collar when visiting the doctor in order to assure a proper fit. The patient is advised to wear the collar at all times during the day, especially while riding in a car, unless this becomes completely impractical. Analgesic medication, either NSAIDs or narcotics, may be required for a few days. While considered of little value in lumbar disc disease, traction with a halter around the occiput and chin may be of some benefit in cervical disc syndromes. Treatment can be administered with the patient recumbent, or it can be performed intermittently in the sitting position, using simple equipment that applies 2 to 10 lb of upward traction while the patient is seated and the weight attached to a rope over the top of the door. Many patients obtain a degree of relief in bed by the use of a "cervical pillow," a foam or inflatable neck rest shaped like a dog bone. A similar appliance is helpful during airplane flights.

In most instances the radicular pain subsides over a period of a few weeks or less. Intractable cases may require surgery, especially if there is substantial weakness in the muscles corresponding to the affected root; mild weakness alone is not recognized as an indication for surgery, and in those few cases where weakness alone has occurred, without pain, the same conservative measures outlined above should be implemented. Most often the surgeon tackles this problem through an anterior approach (transdiscally), which leaves the posterior elements intact and assures stability of the spine.

Cervical Spondylosis (See Chap. 44)

This is basically a chronic degenerative disease of the lower cervical spine that narrows the spinal canal and intervertebral foramina, causing compressive injury of the spinal cord and roots. The problem of central disc protrusion, discussed above, often contributes as one component of the reduction in diameter of the spinal canal. Since the main effects of cervical spondylosis are on the cord, this process is discussed in detail in Chap. 44. Cervical spondylosis is also a common cause of neck and arm pain, as described earlier—symptoms that are helped by bed rest and traction; if minor signs of spinal cord and root involvement are present, a collar to limit movement of the head and neck may halt the progression and even lead to improvement. Decompressive laminectomy or anterior excision of single spondylotic spurs and fusion are reserved for instances of the disease with advancing neurologic symptoms or intractable pain (see Chap. 44). As with lumbar stenosis, success is not assured, but almost invariably, progression of symptoms is prevented.

Thoracic Outlet Syndromes

A number of anatomic anomalies occur in the lateral cervical region; these may, under certain circumstances, compress the brachial plexus, the subclavian artery, and the subclavian vein, causing muscle weakness and wasting, pain, and vascular abnormalities in the hand and arm. The condition is undoubtedly diagnosed more often than is justified and the term is applied ambiguously to a number of conditions, some of which are almost certainly nonexistent.

The most frequent of the abnormalities that cause neural compression and are encompassed by the term “thoracic outlet syndrome” are an anomalous incomplete cervical rib, with a sharp fascial band passing from its tip to the first rib; a taut fibrous band passing from an elongated and down-curving transverse process of C7 to the first rib; less often, a complete cervical rib, which articulates with the first rib; and anomalies of the position and insertion of the anterior and medial scalene muscles. Thus, the sites of potential neurovascular compression extend all the way from the intervertebral foramina and superior mediastinum to the axilla. Depending on the postulated abnormality and mechanism of symptom production, the terms *cervical rib*, *anterior scalene*, *costoclavicular*, and *neurovascular compression* have been applied to this syndrome. The international anatomic term is *superior thoracic aperture syndrome*. In addition, a *droopy shoulder syndrome* has been identified that ostensibly stretches the brachial plexus and gives rise to similar symptoms; a majority of the patients are women in early or midadult life (female-to-male ratio 5:1) in whom sagging of the shoulders, large breasts, and poor muscular tone may be of importance.

Variations in regional anatomy could explain these several postulated mechanisms, but to this day there is not full agreement about the validity of anterior scalene and costoclavicular syndromes. An anomalous cervical rib, which arises from the seventh cervical vertebra and extends laterally between the anterior and medial scalene muscles and then under the brachial plexus and subclavian artery to attach to the first rib, obviously disturbs the anatomic relationships of these structures and may compress them (Fig. 11-8). However, since an estimated 1.0 percent of the population has cervical ribs, usually on both sides, and only about 10 percent of these persons have neurologic or vascular symptoms (almost always one-sided), other factors must be operative in most instances. Clavicular abnormalities, both congenital and traumatic, and certain occupational activities may also play a part.

The anterior and middle scalene muscles, which flex and rotate the neck, are both inserted into the first rib; the subclavian artery and vein and the brachial plexus must pass between them. Hence abnormalities of insertion and hypertrophy of these muscles were once thought to be causes of the syndrome. However, section of these muscles (scalenectomy) has so rarely altered the symptoms that this mechanism is no longer given credence.

Three neurovascular syndromes have been associated with a rudimentary cervical rib (rarely with a complete cervical rib) and related abnormalities at the thoracic outlet. In all three forms of the syndrome, shoulder and arm pain is a prominent complaint. The discomfort is of the aching type and is felt in the posterior hemithorax, pectoral region, and upper arm. These syndromes sometimes coexist, but more often each occurs independently.

1. *Compression of the subclavian vein*, a rare occurrence causing a dusky discoloration, venous distention, and edema of the arm. The vein may become thrombosed after prolonged exercise, the so-called effort-thrombotic syndrome of Paget and Schroetter.
2. *Compression of the subclavian artery*, which results in ischemia of the limb, may be complicated by digital gangrene and retrograde embolization, also a rare entity. A unilateral Raynaud phenomenon, brittle nails, and ulceration of the fingertips are important diagnostic findings. A supraclavicular bruit is suggestive but not in itself diagnostic of subclavian artery compression. The conventional tests for vascular compression—obliteration of the pulse when the patient, seated and with the arm dependent, takes and holds a full breath, tilts the head back, and turns it to the affected side (Adson test) or abducts and externally rotates the arm and braces the shoulders and turns the head to either side (Wright maneuver)—are not entirely reliable. Sometimes these maneuvers fail to obliterate the radial pulse in cases of proved compression; contrariwise, these tests may be positive in normal persons. Nevertheless, a positive test on the symptomatic side (with reproduction of the patient's symptoms) but not on the other side should suggest a local lesion. The addition of plethysmographic recording of the radial pulse and ultrasound of the vessel adds greatly to the accuracy of these positional tests.
3. *A primarily neurologic syndrome*, characterized by slight wasting and weakness of the hypothenar, interosseous, adductor pollicis, and deep flexor muscles of the fourth and fifth fingers (i.e., the muscles innervated by the lower trunk of the brachial plexus and ulnar nerve). Weakness of the

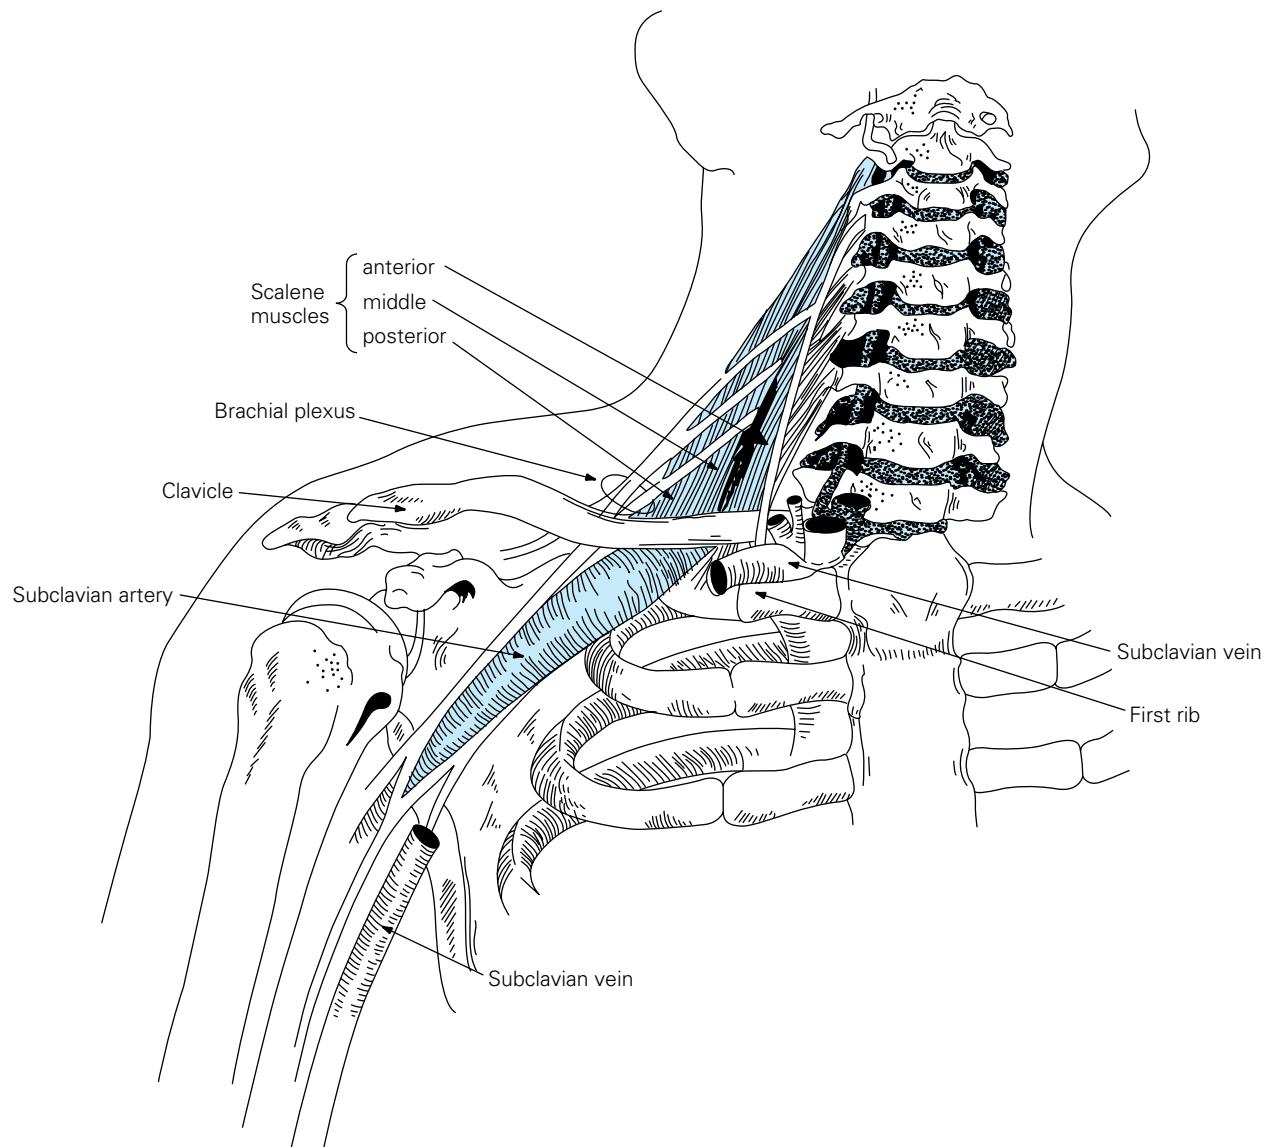

Figure 11-8. Course of the brachial plexus and subclavian artery between the anterior scalene and middle scalene muscles. Dilatation of the subclavian artery just distal to the anterior scalene muscle is illustrated. Immediately distal to the anterior and middle scalene muscles is another potential area of constriction, between the clavicle and the first rib. With extension of the neck and turning of the chin to the affected side (Adson maneuver), the tension on the anterior scalene muscle is increased and the subclavian artery compressed, resulting in a supraclavicular bruit and obliteration of the radial pulse.

flexor muscles of the forearm may be present in advanced cases. Tendon reflexes are usually preserved. In addition, most patients with this form of the syndrome complain of an intermittent aching of the arm, particularly of the ulnar side, and about half of them complain also of numbness and tingling along the ulnar border of the forearm and hand. A loss of superficial sensation in these areas is a variable finding. It may be possible to reproduce the sensory symptoms by firm pressure just above the clavicle or by simple traction on the arm. Vascular features are often absent or minimal in patients with the neurologic form of the syndrome.

Diagnostic measures should include the Adson test or the

Wright maneuver, described earlier, preferably with digital plethysmography to quantitate the degree of positional vascular compromise; also, films of the cervical spine should be obtained looking for a cervical rib or an elongated C7 transverse process (the fibrous bands are not visualized). In the droopy shoulder syndrome, the upper two to four thoracic vertebrae are seen as a result of the low-lying shoulders.

Typically, nerve conduction studies disclose a reduced amplitude of the ulnar sensory potentials. There may be a decreased amplitude of the median motor evoked potentials, a mild but uniform slowing of the median motor conduction velocity, and a prolongation of the F-wave latency. Concentric needle examination of affected hand muscles reveals large-amplitude motor units, sug-

gesting collateral reinnervation. The application of somatosensory evoked potentials may be a useful adjunct to the conventional nerve conduction and EMG studies (Yiannikas and Walsh). Brachial artery angiography is usually reserved for patients with a suspected arterial occlusion, an aneurysm, or an obvious cervical rib. The place of venography in the diagnostic workup is uncertain, for a number of otherwise normal individuals can occlude the subclavian vein by fully abducting the arm.

In the authors' experience, unambiguous instances of thoracic outlet syndrome are not common. This has also been the experience of Wilbourn, whose review of this subject is recommended. Neck and arm pain in slender, neurotic women presents particularly difficult problems in diagnosis; often the physician assumes the presence of a thoracic outlet syndrome, only to discover that operation affords little or no lasting relief. One should be skeptical of the diagnosis unless the clinical and EMG criteria enumerated above have been met. Common mistakes are to confuse the thoracic outlet syndrome with carpal tunnel syndrome, ulnar neuropathy or entrapment at the elbow, or cervical radiculopathy due to arthritis or disc disease. Brachial neuritis may have a similar presentation. Imaging studies and careful nerve conduction and EMG studies may be necessary to exclude all of these disorders.

Treatment of the Thoracic Outlet Syndrome A conservative approach is advisable. If the main symptoms are pain and paresthesias, Leffert suggests the use of local heat, analgesics, muscle relaxants, and an assiduous program of special exercises to strengthen the shoulder muscles. Twice a day, holding a 1- or 2-lb weight in each hand, the patient intermittently shrugs and relaxes the shoulders forward and upward, then backward and upward, and then upward, each performed 10 times. In a second exercise, with the weights held at the side, the extended arms are lifted over the head until the backs of the hands meet; again this is done 10 times. In a third exercise, the patient faces a corner of a room and places one hand on each wall; with elbows bent, he or she leans into the wall and at the same time inhales, then exhales as he or she pushes away. A full range of neck motions is then practiced. On such a regimen, some patients experience a relief of symptoms after 2 to 3 weeks. Instruction by a qualified physical therapist is invaluable.

Only if pain is severe and persistent and is clearly associated with the vascular and/or neurogenic features of the syndrome is surgery indicated. The usual approach is through the supraclavicular space, with cutting of fibrous bands and excision of the rudimentary rib. In cases of venous or minor arterial forms of the syndrome, some thoracic surgeons favor the excision of a segment of the first rib through the axilla. Pain is often dramatically relieved, but the sensorimotor defects improve only slightly. Sectioning of the scalenus muscle is endorsed only in exceptional cases, since as already noted, the role of muscle in causing thoracic outlet syndrome has been questioned.

Vasomotor, sudomotor, and trophic changes in the skin, with atrophy of the soft tissues and decalcification of bone, may follow the prolonged immobilization and disuse of an arm (i.e., frozen shoulder syndrome) or leg for whatever reason. The patient may be reluctant to move the limb because of pain or a lack of motivation to get well or for reasons of monetary gain. Surgery in this group of patients is ill-advised, and the physician's efforts should be directed to mobilization of the affected part through an intensive physical therapy program and settlement of litigation if this is a factor.

Other Painful Conditions Originating in the Neck, Brachial Plexus, and Shoulder

The brachial plexus is an important source of shoulder and arm pain. The main disorders are brachial neuritis and metastatic infiltration and radiation damage to the plexus. These disorders are discussed in detail in Chap. 46.

Metastases to the cervical region of the spine are less common than to other parts of the vertebral column. They are, however, frequently painful and may cause root compression. Posterior extension of the tumor from the vertebral bodies or compression fractures may lead to the rapid development of quadriplegia.

The Pancoast tumor, usually a squamous cell carcinoma in the superior sulcus of the lung, may impinge the lower cervical and upper thoracic (T1 and T2) spinal nerves as they exit the spine. In these cases, a Horner syndrome, numbness of the inner side of the arm and hand, and weakness of all muscles of the hand and of the triceps muscle are combined with pain beneath the upper scapula and in the arm. The neurologic abnormalities may occur long before the tumor becomes visible radiographically.

Shoulder injuries (rotator cuff), subacromial or subdeltoid bursitis, periarthritis or capsulitis (frozen shoulder), tendonitis, and arthritis may develop in patients who are otherwise well, but these conditions also occur occasionally as complications of hemiplegia. The pain tends to be severe and extends toward the neck and down the arm into the hand. The dorsum of the hand may tingle without other signs of nerve involvement. Immobility of an arm following myocardial infarction may be associated with pain in the shoulder and arm and with vasomotor changes and secondary arthropathy of the hand joints (shoulder-hand syndrome); after a time, osteoporosis and atrophy of cutaneous and subcutaneous structures occur (Sudeck atrophy or Sudeck-Leriche syndrome). Similar changes may occur in the foot and leg or all articular structures on the side of a hemiplegia or in association with the painful lesions described in the first part of this chapter. These conditions fall within the province of the orthopedist and are not discussed in detail here. The neurologist, however, should know that they can be prevented by proper exercises and relieved by cooling of the affected limb, exercises, and physiotherapy (see further on).

Medial and lateral epicondylitis (tennis elbow) are readily diagnosed by demonstrating tenderness over the affected parts and an aggravation of pain on certain movements of the wrist. We have observed entrapment of the ulnar nerve in some cases of medial epicondylitis.

The pain of the carpal tunnel syndrome (page 1167) often extends into the forearm and sometimes higher and may be mistaken for disease of the shoulder or neck. Similarly, involvement of the ulnar, radial, or median nerves may be mistaken for brachial plexus or root lesions. EMG and nerve conduction studies are helpful in these circumstances.

PAIN CONFINED TO THE EXTREMITIES

Arthritis of the Extremities The principal symptom of *osteoarthritis* is pain brought on by activity and relieved by rest. Stiffness after sitting and immediately upon arising in the morning is common but seldom persists for more than a few minutes. The more common locations are the terminal phalanges, carpometacarpal joint of the thumb, knees, hips, and spine. *Rheumatoid arthritis* most commonly involves the proximal interphalangeal and meta-

carpophalangeal joints, toes, wrists, ankle, knee, elbow, hip, and shoulder.

Polymyalgia Rheumatica (See also page 1281) This syndrome is observed in middle-aged and elderly persons and is characterized by severe pain, aching, and stiffness in the proximal muscles of the limbs and a markedly elevated erythrocyte sedimentation rate. The shoulders are most affected, but half of these patients have hip or neck pain as well. Constitutional symptoms (loss of weight, fever, and anemia) and articular swelling are less consistent manifestations. A few patients have pitting edema of the hands or feet, as illustrated in the review by Salvarini and colleagues, which is recommended; others have knee or wrist arthritis or carpal tunnel syndrome. Arthroscopy and MRI suggest that the pain originates in a synovitis or, sometimes more accurately, a bursitis, and in an inflammation of periarticular structures. The fundamental cause is not known.

Activity of the disease correlates with elevation of the sedimentation rate, almost always above 40 mm/h and typically higher than 70 mm/h; unlike the case in polymyositis, with which it is confused by the uninitiated, creatine kinase levels are normal. In many patients, polymyalgia rheumatica is associated with giant-cell (temporal, or cranial) arteritis, which may be its only symptomatic expression of the disease (pages 159, 215, and 731). The arteritis may affect one or both optic nerve heads; blindness is the main risk of the disease.

Treatment This disorder is self-limited, lasting 6 months to 2 years, and responds dramatically to corticosteroid therapy, although this may have to be continued in low dosage for several months or a year or longer. We begin treatment with 20 mg of prednisone if there is no evidence of temporal arteritis (which requires higher doses). The absence of improvement in a few days should bring the diagnosis into question. The degree of hip and shoulder pain is the best guide to the duration of steroid therapy and the rate at which the drug is withdrawn, usually in very small increments every 2 weeks. The sedimentation rate or C-reactive protein can be used as an ancillary guide, but neither alone is adequate to alter the medication schedule.

Arteriosclerosis Obliterans Atherosclerosis of large and medium-sized arteries, the most common vascular disease of humans, often leads to symptoms that are induced by exercise (intermittent claudication) but may also occur at rest (ischemic rest pain). The diabetic patient is especially susceptible. The muscle pain that is brought on by exercise and promptly relieved by rest most frequently involves the calf and thigh muscles. If the atherosclerotic narrowing or occlusion implicates the aorta and iliac arteries, it may also cause hip and buttock claudication and impotence in the male (Leriche syndrome). Ischemic rest pain—and sometimes attendant ulceration and gangrene—is usually localized to the foot and toes; it is the consequence of multiple sites of vascular occlusion. Pain at rest is characteristically worse at night and totally or partially relieved by dependency.

The examination of such patients will reveal a loss of one or more peripheral pulses, trophic changes in the skin and nails (in advanced cases), and the presence of bruits over or distal to sites of narrowing. The ankle reflexes are often diminished.

Raynaud Phenomenon Painful blanching of the fingers with emotional stress or exposure to cold is the main feature. In many cases, no cause can be discerned. Other so-called secondary cases

are due to partial obstruction of the brachial circulation, as occurs with some of the forms of the thoracic outlet syndrome; with repeated trauma to the hands, as in sculling or with use of a jackhammer; or with cryoglobulinemia, osteosclerotic myeloma, and autoimmune diseases, particularly scleroderma. The Raynaud phenomenon is discussed further on page 467.

Reflex Sympathetic Dystrophy and Causalgia This painful response to injury of the shoulder, arm, or leg, is usually the result of an incomplete nerve injury (see page 121). It consists of protracted pain, characteristically described as "burning," together with cyanosis or pallor, swelling, coldness, pain on passive motion, osteoporosis, and marked sensitivity of the affected part to tactile stimulation. The condition has been variously described under such terms as *Sudeck atrophy*, *posttraumatic osteoporosis* (in which case the bone scan may show increased local uptake of radioactive nuclide), and the related *shoulder-hand syndrome*. The current term is *complex regional pain syndrome*. The pain syndrome when it occurs in isolation is referred to as *causalgia*. Pharmacologic or surgical sympathectomy appears to relieve the symptoms in some patients. In others, with a hypersensitivity of both C-fiber receptors and postganglionic sympathetic fibers, it is not helpful. This subject is discussed further on page 121.

Neuroma Formation after Nerve Injury Persistent and often incapacitating pain and dysesthesias may follow any type of injury that leads to partial or complete interruption of a nerve, with subsequent *neuroma formation* or *intraneuronal scarring*—fracture, contusion of the limbs, compression from lying on the arm in a drunken stupor, severing of sensory nerves in the course of surgical operations or biopsy of nerve, or incomplete regeneration after nerve suture. It is stated that the nerves in these cases contain a preponderance of unmyelinated C fibers and a reduced number of A- δ fibers; this imbalance is presumably related to the genesis of painful dysesthesias. These cases are best managed by complete excision of the neuromas with end-to-end suture of healthy nerve, but not all cases lend themselves to this procedure.

Another special type of neuroma is the one that forms at the end of a nerve severed at amputation (stump neuroma). Pain from this source is occasionally abolished by relatively simple procedures such as injection of lidocaine, resection of the distal neuroma, proximal neurotomy, or resection of the regional sympathetic ganglia.

Erythromelalgia This rare disorder of the microvasculature produces a burning pain and bright red color change, usually in the toes and forefoot and sometimes in the hands, in association with changes in ambient temperature. Since it was first described by Weir Mitchell in 1878, many articles have been written about it, but the cause of the primary form is still obscure. Each patient has a temperature threshold above which symptoms appear and the feet become bright red, warm, and painful. The afflicted patient rarely wears stockings or regular shoes, since these tend to bring out the symptoms. The pain is relieved by walking on a cold surface or soaking the feet in ice water and by rest and elevation of the legs. The peripheral pulses are intact, and there are no motor, sensory, or reflex changes. The review by Layzer is recommended.

Most cases are idiopathic, some familial and inherited as a dominant trait. There are rare secondary forms of the disease, the most important one being that associated with essential thrombocythemia (up to one-quarter of patients may have erythromelalgia as the first symptom) but also with other myeloproliferative dis-

orders such as polycythemia vera and with collagen vascular diseases, including thrombotic thrombocytopenic purpura (TTP), during the use of calcium channel blockers and certain dopaminergic agonists such as pergolide and bromocriptine, and with occlusive vascular diseases. Some instances arise as a result of a painful polyneuropathy (more often in these latter conditions, the redness and warmth are constant and the result of damage to sympathetic nerve fibers; see Chap. 46).

Treatment According to Abbott and Mitts and others, aspirin is useful in the treatment of paroxysms of secondary erythromelalgia and of some primary cases as well; others recommend methysergide maleate (Pepper). Even small doses of aspirin provide relief within an hour, lasting for several days, a feature that is diagnostic. Reynolds and colleagues report that cyclosporine was of great benefit in a case of familial erythromelalgia that had not responded to other medications.

A similar condition, restricted in topography to the region of an acquired nerve or skin injury, has been described by Ochoa under the term *ABC syndrome* (angry, backfiring C-nociceptors). Episodes of pain and cutaneous vasodilation were induced by mechanical or thermal stimulation and relieved by cooling. There may be persistent hyperalgesia over the affected area. Lance has suggested that a similar mechanism is operative in the “red ear syndrome” as a result of irritation of the third cervical root.

We have seen several patients with a similar bilateral hand pain but with only minor changes in color and temperature; cooling eliminated the symptoms temporarily but no cause could be assigned.

Myofascial Pain Syndrome (Fibromyalgia) A confusing problem in the differential diagnosis of neck and limb pain is posed by the patient with pains that are clearly musculoskeletal in origin but are not attributable to any of the aforementioned diseases of the spine, articular structures, or nerves. The pain is localized to certain points in skeletal muscles, particularly the large muscles of the neck and shoulder girdle, arms, and thighs. Ill-defined, tender nodules or cords can be felt in the muscle tissue (page 1281). Excision of such nodules reveals no sign of inflammation or other disease process. The currently fashionable terms *myofascial pain syndrome*, *fibromyalgia*, and *fibrositis* have been attached to the syndrome, depending on the particular interest or personal bias of the physician. Many of the patients are tense, sedentary women, and there is a strong association with the equally vague chronic fatigue syndrome (page 435). Some relief is afforded by procaine injections, administration of local vapocoolants, stretching of underlying muscles (“spray and stretch”), massage, etc., but the results in any given individual are unpredictable.

SECTION 3

DISORDERS OF THE SPECIAL SENSES

The four chapters in this section are concerned with the clinical aspects of the highly specialized functions of taste and smell, vision, hearing, and the sense of balance. These special senses and the cranial nerves that subserve them represent the most finely developed parts of the sensory nervous system. The sensory dysfunctions of the eye and ear are, of course, the domain of the ophthalmologist and otologist, but they are of interest to the neurologist as well. Some of them reflect the presence of serious systemic disease, and others represent the initial or leading manifestation of neurologic disease. It is from both these points of view that they are considered here. In keeping with the general scheme of this text, the disorders of the special senses (and of ocular movement) are considered in a particular sequence: first, the presentation of certain facts of anatomic and physiologic importance, followed by their cardinal clinical manifestations of their derangements, and then by a consideration of the syndromes of which these manifestations are a part. Because of their specialized nature, some of the diseases that produce these syndromes are discussed here rather than in later chapters of this book.

CHAPTER 12

DISORDERS OF SMELL AND TASTE

The sensations of smell (olfaction) and taste (gustation) are suitably considered together. Physiologically, these modalities share the singular attribute of responding primarily to chemical stimuli; i.e., the end organs that mediate olfaction and gustation are chemoreceptors. Also, taste and smell are interdependent clinically; appreciation of the flavor of food and drink depends to a large extent on their aroma, and an abnormality of one of these senses is frequently misinterpreted as an abnormality of the other. In comparison to sight and hearing, taste and smell play a relatively unimportant role in the life of the individual. However, the role of chemical stimuli in communication between humans has not been fully explored. Pheromones (*pherein*, “to carry”; *hormon*, “exciting”), that is, odorants exuded from the body as well as perfumes, play a part in sexual attraction; noxious body odors repel. Agosta has provided an extensive review of this aspect of the subject. In certain vertebrates the olfactory system is remarkably well developed, rivaling the sensitivity of the visual system, but it has been stated that even humans, in whom the sense of smell is relatively weak, have the capacity to discriminate between as many as 10,000 different odorants (Reed).

Clinically, disorders of taste and smell can be persistently unpleasant, but only rarely is the loss of either of these modalities a serious handicap. Nevertheless, since all foods and inhalants pass through the mouth and nose, these two senses serve to detect noxious odors (e.g., smoke) and to avoid tainted food and potential poisons. The loss of these senses could then have serious consequences. Also, a loss of taste and smell may signify a number of intracranial and systemic disorders, hence they assume clinical importance from this point of view.

OLFACTORY SENSE

Anatomic and Physiologic Considerations

Nerve fibers subserving the sense of smell have their cells of origin in the mucous membrane of the upper and posterior parts of the nasal cavity (superior turbinates and nasal septum). The entire olfactory mucosa covers an area of about 2.5 cm^2 and contains three cell types: the olfactory or receptor cells, which number between 6 and 10 million in each nasal cavity; sustentacular or supporting cells, which maintain the electrolyte (particularly K) levels in the extracellular milieu; and basal cells, which are stem cells and the source of both the olfactory and sustentacular cells during regeneration. The olfactory cells are actually bipolar neurons. Each of these cells has a peripheral process (the olfactory rod) from which project 10 to 30 fine hairs, or cilia. These hair-like processes, which lack motility, are the sites of olfactory receptors. The central processes of these cells, or *olfactory fila*, are very fine (0.2 mm in diameter), unmyelinated fibers that converge to form small fascicles enwrapped by Schwann cells that pass through openings in the cribriform plate of the ethmoid bone into the olfactory bulb (Fig. 12-1). Collectively, the central processes of the olfactory receptor

cells constitute the *first cranial or olfactory nerve*. Notably, this is the only site in the organism where neurons are in direct contact with the external environment. The epithelial surface is covered by a layer of mucus, which is secreted by tubuloalveolar cells (Bowman's glands) and within which there are immunoglobulins A and M, lactoferrin, and lysoenzyme as well as odorant-binding proteins. These molecules are thought to prevent the intracranial entry of pathogens via the olfactory pathway (Kimmelman).

In the olfactory bulb, the receptor-cell axons synapse with granule cells and mitral cells (so-called because they are triangular, like a bishop's miter), the dendrites of which form brush-like terminals or olfactory glomeruli (Fig. 12-1). Smaller “tufted” cells in the olfactory bulb also contribute dendrites to the glomerulus. Approximately 15,000 olfactory-cell axons converge on a single glomerulus. This high degree of convergence is thought to account for an integration of afferent information. The mitral and tufted cells are excitatory; the granule cells—along with centrifugal fibers from the olfactory nuclei, locus ceruleus, and piriform cortex— inhibit mitral cell activity. Presumably, interaction between these excitatory and inhibitory neurons provides the basis for the special physiologic aspects of olfaction.

The axons of the mitral and tufted cells form the olfactory tract, which courses along the olfactory groove of the cribriform plate to the cerebrum. Lying caudal to the olfactory bulbs are groups of cells that constitute the anterior olfactory nucleus (Fig. 12-1). Dendrites of these cells synapse with fibers of the olfactory tract, while their axons project to the olfactory nucleus and bulb of the opposite side; these neurons are thought to function as a reinforcing mechanism for olfactory impulses.

Posteriorly, the olfactory tract divides into medial and lateral olfactory striae. The medial stria contains fibers from the anterior olfactory nucleus; these pass to the opposite side via the anterior commissure. Fibers in the lateral stria originate in the olfactory bulb, give off collaterals to the anterior perforated substance, and terminate in the medial and cortical nuclei of the amygdaloid complex and the prepiriform area (also referred to as the lateral olfactory gyrus). The latter represents the *primary olfactory cortex*, which in humans occupies a restricted area on the anterior end of the parahippocampal gyrus and uncus (area 34 of Brodmann; see Figs. 22-1 and 22-2). Thus olfactory impulses reach the cerebral cortex without relay through the thalamus; in this respect also, olfaction is unique among sensory systems. From the prepiriform cortex, fibers project to the neighboring entorhinal cortex (area 28 of Brodmann) and the medial dorsal nucleus of the thalamus; the amygdaloid nuclei connect with the hypothalamus and septal nuclei. The role of these latter structures in olfaction is not well understood, but presumably they subserve reflexes related to eating and sexual function. As with all sensory systems, feedback regulation occurs at every point in the afferent olfactory pathway.

In quiet breathing, little of the air entering the nostril reaches the olfactory mucosa; sniffing carries the air into the olfactory crypt. To be perceived as an odor, an inhaled substance must be volatile—i.e., spread in the air as very small particles—and sol-

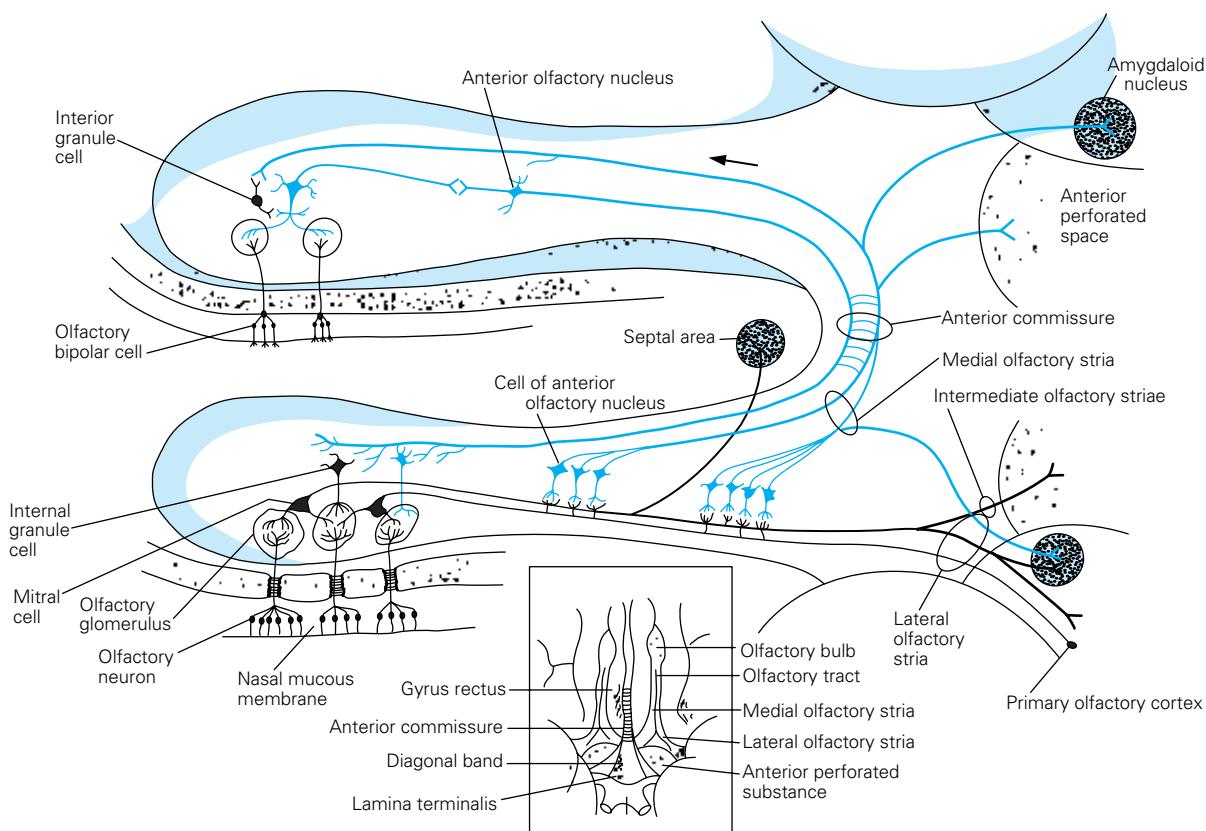

Figure 12-1. Diagram illustrating the relationships between the olfactory receptors in the nasal mucosa and neurons in the olfactory bulb and tract. Cells of the anterior olfactory nucleus are found in scattered groups caudal to the olfactory bulb. Cells of the anterior olfactory nucleus make immediate connections with the olfactory tract. They project centrally via the medial olfactory stria and to contralateral olfactory structures via the anterior commissure. Inset: diagram of the olfactory structures on the inferior surface of the brain (see text for details).

uble in water. Molecules provoking the same odor seem to be related more by their shape than by their chemical quality. When a jet of scented vapor is directed to the sensory epithelium, as by sniffing, a slow negative potential shift called the *electro-olfactogram* (EOG) can be recorded from an electrode placed on the mucosa. The conductance changes that underlie the receptor potential are induced by molecules of odorous material dissolved in the mucus overlying the receptor.

The transduction of odorant stimuli to electrical signals is mediated in part by a GTP-dependent adenylyl cyclase ("G protein"). Like other cyclic AMP pathways, this one utilizes an intracellular second messenger; but in the case of olfaction, the responsible molecule has not been identified. There follow conformational changes in transmembrane receptor proteins and a series of intracellular biochemical events that generate axon potentials.

Intensity of olfactory sensation is determined by the frequency of firing of afferent neurons. The quality of the odor is thought to be provided by "cross-fiber" activation and integration, as described earlier, since the individual receptor cells are responsive to a wide variety of odorants and exhibit different types of responses to stimulants—excitatory, inhibitory, and on-off responses have been obtained. The olfactory potential can be eliminated by destroying the olfactory receptor surface or the olfactory filaments. The loss of EOG occurs 8 to 16 days after severance of the nerve; the receptor cells disappear, but the sustentacular cells are not altered. Most significant is the fact that, as a result of division of the

basal cells of the olfactory epithelium, the olfactory receptor cells are constantly dying and being replaced by new ones. In this respect the chemoreceptors, both for smell and for taste, are unique, constituting the best-defined examples of neuronal regeneration in humans.

The trigeminal system also participates in chemesthesia through undifferentiated receptors in the nasal mucosa. These receptors have little discriminatory ability but a great sensitivity to all irritant stimuli. The trigeminal afferents also release neuropeptides that result in hypersecretion of mucus, local edema, and sneezing. Finally, it should be noted that stimulation of the olfactory pathway at sites other than the receptor cells may also induce olfactory experiences.

The olfactory system adapts quickly to a sensory stimulus, and for sensation to be sustained, there must be repeated stimulation. The olfactory sense differs from other senses in yet another way. It is common experience that an aroma can restore long-forgotten memories of complex experiences. That olfactory and emotional stimuli are strongly linked is not surprising in view of their common roots in the limbic system. Yet, paradoxically, the ability to recall an odor is negligible in comparison with the ability to recall sounds and sights. As Vladimir Nabokov has remarked: "Memory can restore to life everything except smells."

The remarkable evolutionary role of these receptors can be appreciated by the fact that about 2 percent of the human genome exists to express unique odorant receptors (over 500 distinct genes).

The wide diversity of these transmembrane proteins permits subtle differentiation of thousands of different odorant molecules, as outlined by Young and Trask.

This specificity for molecules is encoded neuroanatomically. Different odorant molecules activate specific olfactory receptors. Each olfactory neuron expresses only one allele of one receptor gene. Moreover, each olfactory glomerulus receives inputs from neurons expressing only one type of odorant receptor. In this way, each of the glomeruli is attuned to a distinct type of odorant stimulus. Presumably, this encoding is preserved in the olfactory cortex.

Something is to be learned from olfaction in lower vertebrates, which have a second, physically distinct olfactory system (the vomeronasal olfactory system or organ of Jacobson), in which the repertoire of olfactory receptors is much more limited than in their main olfactory system. This functionally and anatomically distinct olfactory tissue is attuned to, among other odorants, pheromones and thereby importantly influence menstrual, reproductive, ingestive, and defensive behavior (see review of Wysocki and Meredith). The vomeronasal receptors employ different signaling mechanisms than other olfactory receptors and project to the hypothalamus and amygdala via a distinct accessory olfactory bulb.

Clinical Manifestations of Olfactory Lesions

Disturbances of olfaction may be subdivided into four groups, as follows:

1. Quantitative abnormalities: loss or reduction of the sense of smell (anosmia, hyposmia) or, rarely, increased olfactory acuity (hyperosmia)
2. Qualitative abnormalities: distortions or illusions of smell (dysosmia or parosmia)
3. Olfactory hallucinations and delusions caused by temporal lobe disorders or psychiatric disease
4. Higher-order loss of olfactory discrimination (olfactory agnosia)

Anosmia or Loss of the Sense of Smell (Table 12-1) This is the most frequent clinical abnormality, and, if unilateral, will not be recognized by the patient. Unilateral anosmia can sometimes be demonstrated in the hysterical patient on the side of anesthesia, blindness, or deafness. Bilateral anosmia, on the other hand, is a not uncommon complaint, and the patient is usually convinced that the sense of taste has been lost as well (*ageusia*). This calls attention to the fact that taste depends largely on the volatile particles in foods and beverages, which reach the olfactory receptors through the nasopharynx, and that the perception of flavor is a combination of smell, taste, and tactile sensation. This can be proved by demonstrating that such patients are able to distinguish the elementary taste sensations on the tongue (sweet, sour, bitter, and salty). The olfactory defect can be verified readily enough by presenting a series of nonirritating olfactory stimuli (vanilla, peanut butter, coffee, tobacco, etc.), first in one nostril, then in the other, and asking the patient to sniff and identify them. If the odors can be detected and described, even if they cannot be named, it may be assumed that the olfactory nerves are relatively intact (humans can distinguish many more odors than they can identify by name). If they cannot be detected, there is an olfactory defect. Ammonia and similar pungent substances are unsuitable stimuli because they do not

Table 12-1
Main causes of anosmia

<i>Nasal</i>	
Smoking	
Chronic rhinitis (allergic, atrophic, cocaine, infectious—herpes, influenza)	
Overuse of nasal vasoconstrictors	
<i>Olfactory epithelium</i>	
Head injury with tearing of olfactory filaments	
Cranial surgery	
Subarachnoid hemorrhage, meningitis	
Toxic (organic solvents, certain antibiotics-aminoglycosides, tetracyclines, corticosteroids, methotrexate, opiates, L-dopa)	
Metabolic (thiamine deficiency, adrenal and thyroid deficiency, cirrhosis, renal failure, menses)	
Wegener granulomatosis	
Compressive and infiltrative lesions (craniopharyngioma, meningioma, aneurysm, meningoencephalocele)	
<i>Central</i>	
Degenerative diseases (Parkinson, Alzheimer, Huntington)	
Temporal lobe epilepsy	
<i>Malingering and hysteria</i>	

test the sense of smell but have a primary irritating effect on the mucosal free nerve endings of the trigeminal nerves.

A more elaborate scratch-and-sniff test has been developed and standardized by Doty and colleagues (University of Pennsylvania Smell Identification Test). In this test the patient attempts to identify 40 microencapsulated odorants and his or her olfactory performance is compared with that of age- and sex-matched normal individuals. Unique features of this test are a means for detecting malingering and amenability to self-administration. Air-dilution olfactory detection is a more refined way of determining thresholds of sensation and of demonstrating normal olfactory perception in the absence of odor identification. The use of olfactory evoked potentials is being investigated in some electrophysiology laboratories, but their reliability is uncertain. These refined techniques are essentially research tools and are not used in neurologic practice.

The loss of smell usually falls into one of three categories: *nasal* (in which odorants do not reach the olfactory receptors), *olfactory neuroepithelial* (due to destruction of receptors or their axon filaments), and *central* (olfactory pathway lesions). In an analysis of 4000 cases of anosmia from specialized clinics, Hendriks found that three categories of pathology—viral infection of the upper respiratory tracts (the largest group), nasal or paranasal sinus disease, and head injury—accounted for most of the cases.

Regarding the nasal diseases responsible for bilateral hyposmia or anosmia, the most frequent are those in which hypertrophy and hyperemia of the nasal mucosa prevent olfactory stimuli from reaching the receptor cells. Heavy smoking is probably the most frequent cause of hyposmia in clinical practice. Chronic atrophic rhinitis; sinusitis of allergic, vasomotor, or infective types; nasal polypsis; and overuse of topical vasoconstrictors are other common causes. Biopsies of the olfactory mucosa in cases of allergic rhinitis have shown that the sensory epithelial cells are still present, but their cilia are deformed and shortened and are buried under other mucosal cells. Influenza, herpes simplex, and hepatitis virus infections may be followed by hyposmia or anosmia due to destruction of receptor cells; if the basal cells are also destroyed, this may be

permanent. These cells may also be affected as a result of atrophic rhinitis and local radiation therapy or by a very rare type of tumor (*esthesioneuroblastoma*) that originates in the olfactory epithelium. There is also a group of rare diseases in which the primary receptor neurons are congenitally absent or hypoplastic and lack cilia. One of these is the Kallman syndrome of congenital anosmia and hypogonadotropic hypogonadism. A similar disorder occurs in the Turner syndrome and in albinos because of the absence of “olfactory pigment” or some other congenital structural defect.

Anosmia that follows head injury is most often due to tearing of the delicate filaments of the receptor cells as they pass through the cribriform plate, especially if the injury is severe enough to cause fracture. The damage may be unilateral or bilateral. With closed head injury, anosmia is relatively infrequent (6 percent of Sumner's series of 584 cases). Some recovery of olfaction occurs in about one-third of cases over a period of several days to months. Beyond 6 to 12 months, recovery is negligible. Cranial surgery, subarachnoid hemorrhage, and chronic meningeal inflammation may have a similar effect. Strangely, in some of the cases of traumatic anosmia, there is also a loss of taste (ageusia). Ferrier, who first described traumatic ageusia in 1876, noted that there was always anosmia as well—an observation subsequently corroborated by Sumner. Often the ageusia clears within a few weeks. A bilateral lesion near the frontal operculum and paralimbic region, where olfactory and gustatory receptive zones are in close proximity, would best explain this concurrence, but this has not been proven. Obviously the interruption of olfactory filaments alone would not explain ageusia.

In women, olfactory acuity varies throughout the menstrual cycle and may be disordered during pregnancy. Nutritional and metabolic diseases such as thiamine deficiency, vitamin A deficiency, adrenal and perhaps thyroid insufficiency, cirrhosis, and chronic renal failure may give rise to transient anosmia, all as a result of sensorineural dysfunction. A large number of toxic agents—the more common ones being organic solvents (benzene), metals, dusts, cocaine, corticosteroids, methotrexate, aminoglycoside antibiotics, tetracyclines, opiates, and L-dopa—can damage the olfactory epithelium (Doty et al).

It has been reported that a large proportion of patients with degenerative disease of the brain show anosmia or hyposmia, for reasons that are quite unclear. Included in this group are Alzheimer, Parkinson, Huntington, and Pick disease and the Parkinson-dementia syndrome of Guam. The studies relating to this subject have been reviewed by Doty. A number of theories have been proposed to explain these findings, but they are conjectural. It has been known for some time that alcoholics with Korsakoff psychosis have a defect in odor discrimination (Mair et al). In this disorder, anosmia is presumably due to degeneration of neurons in the higher-order olfactory systems involving the medial thalamic nuclei. Hyman and colleagues have remarked on the early neuronal degeneration in the region of the hippocampus in cases of Alzheimer disease, but we know of no systematic studies of the central olfactory connections in this or any other degenerative disorder. Anosmia has been found in some patients with temporal lobe epilepsy and particularly in such patients who had been subjected to anterior temporal lobectomy. In these conditions, Andy and co-workers have found an impairment in discriminating the quality of odors and in matching odors with test objects seen or felt.

As with other sensory modalities, olfaction (and taste) are diminished with aging. The receptor cell population is depleted, and if the loss is regional, neuroepithelium is slowly replaced with res-

piratory epithelium (which is normally present in the nasal cavity and serves to filter, humidify, and warm incoming air). Neurons of the olfactory bulb may also be reduced as part of the aging process.

Bilateral anosmia is an increasingly common manifestation of *malingering*, now that it has been recognized as a compensable disability by insurance companies. The fact that true anosmics will complain inordinately of a loss of taste (but show normal taste sensation) may help to separate them from malingerers. If it were to be perfected, testing of olfactory evoked potentials would be of use here.

The nasal epithelium or the olfactory nerves themselves may be affected in Wegener granulomatosis and by craniopharyngioma. A meningioma of the olfactory groove may impinge on the olfactory bulb and tract and may extend posteriorly to involve the optic nerve, sometimes with optic atrophy; if combined with papilledema on the opposite side, these abnormalities are known as the Foster Kennedy syndrome (page 213). A large aneurysm of the anterior cerebral or anterior communicating artery may produce a similar constellation. With tumors confined to one side, the anosmia may be strictly unilateral, in which case it will not be reported by the patient but will be found on examination. Children with anterior meningoencephaloceles are usually anosmic and, in addition, may exhibit cerebrospinal fluid (CSF) rhinorrhea when the head is held in certain positions. Injury of the cribriform plate and hydrocephalus are other causes of CSF rhinorrhea. These defects in the sense of smell are attributable to lesions of either the receptor cells and their axons or the olfactory bulbs, and current test methods do not distinguish between lesions in these two localities. It is not known whether olfactory symptoms may be produced by lesions of the anterior perforated space or of the medial and lateral olfactory striae. In some cases of increased intracranial pressure, olfactory sense has been impaired without evidence of lesions in the olfactory bulbs.

The term *specific anosmia* has been applied to an unusual olfactory phenomenon in which a person with normal olfactory acuity for most substances encounters a particular compound or class of compounds that is odorless to him or her, although obvious to others. In a sense, this is a condition of “smell blindness,” analogous to color blindness. The basis of this disorder is unclear, although there is evidence that specific anosmia for musky and urinous odors is inherited as an autosomal recessive trait (see Amoore).

Whether a true *hyperosmia* exists is a matter of conjecture. Neurotic individuals may complain of being unduly sensitive to odors, but there is no proof of an actual change in their threshold of perception of odors. During migraine attacks and in some cases of aseptic meningitis, the patient may be unusually sensitive not only to light and sound but sometimes to odors as well.

Dysosmia or Parosmia These terms refer to distortions of odor perception where an odor is present. Parosmia may occur with local nasopharyngeal conditions such as empyema of the nasal sinuses and ozena. In some instances the abnormal tissue itself may be the source of unpleasant odors; in others, where partial injuries of the olfactory bulbs have occurred, parosmia is in the nature of an olfactory illusion. Parosmia may also be a troublesome symptom in middle-aged and elderly persons with a depressive illness, who may report that every article of food has an extremely unpleasant odor (cacosmia). Sensations of disagreeable taste are often associated (cacogeusia). Nothing is known of the basis of this state; there is usually no loss of discriminative sensation.

The treatment of parosmia is difficult. The use of antipsychotic drugs has given unpredictable results. Claims for the efficacy of zinc and vitamins have not been verified. Some reports indicate that repeated anesthetization of the nasal mucosa reduces or abolishes the parosmic disturbance. In many cases the disorder subsides spontaneously. Minor degrees of parosmia are not necessarily abnormal, for unpleasant odors have a way of lingering for several hours and of being reawakened by other olfactory stimuli (phantosmia), as every pathologist knows.

Olfactory Hallucinations These are always of central origin. The patient claims to smell an odor that no one else can detect (phantosmia). Most often this is due to temporal lobe seizures ("uncinate fits"), in which circumstances the olfactory hallucinations are brief and accompanied by an alteration of consciousness and other manifestations of epilepsy (page 277).

If the patient is convinced of the presence of a hallucination and also gives it personal reference, the symptom assumes the status of a delusion. The combination of olfactory hallucinations and delusions of this type signifies a psychiatric illness. Zilstorff has written informatively on this subject. There is often a complaint of a large array of odors, most of them foul. In most cases, the smells seem to emanate from the patient (intrinsic hallucinations); in others, they seem to come from an external source (extrinsic hallucinations). Both types vary in intensity and are remarkable with respect to their persistence. They may be combined with gustatory hallucinations. According to Pryse-Phillips, who took note of the psychiatric illness in a series of 137 patients with olfactory hallucinations, most were associated with endogenous depression and schizophrenia. In schizophrenia, the olfactory stimulus is usually interpreted as arising externally and as being induced by someone for the purpose of upsetting the patient. In depression, the stimulus is usually intrinsic and is more overwhelming. The patient uses all manner of ways to get rid of the perceived stench, the usual ones being excessive washing and use of deodorants; the condition may lead to social withdrawal. There is some reason to believe that the amygdaloid group of nuclei is the source of the hallucinations, since stereotactic lesions here have reportedly abolished both the olfactory hallucinations and the psychiatric disorder (see Chitanondh).

Olfactory hallucinations and delusions may occur in conjunction with Alzheimer dementia, but when this happens one should also consider the possibility of an associated late-life depression. Occasionally olfactory hallucinations are part of an alcohol withdrawal syndrome. Peculiar reactions to smell characterize certain sexual psychopathies. Usually the stimuli appear to be extrinsic, but in this regard it should be noted that odors imagined by normal individuals are also perceived as coming from outside the person through inspired air, and unpleasant ones are more clearly represented than pleasant ones.

Loss of Olfactory Discrimination (Olfactory Agnosia) Finally, one must consider a disorder in which the primary perceptual aspects of olfaction (detection of odors, adaptation to odors, and recognition of different intensities of the same odor) are intact but the capacity to distinguish between odors and their recognition by quality is impaired or lost. In the writings on this subject, this deficit is usually referred to as a disorder of olfactory discrimination. In dealing with other sense modalities, however, the inability to identify and name a perceived sensation would be called an *agnosia*. To recognize this deficit requires special testing, such as matching

to sample, the identification and naming of a variety of scents, and determining whether two odors are identical or different. Such an alteration of olfactory function has been shown to characterize patients with the alcoholic form of Korsakoff psychosis; this impairment is not attributable to impaired olfactory acuity or to failure of learning and memory (Mair et al). As indicated above, the olfactory disorder in the alcoholic Korsakoff patient is most likely due to lesions in the medial dorsal nucleus of the thalamus; several observations in animals indicate that this nucleus and its connections with the orbitofrontal cortex give rise to deficits in odor discrimination (Mair et al; Slotnick and Kaneko). Eichenbaum and associates demonstrated a similar impairment of olfactory capacities in a patient who had undergone extensive bilateral medial temporal lobe resections. The operation was believed to have eliminated a substantial portion of the olfactory afferents to the frontal cortex and thalamus, though there was no anatomic verification of this. In patients with stereotactic or surgical amygdalotomies, Andy and coworkers noted a similar reduction in odor discrimination. Thus it appears that both portions of the higher olfactory pathways (medial temporal lobes and medial dorsal nuclei) are necessary for the discrimination and identification of odors.

GUSTATORY SENSE

Anatomic and Physiologic Considerations

The sensory receptors for taste (taste buds) are distributed over the surface of the tongue and, in smaller numbers, over the soft palate, pharynx, larynx, and esophagus. Mainly they are located in the epithelium along the lateral surfaces of the circumvallate and foliate papillae and to a lesser extent on the surface of the fungiform papillae. The taste buds are round or oval structures, each composed of up to 200 vertically oriented receptor cells arranged like the staves of a barrel. The superficial portion of the bud is marked by a small opening, the taste pore or pit, which opens onto the mucosal surface. The tips of the sensory cells project through the pore as a number of filiform microvilli ("taste hairs"). Fine, unmyelinated sensory fibers penetrate the base of the taste bud and synapse directly with the sensory taste cells, which have no axons.

The taste receptors are activated by chemical substances in solution and transmit their activity along the sensory nerves to the brainstem. There are four primary and readily tested taste sensations that have been long known: salty, sweet, bitter, and sour; recently a fifth, "*umami*"—the taste of glutamate, aspartate, and certain ribonucleotides—has been added. The full range of taste sensations is much broader, consisting of combinations of these elementary gustatory sensations. Older notions of a "tongue map," which implied the existence of specific areas subserving one or another taste, are incorrect. Any one taste bud is capable of responding to a number of sapid substances, but it is always preferentially sensitive to one type of stimulus. In other words, the receptors are only relatively specific. The sensitivity of these receptors is remarkable: as little as 0.05 mg/dL of quinine sulfate will arouse a bitter taste when applied to the base of the tongue.

In recent years, a G-protein transduction system (gustaductin), similar to the one for olfaction, has been found to be operative in signaling taste sensations in the tongue receptors. A discussion of this system can be found in the commentary by Brand cited in the References.

The receptor cells of the taste buds have a brief life cycle

(about 10 days), being replaced constantly by mitotic division of adjacent basal epithelial cells. The number of taste buds, not large to begin with, is gradually reduced with age; also, changes occur in the taste cell membranes, with impaired function of ion channels and receptors (Mistretta). Both gustatory (and olfactory) acuity diminish (everything begins to taste and smell the same). According to Schiffman, taste thresholds for salt, sweeteners, and amino acids are 2 to 2 1/2 times higher in the elderly than in the young. The reduction in the acuity of taste and smell with aging may lead to a distortion of food habits (e.g., excessive use of salt and other condiments) and contribute to the anorexia and weight loss of elderly persons.

Richter has explored the biologic role of taste in normal nutrition. Animals made deficient in sodium, calcium, certain vitamins, proteins, etc., will automatically select the correct foods, on the basis of their taste, to compensate for their deficiency. Interesting genetic polymorphisms in the receptor for sweet substances in rats have been found to underlie differences in the proclivity to ingest sweet substances, and a similar system has been proposed in humans (Chaudhari and Kinnamon).

Neural Innervation of Tongue Regions Sensory impulses for taste arise from several sites in the oropharynx and are transmitted to the medulla via several cranial nerves (V, VII, IX, and X). The main pathway arises on the *anterior two-thirds of the tongue*; these taste fibers first run in the lingual nerve [a major branch of the mandibular-trigeminal (fifth) cranial nerve]. After coursing within the lingual nerve for a short distance, the taste fibers diverge to enter the chorda tympani (a branch of the seventh nerve); thence they pass through the pars intermedia and geniculate ganglion of the seventh nerve to the rostral part of the nucleus of the tractus solitarius in the medulla, where all taste afferents converge (see below). Fibers from the palatal taste buds pass through the pterygopalatine ganglion and greater superficial petrosal nerve, join the facial nerve at the level of the geniculate ganglion, and proceed to the nucleus of the solitary tract (see Fig. 47-3). Possibly, some taste fibers from the tongue may also reach the brainstem via the mandibular division of the trigeminal nerve. The presence of this alternative pathway probably accounts for reported instances of unilateral taste loss that have followed section of the root of the trigeminal nerve and instances in which no loss of taste has occurred with section of the chorda tympani.

From the *posterior third of the tongue*, soft palate, and palatal arches, the sensory taste fibers are conveyed via the glossopharyngeal nerve and ganglion nodosum to the nucleus of the tractus solitarius. Taste fibers from the extreme dorsal part of the tongue and the few that arise from taste buds on the pharynx and larynx run in the vagus nerve. Rostral and lateral parts of the nucleus tractus solitarius, which receive the special afferent (taste) fibers from the facial and glossopharyngeal nerves, constitute the *gustatory nucleus*. Probably both sides of the tongue are represented in this nucleus.

The second sensory neuron for taste has been difficult to track. Neurons of the nucleus solitarius project to adjacent nuclei (e.g., dorsal motor nucleus of the vagus, ambiguus, salivatorius superior and inferior, trigeminal, and facial nerves), which serve viscerovisceral and viscerosomatic reflex functions, but those concerned with the conscious recognition of taste are believed to form an ascending pathway to a pontine parabrachial nucleus. From the latter, two ascending pathways have been traced (in animals). One is the solitariothalamic lemniscus to the ventroposteromedial nu-

cleus of the thalamus. A second passes to the ventral parts of the forebrain, to parts of the hypothalamus (which probably influences autonomic function), and to other basal forebrain limbic areas in or near the uncus of the temporal lobe. Other ascending fibers lie near the medial lemniscus and are both crossed and uncrossed. Experiments in animals indicate that taste impulses from the thalamus project to the tongue-face area of the postrolenticular sensory cortex. This is probably the end station of gustatory projections in humans as well, insofar as gustatory hallucinations have been produced by electrical stimulation of the parietal and/or rolandic opercula (Hausser-Hauw and Bancaud). Penfield and Faulk evoked distinct taste sensations by stimulating the anterior insula.

Clinical Manifestations

Testing of Taste Sensation Unilateral gustatory impairment can be identified by withdrawing the tongue with a gauze sponge and using a moistened applicator to place a few crystals of salt or sugar on discrete parts of the tongue; the tongue is then wiped clean and the subject is asked to report what he or she had sensed. A stimulus that has been used as a surrogate for sour sensation is a low-voltage direct current, the electrodes of which can be accurately placed on the tongue surface. If the taste loss is bilateral, mouthwashes with a dilute solution of sucrose, sodium chloride, citric acid, and caffeine may be used. After swishing, the test fluid is spat out and the mouth rinsed with water. The patient indicates whether he or she had tasted a substance and is asked to identify it. Special types of apparatus (electrogustometers) have been devised for the measurement of taste intensity and for determining the detection and recognition thresholds of taste and olfactory stimuli (Krarup; Henkin et al), but these are beyond the scope of the usual clinical examination.

Causes of Loss of Taste Apart from the loss of taste sensation that accompanies normal aging (see above), smoking, particularly pipe smoking, is probably the most common cause of impairment of taste sensation. Extreme drying of the tongue from any cause may lead to temporary loss or reduction of the sense of taste (*ageusia* or *hypogeusia*), since saliva is essential for normal taste function. Saliva acts as a solvent for chemical substances in food and for conveying them to taste receptors. Dryness of the mouth (*xerostomia*) from inadequate saliva, as occurs in the Sjögren syndrome; hyperviscosity of saliva, as in cystic fibrosis; irradiation of head and neck; and pandysautonomia all interfere with taste. Also, in familial dysautonomia (Riley-Day syndrome), the number of circumvallate and fungiform papillae is reduced, accounting for a diminished ability to taste sweet and salty foods. If unilateral, ageusia is seldom the source of complaint. Taste is frequently lost over one-half of the tongue (except posteriorly) in cases of Bell's palsy (as indicated on page 1181).

A permanent decrease in the acuity of taste and smell (hypogeusia and hyposmia), sometimes associated with perversions of these sensory functions (dysgeusia and dysosmia), may follow influenza-like illnesses. These abnormalities have been associated with pathologic changes in the taste buds as well as in the nasal mucous membranes. In a group of 143 patients who presented with hypogeusia and hyposmia, 87 were of this postinfluenza type, as determined by Henkin and colleagues; the remainder developed their symptoms in association with scleroderma, acute hepatitis, viral encephalitis, myxedema, adrenal insufficiency, malignancy, deficiency of vitamins B and A, and the administration of a wide

variety of drugs. According to Schiffman, more than 250 drugs have been implicated in the alteration of taste sensation. Lipid-lowering drugs, antihistamines, antimicrobials, antineoplastics, bronchodilators, antidepressants, and anticonvulsants are the main offenders. Little is known about the mechanisms by which drugs induce these effects.

Distortions of taste and loss of taste are sources of complaint in patients with certain malignant tumors. Oropharyngeal tumors may, of course, abolish taste by invading the chorda tympani or lingual nerves. Malnutrition due to neoplasm or radiation therapy may also cause ageusia, as pointed out by Settle and colleagues. Some patients with certain carcinomas remark on an increase in their threshold for bitter foods, and some who have been radiated for breast cancer or sublingual or oropharyngeal tumors find sour foods intolerable. The loss of taste from radiation of the oropharynx is usually recovered within a few weeks or months; the reduced turnover of taste buds caused by radiation therapy is only temporary.

An interesting syndrome called *idiopathic hypogeusia*—in which a decreased taste acuity is associated with dysgeusia, hyposmia, and dysosmia—has been described by Henkin and co-workers. Food has an unpleasant taste and aroma, to the point of being revolting (cacogenusia and cacosmia); the persistence of these symptoms may lead to a loss of weight, anxiety, and depression. Patients with this disorder were said to have a decreased concentration of zinc in their parotid saliva and to respond to small oral doses of zinc sulfate. The authors have had no opportunity to confirm these observations.

Another poorly defined disorder is the so-called *burning mouth syndrome*, which occurs mainly in postmenopausal women and is characterized by persistent, severe intraoral pain (particularly

of the tongue). We have seen what we believe to be fragmentary forms of the syndrome in which pain and burning are isolated to the alveolar ridge or gingival mucosa. The oral mucosa appears normal and some patients may report a diminution of taste sensation. A small number of such patients prove to have diabetes or vitamin B₁₂ deficiency, but in most no systemic illness or local abnormality can be found. The few such patients that we have encountered appeared to have a depressive illness, but they responded variably to administration of tricyclic antidepressants. Clonazepam may be useful and capsaicin has been tried with uncertain results. This disorder is commented on in Chap. 10.

Unilateral lesions of the medulla oblongata have not been reported to cause ageusia, perhaps because the nucleus of the tractus solitarius is usually outside the zone of infarction or because there is representation from both sides of the tongue in each nucleus. Unilateral thalamic and parietal lobe lesions, however, have both been associated with contralateral impairment of taste sensation.

As indicated above, a gustatory aura occasionally marks the beginning of a seizure originating in the frontoparietal (suprasylvian) cortex or in the uncus region. Gustatory hallucinations are much less frequent than olfactory ones. Nevertheless, the gustatory sensations were reported in 30 of 718 cases of intractable epilepsy (Haussner-Hauw and Bancaud). During surgery, these investigators produced an aura of disagreeable taste by electrical stimulation of the parietal and frontal opercula and also by stimulation of the hippocampus and amygdala (uncinate seizures). In their view, the low-threshold seizure focus for taste in the temporal lobe is secondary to functional disorganization of the opercular gustatory cortex by the seizure. Gustatory hallucinations were more frequent with right-hemisphere lesions, and in half of the cases, the gustatory aura was followed by a convulsion.

CHAPTER 13

DISTURBANCES OF VISION

The faculty of vision is our most important source of information about the world. Attesting to its importance is the magnitude of its representation in the central nervous system (CNS). The largest part of the cerebrum is committed to vision, including the visual control of movement and the perception of printed words and the form and color of objects. The optic nerve, which is a CNS structure, contains over a million fibers (compared to 50,000 in the auditory nerve). The visual system has special significance in several other respects, and study of this system has greatly advanced our knowledge of the nervous system with respect to both the organization of all sensory neuronal systems as well as the relation of perception to cognition. Indeed, we know more about vision than about any other sensory function. The eyes, because of their diverse composition of epithelial, vascular, collagenous, neural, and pigmentary tissues, are virtually a medical microcosm, susceptible to many diseases. Moreover, the eye's transparent medium permits direct inspection of these tissues and affords an opportunity to observe, during life, many lesions of both neurologic and systemic medical disease.

Since the eye is the sole organ of vision, impairment of visual function, expressed as defects in acuity and alterations of visual fields, obviously stands as the most frequent and important symptoms of eye disease. A number of terms are commonly used to describe visual loss. *Amaurosis* refers to blindness, specifically blindness that is not due to intrinsic disease of the eye itself. *Amblyopia* is a related term denoting a reduction of vision from any cause, ocular or nonocular. *Nyctalopia* is the term for poor twilight or night vision and is associated with extreme myopia, cataracts, vitamin A deficiency, retinitis pigmentosa, and, often, color blindness. There are also positive visual symptoms (phosphenes, visual illusions, and hallucinations), but they are less significant than symptoms of visual loss. Irritation, redness, photophobia, pain, diplopia and strabismus, changes in pupillary size, and drooping or closure of the eyelids are another group of major ocular symptoms and signs. The impairment of vision may be unilateral or bilateral, sudden or gradual, episodic or enduring.

The common causes of failing eyesight vary with age. In infancy, congenital defects, severe myopia, hypoplasia of the optic nerve, optic pits, and coloboma are the main causes. In childhood and adolescence, nearsightedness or myopia and amblyopia due to strabismus are the usual causes, (see Chap. 14), though a pigmentary retinopathy or a retinal, optic nerve, or suprasellar tumor must not be overlooked. In middle age, beginning usually in the fifth decade, farsightedness (presbyopia, a progressive loss of accommodation) is almost invariable (at this age, half or more of the amplitude of accommodative power is lost and must be replaced by plus lenses). Still later in life, cataracts, glaucoma, retinal vascular occlusion and detachments, macular degeneration, and tumor, unilateral or bilateral, are the most frequent causes of visual impairment.

As a rule, *episodic visual loss* in early adult life, often hemianopic in this age group, is due to migraine. The other important cause of transient (weeks) monocular visual loss in this age period is optic neuritis, often a harbinger of multiple sclerosis. Later in life, transient monocular blindness, or *amaurosis fugax*, lasting minutes to hours is more common; it is caused by vascular disease,

particularly stenosis of the ipsilateral carotid artery or, less often, to embolism or vasculitis of retinal arterioles. Amaurosis occurs in the child or young adult, in which case systemic lupus erythematosus and the related antiphospholipid syndrome may be responsible, or there may be no discernible cause. A listing of the causes of episodic visual loss is give in Table 13-1. Of course, at any age, diseases of the retina and of other components of the ocular apparatus are important causes of *progressive visual loss*, and the problem may at first be transient.

APPROACH TO THE PROBLEM OF VISUAL LOSS

In the investigation of a disturbance of vision, one must always inquire as to what the patient means when he claims not to see properly, for the disturbance in question may vary from near- or farsightedness to excessive tearing, diplopia, partial syncope, or even giddiness or dizziness. Fortunately the patient's statement can be checked by the measurement of visual acuity, which is the single most important part of the ocular examination. Inspection of the refractive media and the optic fundi—especially the macular region—the testing of pupillary reflexes, and the plotting of visual fields complete this part of the examination. Examination of the eye movements is also essential, particularly if amblyopia predicated on an early-life strabismus is suspected, as discussed in Chap. 14. In the measurement of distance visual acuity the *Snellen chart*, which contains letters (or numbers or pictures) arranged in rows of decreasing size, is used. Each eye is tested separately and, if glasses are required, glasses for distance, not reading glasses, should be used. The letter at the top of the chart subtends 5 min of an arc at a distance of 200 ft (or roughly 60 m). The patient follows rows of letters that can normally be read at lesser distances. Acuity is reported as a nonmathematical fraction that represents the patient's ability compared to that of a person with normal distance vision. Thus, if the patient can read only the top letter at 20 rather than

Table 13-1
Causes of episodic visual loss

Adolescence and young adulthood

- Migraine
- Optic neuritis
- Antiphospholipid antibody syndrome and systemic lupus erythematosus
- Early tumor compression of the optic nerve
- Takayasu aortic arteritis
- Viral neuroretinitis
- Idiopathic

Adulthood

- Carotid stenosis or dissection
- Embolism to the retina
- Intrinsic central retinal artery atherosclerotic disease
- Temporal arteritis (generally over age 55)
- Glaucoma

the normal 200 ft, the acuity is expressed as 20/200 or, if the distance is measured in meters rather than feet, 6/60. If the patient's eyesight is normal, the visual acuity will equal 20/20, or 6/6 using the metric scale. Many persons, especially during youth, can read at 20 ft the line that can normally be read at 15 ft from the chart (20/15) and hence have better than normal vision. Patients with a corrected refractive error should wear their glasses for the test. For bedside testing, a "near card" or newsprint held 14 in. from the eyes can be used and the results expressed in a distance equivalent as if a distance chart had been used. Here, the Jaeger system is sometimes used also (J1 is "normal" vision, corresponding to 20/25, J5 to 20/50, J10 to 20/100, J16 to 20/200, and so on). In young children, acuity can be estimated by having them mimic the examiner's finger movements at varying distances or having them recognize and pick up objects of different sizes from varying distances. In most jurisdictions, a corrected acuity of 20/40 or better in one eye is required to obtain and retain a driver's license.

If the visual acuity (with glasses) is less than 20/20, either the refractive error has not been properly corrected or there is some other reason for the diminished acuity. The possibility of a non-refractive error can usually be ruled out if the patient can read the 20/20 line (not the near card) through a pinhole in a cardboard held in front of the eye. The pinhole permits a narrow shaft of light to fall on the macular fovea (the area of greatest visual acuity) without distortion by the curvature of the lens; this eliminates the eye's optical system, thereby testing the macula alone, and should give an acuity of 20/20 if the structures of the ocular media (cornea, lens, aqueous and vitreous humors) are clear. Minor degrees of visual impairment may be disclosed by alternately stimulating each eye with a bright white or colored object, enabling the patient to compare the intensity of vision in the two eyes. Objects look less bright and colors less saturated when viewed by the faulty eye.

Light entering the eye is focused by the biconvex lens onto the outer layer of the retina. Consequently the cornea, fluid of the anterior chamber, lens, vitreous, and retina itself must be transparent. The clarity of these media can be determined ophthalmoscopically, and a complete examination requires that the pupil be dilated to at least 6 mm in diameter. This is best accomplished by instilling two drops of 2.5 phenylephrine (Neosynephrine) and/or 0.5 to 1.0% tropicamide (Mydriacyl) in each eye after the visual acuity has been measured, the pupillary response recorded, and the intraocular pressure estimated. In elderly persons, lower concentrations of these mydriatics should be used. The mydriatic action of phenylephrine lasts for 3 to 6 h. Very rarely, an *attack of angle-closure glaucoma* (manifesting itself by diminished vision, ocular pain, nausea, and vomiting) may be precipitated by pharmacologic pupillary dilation; this requires the immediate attention of an ophthalmologist.

By looking through a high-plus lens of the ophthalmoscope from a distance of 6 to 12 in., the examiner can visualize opacities in the refractive media; by adjusting the lenses from a high-plus to a zero or minus setting, it is possible to "depth-focus" from the cornea to the retina. Depending on the refractive error of the examiner, lenticular opacities are best seen within the range of +20 to +12. The retina comes into focus with +1 to +1 lenses. The pupil appears as a red circular structure (red reflex), the color being provided by blood in the capillaries of the choroid layer. If all the refractile media are clear, reduced vision that is uncorrectable by glasses is due to a defect in the macula, the optic nerve, or parts of the brain with which they are connected. The main limit of direct ophthalmoscopy is its inability to visualize lesions in the retina that

lie anterior to the equator of the globe; these are seen only by the indirect method.

NONNEUROLOGIC CAUSES OF REDUCED VISION

It is hardly possible within the confines of this chapter to describe all the causes of opacification of the refractive media. Those with the most important medical or neurologic implications are briefly commented upon. Although changes in the refractive media do not involve neural tissue primarily, certain ones assume importance because they are often associated with neurologic disease and provide clues to its presence.

In the *cornea*, the most common abnormality that reduces vision is scarring due to trauma and infection. Ulceration and subsequent fibrosis may occur following recurrent herpes simplex, herpes zoster, and trachomatous infections of the cornea or with certain mucocutaneous-ocular syndromes (Stevens-Johnson, Reiter). Hypercalcemia secondary to sarcoid, hyperparathyroidism, and vitamin D intoxication or milk-alkali syndrome may give rise to precipitates of calcium phosphate and carbonate beneath the corneal epithelium, primarily in a plane corresponding to the interpalpebral fissure—so-called band keratopathy. Other causes include chronic uveitis, interstitial keratitis, corneal edema, lattice corneal dystrophy (amyloid), and long-standing glaucoma. Polysaccharides are deposited in the corneas in some of the mucopolysaccharidoses (Chap. 37), and copper is deposited in hepatolenticular degeneration (Kayser-Fleischer ring, page 831). Crystal deposits may be observed in multiple myeloma and cryoglobulinemia. The corneas are also diffusely clouded in certain lysosomal storage diseases (Chap. 37). Arcus senilis occurring at an early age (due to hypercholesterolemia), sometimes combined with yellow lipid deposits in the eyelids and periorbital skin (xanthelasma), serves as a marker of atherosomatous vascular disease.

In the *anterior chamber* of the eye, a common problem is one of impediment to the outflow of aqueous fluid, leading to excavation of the optic disc and visual loss, i.e., *glaucoma*. In more than 90 percent of cases (of the open-angle type), the cause of this syndrome is unknown; a genetic factor is suspected. The drainage channels in this type appear normal. In about 5 percent, the angle between iris and the peripheral cornea is narrow and blocked when the pupil is dilated (angle-closure glaucoma). In the remaining cases, the condition is due to some disease process that blocks outflow channels—*inflammatory debris of uveitis, red blood cells from hemorrhage in the anterior chamber (hyphema), new formation of vessels and connective tissue on the surface of the iris (rubesis iridis)*, a relatively infrequent complication of ocular ischemia secondary to diabetes mellitus, retinal vein occlusion, or carotid artery occlusion. The visual loss is gradual in open-angle glaucoma and the eye looks normal, unlike the red, painful eye of angle-closure glaucoma. However, some cases of open-angle glaucoma may progress to rapid loss of vision.

Intraocular pressures that are persistently above 20 mmHg may damage the optic nerve over time. This may be manifest first as an arcuate defect in the upper or lower nasal field or as an enlargement of the blind spot, which, if untreated, may proceed to blindness. The classic finding in glaucoma, termed the *Bjerrum field defect*, consists of an arcuate scotoma extending from the blind spot and sweeping around the macula to end in a horizontal line at the nasal equator. Other characteristic glaucomatous field

patterns are winged extensions from the blind spot (Seidel scotoma) and a narrowing of the superior nasal quadrant that may progress to a horizontal edge, corresponding to the horizontal raphe of the retina (nasal step). The damage is at the optic nerve head; with the ophthalmoscope, the optic disc appears excavated and any pallor that is present extends only to the rim of the disc and not beyond, thus distinguishing it from optic neuropathy. Contrary to popular notions among physicians, it is now appreciated that elevated intraocular pressure is only a risk factor for glaucoma and optic damage may be seen in patients with normal pressure.

In the *lens*, cataract formation is the most common and mundane abnormality. The cause of the common type in the elderly is unknown. The “sugar cataract” of diabetes mellitus is the result of sustained high levels of blood glucose, which is changed in the lens to sorbitol, the accumulation of which leads to a high osmotic gradient with swelling and disruption of the lens fibers. Galactosemia is a much rarer cause, but the mechanism of cataract formation is similar, i.e., the accumulation of dulcitol in the lens. In hypoparathyroidism, lowering of the concentration of calcium in the aqueous humor is in some way responsible for the opacification of newly forming superficial lens fibers. Prolonged high doses of chlorpromazine and corticosteroids as well as radiation therapy induce lenticular opacities in some patients. Down syndrome and oculocerebrorenal syndrome (Chap. 38), spinocerebellar ataxia with oligophrenia (Chap. 39), and certain dermatologic syndromes (atopic dermatitis, congenital ichthyosis, incontinentia pigmenti) are also accompanied by lenticular opacities. Myotonic dystrophy (Chap. 50) and, rarely, Wilson disease (Chap. 37) are associated with special types of cataract. Subluxation of the lens, the result of weakening of its zonular ligaments, occurs in syphilis, Marfan syndrome (upward), and homocystinuria (downward).

In the *vitreous humor*, hemorrhage may occur from rupture of a ciliary or retinal vessel. On ophthalmoscopic examination, the hemorrhage appears as a diffuse haziness of part or all of the vitreous or, if the blood is between the retina and the vitreous and displaces the latter rather than mixing with it, takes the form of a sharply defined mass. The common cause is rupture of newly formed vessels of proliferative retinopathy in patients with diabetes mellitus, but there are many others including orbital or cranial trauma, rupture of an intracranial aneurysm or arteriovenous malformation with high intracranial pressure, retinal vein occlusion, sickle cell disease, age-related macular degeneration, and retinal tears, in which the hemorrhage breaks through the internal limiting membrane of the retina. The most common vitreous opacities are the benign “floaters” or “spots before the eyes,” which appear as gray flecks or threads with changes in the position of the eyes; they may be annoying or even alarming until the person stops looking for them.

A sudden burst of flashing lights associated with an increase in floaters may mark the onset of retinal detachment. Patients complaining of bright flashes and spots in vision should be examined with the indirect ophthalmoscope to rule out tears, holes, or detachments. Another common occurrence with advancing age is shrinkage of the vitreous humor and retraction from the retina, causing persistent streaks of light (phosphenes), usually in the periphery of the visual field. The phosphenes, known as *Moore's lightning streaks*, had been thought to be quite benign, but they may indicate incipient retinal or vitreous tears or detachment and require prompt evaluation by an ophthalmologist. They are most prominent on movement of the globe, on closure of the eyelids, at

the moment of accommodation, with saccadic eye movements, and with sudden exposure to dark. The vitreous may be infiltrated by lymphoma originating in the brain; biopsy by planar vitrectomy may be used to establish the diagnosis in those rare instances where the lymphoma is restricted to the eye; its presence can be inferred when there is vitreous infiltration and also a brain lymphoma.

The term *uveitis* refers to an infective or noninfective inflammatory disease that affects any of the uveal structures (iris, ciliary body, and choroid). According to Bienfang and colleagues, uveitis accounts for 10 percent of all cases of legal blindness in the United States. Infective causes of posterior uveitis are toxoplasmal and cytomegalic inclusion disease, occurring mainly in patients with AIDS and other forms of reduced immune function. Noninfective autoimmune types are more frequent in the adult. The inflammation may be in the anterior part of the eye or in the posterior part, behind the iris and extending to the retina and choroid. Anterior uveitis is sometimes linked to ankylosing spondylitis and the HLA B-27 marker, sarcoidosis, and recurrent meningitis (Vogt-Koyanagi-Harada disease); the posterior forms are associated with sarcoidosis, Behcet disease, multiple sclerosis, and lymphoma.

Retinal diseases, particularly age-related macular degeneration and diabetic retinopathy, are a more common cause of blindness than are neurologic diseases, as discussed further on, under “Other Diseases of the Retina.”

NEUROLOGIC CAUSES OF REDUCED VISION

Certain anatomic and physiologic facts are requisite for an interpretation of the neurologic lesions that affect vision. Visual stimuli entering the eye traverse the inner layers of the retina to reach its outer (posterior) layer, which contains two classes of photoreceptor cells—the flask-shaped cones and the slender rods. The photoreceptors rest on a single layer of pigmented epithelial cells, which form the outermost surface of the retina. The rods and cones and pigmentary epithelium receive their blood supply from the capillaries of the choroid and, to a smaller extent, from the retinal arterioles. The rod cells contain rhodopsin, a conjugated protein in which the chromophore group is a carotenoid akin to vitamin A. The rods function in the perception of visual stimuli in subdued light (twilight or scotopic vision), and the cones are responsible for color discrimination and the perception of stimuli in bright light (photopic vision). Most of the cones are concentrated in the macular region, particularly in its central part, the *fovea*, and are responsible for the highest level of visual acuity. Specialized pigments in the rods and cones absorb light energy and transform it into electrical signals, which are transmitted to the bipolar cells of the retina and then, in turn, to the superficially (anteriorly) placed neurons, or ganglion cells (Fig. 13-1). There are no ganglion cells in the fovea.

The axons of the retinal ganglion cells, as they stream across the inner surface of the retina, pursue an arcuate course. Being unmyelinated, they are not visible, although fluorescein angiography shows a trace of their outlines; an experienced examiner, using a bright light and deep green filter, can visualize them through direct ophthalmoscopy. The axons of ganglion cells are collected in the optic discs and then pass uninterruptedly through the *optic nerves*, *optic chiasm*, and *optic tracts* to synapse in the lateral geniculate nuclei, the superior colliculi, and the midbrain pretectum (Figs. 13-1 and 13-2). The fibers derived from macular

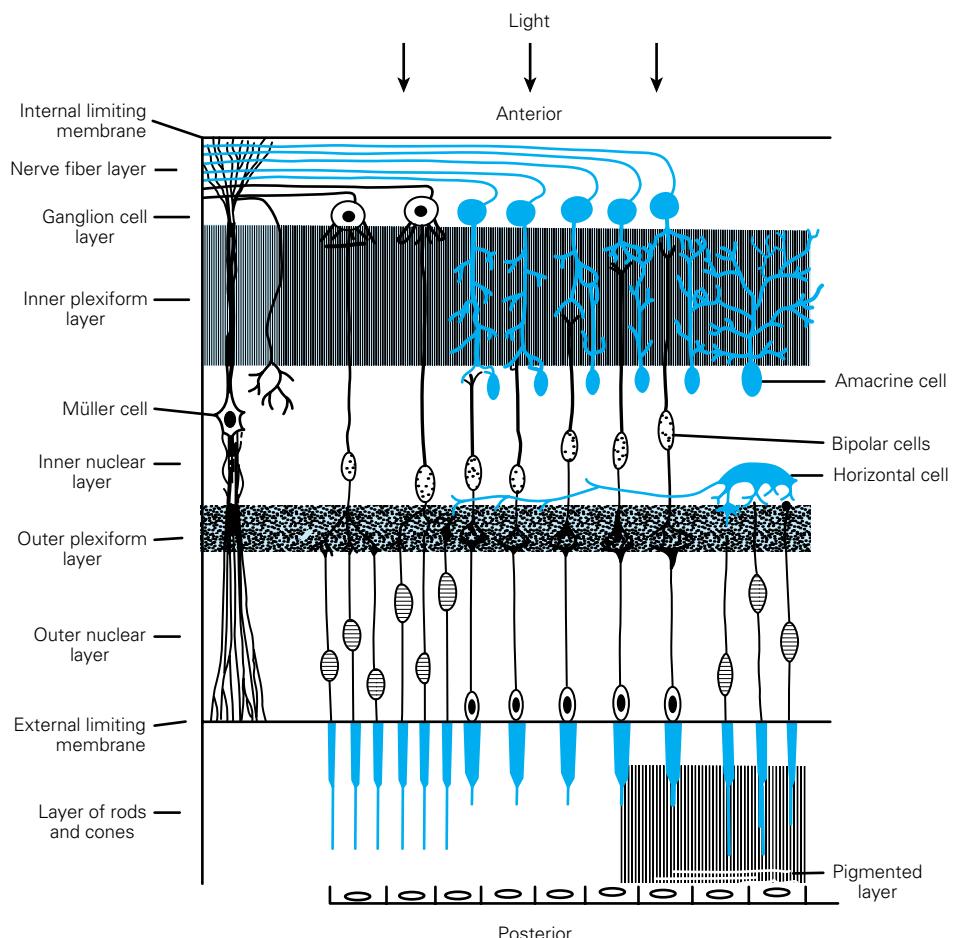

Figure 13-1. Diagram of the cellular elements of the retina. Light entering the eye anteriorly passes through the full thickness of the retina to reach the rods and cones (first system of retinal neurons). Impulses arising in these cells are transmitted by the bipolar cells (second system of retinal neurons) to the ganglion cell layer. The third system of visual neurons consists of the ganglion cells and their axons, which run uninterruptedly through the optic nerve, chiasm, and optic tracts, synapsing with cells in the lateral geniculate body. (Courtesy of Dr. E. M. Chester.)

cells form a discrete bundle that first occupies the temporal side of the disc and optic nerve and then assumes a more central position within the nerve (papillomacular bundle). These fibers are of smaller caliber than the peripheral optic nerve fibers. It is important to keep in mind that the retinal ganglion cells and their axonic extensions are, properly speaking, an exteriorized part of the brain and that their pathologic reactions are the same as in other parts of the CNS.

In the optic chiasm, the fibers derived from the nasal half of each retina decussate and continue in the optic tract with uncrossed temporal fibers of the other eye (Figs. 13-2 and 13-3). Thus, interruption of the left optic tract causes a right hemianopic defect in each eye, i.e., a homonymous (left nasal and right temporal) field defect (Fig. 13-2D). In partial tract lesions, the visual defects in the two eyes are not exactly congruent, since the tract fibers are not evenly admixed. A variable bundle of fibers from the inferior nasal part of the optic nerve turns anteriorly into the opposite optic nerve as it crosses in the chiasm (Wilbrand's knee). Lesions at this "junctional" point of the optic nerve and the chiasm, generally compressive in nature, may therefore cause a contralateral quadrantic defect in addition to the expected central scotoma in the ipsilateral

eye that is due to the optic nerve lesion, as shown in Fig. 13-2B. The optic chiasm lies just above the pituitary body and also forms part of the anterior wall of the third ventricle; hence the crossing fibers may be compressed from below by a pituitary tumor, a meningioma of the tuberculum sellae, or an aneurysm and from above by a dilated third ventricle or craniopharyngioma. The resulting field defect is bitemporal (Fig. 13-2C); if one optic nerve is also implicated, there will be a loss of full-field vision in that eye. Optic tract lesions, in comparison with chiasmatic and nerve lesions, are relatively rare. Surprisingly, in albinism, there is an abnormality of chiasmatic decussation, in which a majority of the fibers, including many that would not normally cross to the other side, decussate. How this relates to the albinic defect in the pigment epithelium is not known.

About 80 percent of the fibers of the optic tract terminate in the lateral geniculate body and synapse with the six laminae of its neurons. Three of these laminae (1, 4, 6), which constitute the large dorsal nucleus, receive crossed (nasal) fibers from the contralateral eye, and three (2, 3, 5) receive uncrossed (temporal) fibers from the ipsilateral eye. The geniculate cells project to the visual (striate) cortex of the occipital lobe, also called area 17 or V₁ (Fig. 13-4). Other optic tract fibers terminate in the pretectum and innervate both

Edinger-Westphal nuclei, which subserve pupillary constriction and accommodation (see Fig. 14-7). A small group of fibers terminate in the suprachiasmatic nuclei in animals and presumably also in humans. These anatomic details explain several useful clinical signs. If there is a lesion in one optic nerve, a light stimulus to the affected eye will have no effect on the pupil of either eye, although the ipsilateral pupil will still constrict consensually, i.e., in response to a light stimulus from the normal eye. This is termed an *afferent pupillary defect*. The vascular supply of the lateral geniculate body is from both the posterior and anterior choroidal and thalamogeniculate arteries; it is therefore rarely infarcted.

In their course through the temporal lobes, the fibers from the lower and upper quadrants of each retina diverge. The lower ones arch around the anterior pole of the temporal horn of the lateral ventricle before turning posteriorly; the upper ones follow a more direct path through the white matter of the uppermost part of the temporal lobe (Fig. 13-2) and possibly of the adjacent parietal lobe. Both groups of fibers merge posteriorly at the internal sagittal stratum. For these reasons, incomplete lesions of the geniculocalcarine pathways cause visual field defects that are partial and often not fully congruent (Fig. 13-2E and F).

It is in Brodmann's area 17, embedded in the medial lip of the occipital pole, that cortical processing of the retinogeniculate projections occurs. The receptive neurons are arranged in columns, some of which are activated by form and others by moving stimuli or by color. The neurons for each eye are grouped together and have concentric, center-surround receptive fields.

The deep neurons of area 17 project to the secondary and tertiary visual areas of the occipitotemporal cortex of the same and opposite cerebral hemispheres and also to other multisensory parietal and temporal cortices. Several of these extrastriate connections are just now being identified. Separate visual systems are utilized in the perception of motion, color, stereopsis, contour, and depth perception. The classic studies of Hubel and Wiesel have elucidated much of this visual cortical physiology.

The *normal development* of the connections described above requires that the visual system be activated at each of several critical periods of development. The early deprivation of vision in one eye causes a failure of development of the geniculate and cortical receptive fields of that eye. Moreover, the cortical receptive fields of the seeing eye become abnormally large and usurp the monocular dominance columns of the blind eye (Hubel and Wiesel). In children with congenital cataracts, the eye will remain amblyopic if the opacity is removed after a critical period of development. A severe strabismus in early life, especially an esotropia, will have the same effect (amblyopia exanopia).

In regard to the *vascular supply* of the eye, the *ophthalmic branch of the internal carotid artery* supplies the retina, posterior coats of the eye, and optic nerve head. This artery gives origin to the posterior ciliary arteries; the latter form a rich circumferential plexus of vessels (arterial circle of Zinn-Haller) located deep to the lamina cribrosa. This arterial circle supplies the optic disc and adjacent part of the distal optic nerve, the choroid, and the ciliary body; it anastomoses with the pial arterial plexus that surrounds the optic nerve. The other major branch of the ophthalmic artery is the *central retinal artery*. It supplies the inner retinal layers and issues from the optic disc, where it divides into four branches, each of which supplies a quadrant of the retina; it is these vessels and their branches that are visible by ophthalmoscopy. A short distance from the disc, these vessels lose their internal elastic lamina and the media (muscularis) becomes thin; they are properly classed as arterioles. The inner layers of the retina, including the ganglion and bipolar cells, receive their blood supply from these arterioles and their capillaries, whereas the deeper photoreceptor elements and the fovea are nourished by the underlying choroidal vascular bed, by diffusion through the retinal pigmented cells and the semipermeable Bruch's membrane upon which they rest.

Abnormalities of the Retina

As indicated above, this thin (100- to 350-mm) sheet of transparent tissue and the optic nerve head, into which all visual information

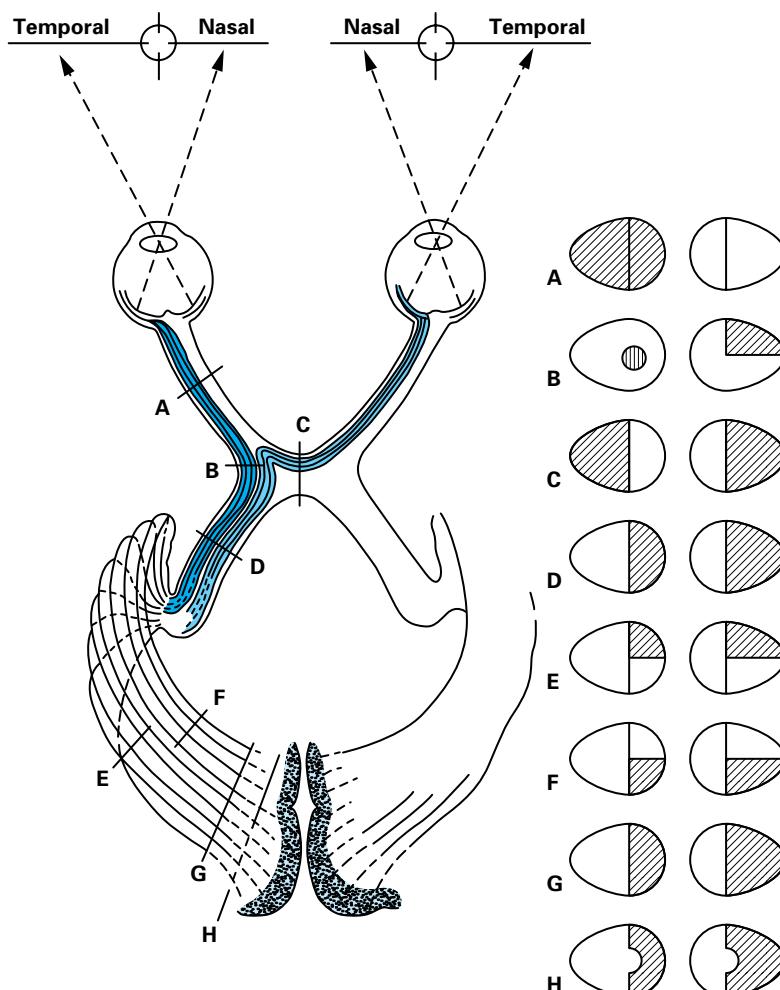

Figure 13-2. Diagram showing the effects on the fields of vision produced by lesions at various points along the optic pathway: A. Complete blindness in left eye from an optic nerve lesion. B. The usual effect is a left-junction scotoma in association with a right upper quadrantanopia. The latter results from interruption of right retinal nasal fibers that project into the base of the left optic nerve (Wilbrand's knee). A left nasal hemianopia could occur from a lesion at this point but is rare. C. Chiasmatic lesion causing bitemporal hemianopia. D. Right homonymous hemianopia from optic tract lesion. E and F. Right superior and inferior quadrant hemianopia from interruption of visual radiations. G. Right homonymous hemianopia due to lesion of occipital striate cortex. H. Hemianopia with macular sparing.

flows, are an exteriorized part of the CNS and the only part of the nervous system that can be inspected directly by ophthalmoscopic examination. Common deficiencies in the funduscopic examination in cases of visual loss are failure to carefully inspect the macular zone (which is located 3 to 4 mm lateral to the optic disc and provides for 95 percent of visual acuity) and to search the periphery of the retina through a dilated pupil. There are variations in the appearance of the normal macula and optic disc, and these may prove troublesome. A normal macula may be called abnormal because of a slight aberration of the retinal pigment epithelium or a few drusen (see further on). With experience, the examiner can visualize the unmyelinated nerve fiber layer of the retina by using bright-green (red-free) illumination. This is most often helpful in detecting demyelinative lesions of the optic nerve, which produce a loss of discrete bundles of the radially arranged and arching retinal fibers as they converge to the disc.

The normal optic disc varies in color, being paler in infants

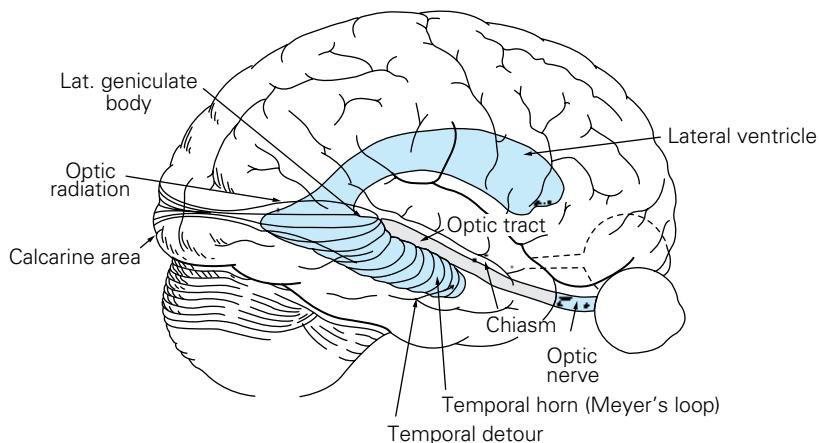

Figure 13-3. The geniculocalcarine projection, showing the detour of lower fibers around the temporal horn. Note that a very small proportion of the pathway traverses the parietal lobe.

and in blond individuals, and the prominence of the lamina cribrosa (a sieve-like structure in the central and nasal part of the disc through which run the fascicles of unmyelinated axons of the retinal ganglion cells) differs from one individual to another. The absence of receptive elements in the optic disc, or papilla, accounts for the normal blind spot. The ganglion-cell axons normally acquire their myelin sheaths after penetration of the lamina cribrosa, but they sometimes do so in their intraretinal course, as they approach the disc. These myelinated fibers adjacent to the disc appear as white patches with fine-feathered edges and are a normal variant, not to be confused with exudates.

In evaluating changes in the retinal vessels, one must remember that these are arterioles and not arteries. Since the walls of retinal arterioles are transparent, what is seen with the ophthalmoscope is the column of blood within them. The central light streak of many normal arterioles is thought to represent the reflection of light from the ophthalmoscope as it strikes the interface of the column of blood and the concave vascular wall. In *arteriolosclerosis* (usually coexistent with hypertension), the lumina of the vessels are segmentally narrowed because of fibrous tissue replacement of the media and thickening of the basement membrane. Straightening of the arterioles and arteriolar-venous compression are other signs of hypertension and arteriolosclerosis. In this circumstance the vein is compressed by the thickened arteriole within the adventitial envelope shared by both vessels at the site of crossing; this compression may rarely lead to occlusion of branches of the retinal veins. Progressive arteriolar disease, to the point of occlusion of the lumen, results in a narrow, white ("silver-wire") vessel with no visible blood column. This change is associated most often with severe hypertension but may follow other types of occlusion of the central retinal artery or its branches (see descriptions and retinal illustrations further on). Sheathing of the venules, probably representing focal leakage of cells from the vessels, is reportedly observed in up to 25 percent of patients with multiple sclerosis, but we have only rarely been able to detect it. Similar alterations are also seen in leukemia, malignant hypertension, sarcoid, Behcet disease, and other forms of vasculitis.

In *malignant hypertension* there are, in addition to swelling of the optic nerve head and the retinal arteriolar changes noted above, a number of extravascular lesions: the so-called soft exudates or cotton-wool patches, sharply marginated and glistening "hard" exudates, retinal hemorrhages, and edema of the disc. In

many patients who show these retinal changes, analogous lesions are found in the brain (necrotizing arteriitis and microinfarcts). These are the changes that underlie hypertensive encephalopathy. There may be associated congestive heart failure and kidney failure; the elevated blood pressure must, of course, be controlled rapidly, but too precipitous a drop can result in retinal hypoperfusion and blindness.

The ophthalmoscopic appearance of *retinal hemorrhages* is determined by the structural arrangements of the particular tissue in which they occur. In the superficial layer of the retina, they are linear or flame-shaped ("splinter" hemorrhages) because of their confinement by the horizontally coursing nerve fibers in that layer. These hemorrhages usually overlie and obscure the retinal vessels. Round or oval ("dot-and-blot") hemorrhages lie behind the vessels, in the outer plexiform layer

of the retina (synaptic layer between bipolar cells and nuclei of rods and cones—Fig. 13-1); in this layer, blood accumulates in the form of a cylinder between vertically oriented nerve fibers and appears round or oval when viewed end-on with the ophthalmoscope. Rupture of arterioles on the inner surface of the retina—as occurs with ruptured intracranial saccular aneurysms, arteriovenous malformations, and other conditions causing sudden severe elevation of intracranial pressure—permits the accumulation of a sharply outlined lake of blood between the internal limiting mem-

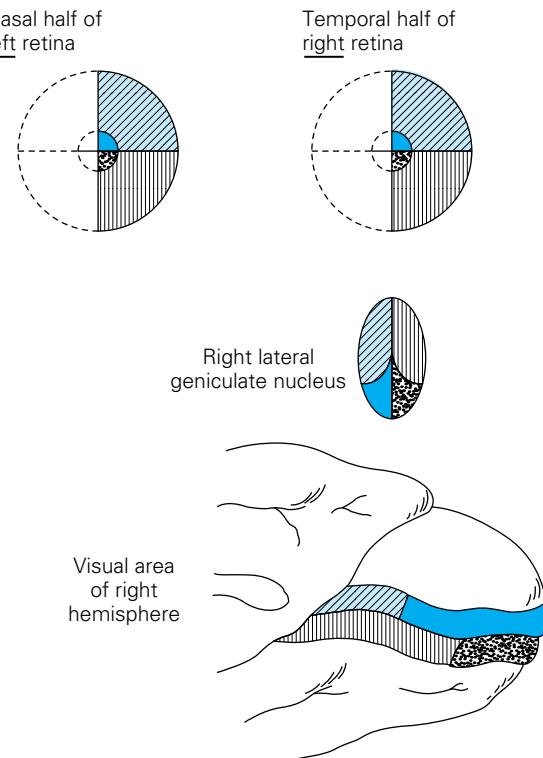

Figure 13-4. Diagrammatic depiction of the retinal projections, showing the disproportionately large representation of the macula in the lateral geniculate nucleus and visual (striate) cortex. (Redrawn by permission from Barr ML, Kiernan J: The Human Nervous System, 4th ed. Philadelphia, Lippincott, 1983.)

brane of the retina and the vitreous or hyaloid membrane (the condensed gel at the periphery of the vitreous body); this is the subhyaloid or preretinal hemorrhage. Either the small superficial or deep retinal hemorrhage may show a central or eccentric pale (Roth) spot, which is caused by an accumulation of white blood cells, fibrin, histiocytes, or amorphous material between the vessel and the hemorrhage. This lesion is said to be characteristic of bacterial endocarditis, but it is also seen in leukemia and in embolic retinopathy due to carotid disease.

Cotton-wool patches, or soft exudates, like splinter hemorrhages, overlie and tend to obscure the retinal blood vessels. These patches, even large ones, rarely cause serious disturbances of vision unless they involve the macula. Soft exudates are in reality infarcts of the nerve fiber layer, due to occlusion of precapillary arterioles; they are composed of clusters of ovoid structures called *cytoid bodies*, representing the terminal swellings of interrupted axons. *Hard exudates* appear as punctate white or yellow bodies; they lie in the outer plexiform layer, behind the retinal vessels, like the punctate hemorrhages. If present in the macular region, they are arranged in lines radiating toward the fovea (*macular star*). Hard exudates consist of lipid and other serum precipitants due to abnormal vascular permeability of a type that is not completely understood. They are observed most often in cases of diabetes mellitus and chronic hypertension. *Drusen (colloid bodies)* appear ophthalmoscopically as pale yellow spots and are difficult to distinguish from hard exudates except when they occur alone; as a rule, hard exudates are accompanied by other funduscopic abnormalities. The source of retinal drusen is uncertain; probably they represent benign accumulations of lipofuscin and other cellular debris derived from the retinal pigment epithelium (see the review by D'Amico). *Hyaline bodies*, located on or near the optic disc, are also referred to as drusen but must be distinguished from those occurring peripherally. Drusen of the optic discs are probably mineralized residues of dead axons and can be seen on computed tomography (CT) in some cases. Their main significance for neurologists is that they are often associated with anomalous elevation of the disc and can be mistaken for papilledema (Table 13-1).

Microaneurysms of retinal vessels appear as small, discrete red dots and are located in largest number in the paracentral region. They are most often a sign of diabetes mellitus, sometimes appearing before the usual clinical manifestations of that disease have become obvious. The use of the red-free (green) light on the ophthalmoscope helps to pick out microaneurysms from the background. Microscopically, the aneurysms take the form of small (20- to 90-mm) saccular outpouchings from the walls of capillaries, venules, or arterioles. The vessels of origin of the aneurysms are invariably abnormal, being either acellular branches of occluded vessels or themselves occluded by fat or fibrin.

Finally, the periphery of the retina may harbor a hemangioblastoma, which may appear during adolescence, before the more characteristic cerebellar lesion. A large retinal artery may be seen leading to it and a large vein draining it. Occasionally, retinal examination discloses the presence of a vascular malformation that may be coextensive with a much larger malformation of the optic nerve and basilar portions of the brain.

Ischemic Lesions of the Retina Transient ischemic attacks of visual loss, involving all or part of the field of vision of one eye, are referred to as *amaurosis fugax* or *transient monocular blindness (TMB)*. They are common manifestations of atherosclerotic carotid stenosis or ulceration. Fortuitous inspection of the retina during an

attack usually shows stagnation of arterial blood flow, which returns within seconds or minutes as vision is restored (Fisher). One or a hundred attacks may precede infarction of a cerebral hemisphere in the territory of the anterior or middle cerebral artery. In one series of 80 such patients followed by Marshall and Meadows for 4 years, 16 percent developed permanent unilateral blindness, a completed hemispherical stroke, or both. If one eye is affected, there is one chance in four that the other will be involved, usually within the first year according to Sawle et al, but this involvement of the contralateral eye has occurred far less often in our patients (unless the underlying cause is temporal arteritis; see further on). This subject is discussed further in Chap. 34, on cerebrovascular diseases.

Occlusion of the internal carotid artery may cause no disturbance of vision whatsoever provided that there are adequate anastomotic branches from the external carotid artery in the orbit. Rarely, carotid occlusion with inadequate collateralization is associated with a chronic ischemic oculopathy, which may predominantly affect the anterior or posterior segment or both. Insufficient circulation to the anterior segment is manifest by episcleral vascular congestion, cloudiness of the cornea, anterior chamber flare, rubeosis and iris atrophy (rubeosis iridis), and an abnormally low or high intraocular pressure. Ischemia of the posterior segment is manifest by circulatory changes in the retina and optic nerve and by venous stasis. Other neurologic signs of carotid disease may be present, for example, a local bruit (page 669).

More often, ischemia of the retina can be traced to the central retinal artery or its branches, which may be occluded by thrombi or emboli—*central retinal artery occlusion* (often abbreviated CRAO). Occlusion of the main artery is attended by sudden blindness. The retina becomes opaque and has a gray-yellow appearance; the arterioles are narrowed, with segmentation of columns of blood and a cherry-red appearance of the fovea (Fig. 13-5). With branch occlusions by emboli, one may be able to see the occluding material. Most frequently observed are so-called Hollenhorst plaques—glistening, white-yellow atheromatous particles (Fig. 13-6) seen in 40 of 70 cases of retinal embolism in the series of Arruga and Sanders. The remainder are white calcium particles, from calcified aortic or mitral valves or atheroma of the great vessels, and red or white fibrin-platelet emboli from a number of sources, mostly undefined. The latter may be asymptomatic or as-

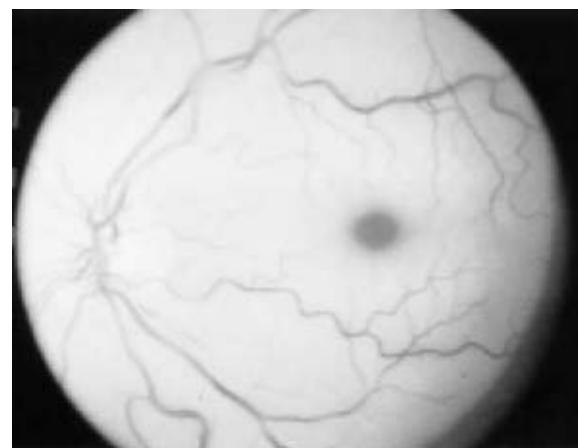

Figure 13-5. Appearance of the fundus in central retinal artery occlusion. In addition to the paucity of blood flow in retinal vessels, the retina has a creamy gray appearance and there is a “cherry-red spot” at the fovea.

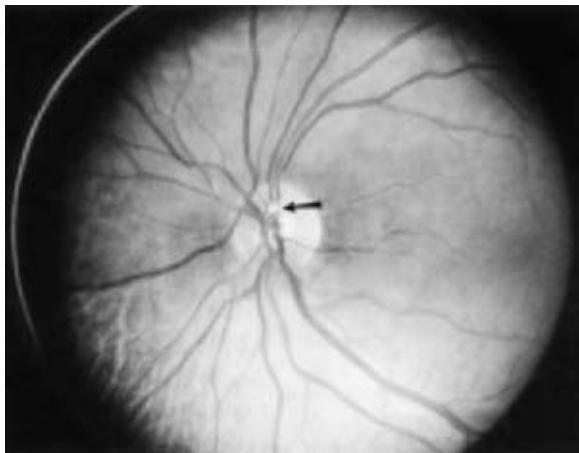

Figure 13-6. Glistening “Hollenhorst plaque” occlusion of a superior retinal artery branch (arrow). These occlusions represent atheromatous particles or, less often, platelet-fibrin emboli. Some are asymptomatic and others are associated with segmental visual loss or are seen after central retinal artery occlusion.

sociated with transient blindness and may be difficult to see without fluorescein retinography; these emboli soon disappear.

It has become routine in some centers to treat acute central retinal artery occlusion in an urgent manner with a number of methods in the hope that the embolus or thrombus will be propelled into more distal vessels. These treatments are generally aimed at lowering intraocular pressure or dilating retinal vessels. We can only offer the impression that these procedures have not been successful in our practice.

Since the central retinal artery and vein share a common adventitial sheath, atheromatous plaques in the artery are said to be associated in some instances with *thrombosis of the retinal vein*. There is then a spectacular display of retinal lesions that differs from the picture of central retinal artery occlusion. The veins are engorged and tortuous, and there are diffuse dot-and-blot and streaky linear retinal hemorrhages (Fig. 13-7). Retinal vein thrombosis is observed most frequently with diabetes mellitus, hypertension, and leukemia; less frequently with sickle cell disease; and

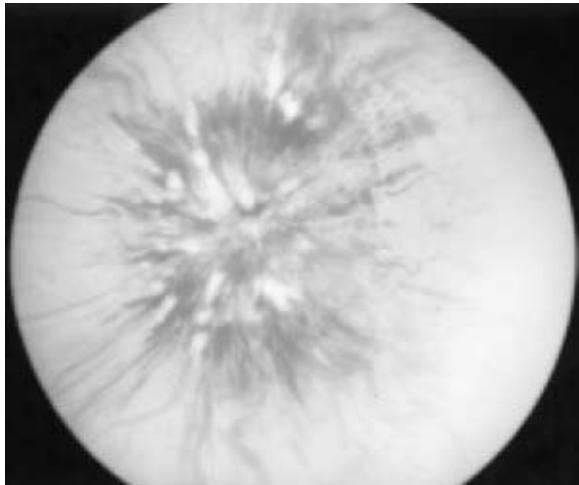

Figure 13-7. Occlusion of the central retinal vein with suffusion of the veins, swelling of the disc, and florid retinal hemorrhages.

rarely with multiple myeloma and macroglobulinemia in relation to the hyperviscosity they cause. Sometimes no associated systemic disease can be identified, in which case the possibility of an orbital mass (e.g., optic nerve glioma) should always be considered. In retinal vein thrombosis, visual loss is variable and there may be recovery of useful vision.

A transitory retinal ischemia is observed occasionally as a manifestation of migraine; it has also been observed in polycythemia, hyperglobulinemia, and sickle cell anemia. Massive blood loss or intraoperative hypotension, particularly in association with the use of a heart bypass pump, may also produce visual loss and ischemic infarction of the retina and optic nerve. In younger persons, transient monocular blindness is relatively uncommon and the cause is often not immediately apparent, although ischemia related to the antiphospholipid antibody or migraine is presumed to be responsible for many cases.

A common and critical cause of sudden monocular blindness, especially in elderly persons, is *ischemic optic neuropathy*. It is due to disease of ciliary vessels that supply the optic nerve; it is therefore considered further on, in the discussion of diseases of the optic nerve. The retinal vessels in this condition usually have a normal appearance.

In summary, *sudden painless monocular loss of vision* should always raise the question of ischemia of the retina, due either to occlusive disease of the central retinal artery or vein or to ischemic optic neuropathy from disease of the ciliary vessels. Detachment of the retina, macular or vitreous hemorrhage, and acute glaucoma are less common but obvious causes.

Other Diseases of the Retina Aside from vascular lesions, other alterations of the retina, namely tears and detachments, may impair vision acutely. The most common form of retinal detachment is an intraretinal detachment due to separation of the pigment epithelium layer from the sensory retina with fluid accumulation through a tear or hole in the retina. In so-called traction detachment—observed in cases of premature birth or proliferative retinopathy secondary to diabetes or other vascular disease—contracting fibrous tissue may pull the retina from the choroid.

Serous retinopathy, a fairly common disease, and chorioretinitis represent another category of retinal disease. In *serous retinopathy*, a condition that occurs most often in young or middle-aged males, the entire perimacular zone is elevated by edema fluid. It may arise acutely or more slowly. Metamorphopsia (distortion of vision) in one eye is a common presentation, and although vision is usually distorted, acuity is not much impaired. The optic disc remains normal. The retinal change (leakage of fluid into the subretinal space) causes a loss of visualization of the detail of the choroid and is demonstrated by fluorescein angiography. The condition tends to resolve over several months or may be treated with laser to seal the site of leakage. In *chorioretinitis*, generally an infectious process, there may also be difficulty in diagnosis and, in a many of our cases, the initial diagnosis had been retrobulbar neuritis. One cannot depend upon the appearance of a macular star (see above) for diagnosis.

A majority of patients with acquired immunodeficiency syndrome (AIDS) develop retinal lesions. Infarcts of the nerve-fiber layer (cotton-wool patches), hemorrhages, and perivascular sheathing are the usual findings. Toxoplasmosis is the most common infective lesion, followed in frequency by cytomegalovirus (CMV), but histoplasmosis, *Pneumocystis carinii*, herpes zoster, syphilis, and tuberculosis are well-documented causes. CMV may cause a

particularly severe necrotizing retinitis and permanent impairment of vision. Both the retina and choroid may be involved by these diseases, in which case the ophthalmoscopic picture is characteristic. Destruction of the retina and the pigment epithelium of the choroid produces “punched-out” lesions, exposing the whitish sclera and deposits of black pigment in various forms. The choroid may be the site of viral and also noninfective inflammatory reactions, often in association with painful recurrent iridocyclitis and lacrimal inflammation.

Degenerations of the retina are an important cause of chronic visual loss. They assume several forms and may be associated with other neurologic abnormalities. The most frequent in youth and middle age is *retinitis pigmentosa*, a hereditary disease of the outer photoreceptor layer and subjacent pigment epithelium. The retina is thin, and there are fine deposits of black pigment in the shape of bone corpuscles, more in the periphery; later the optic discs become pale. Clinically this disorder is marked by constriction of the fields with relative sparing of central vision (“gun-barrel” vision), metamorphopsia (distorted vision), delayed recovery from glare, and nyctalopia (reduced twilight vision). There are widely diverse causes of retinitis pigmentosa and related retinal degenerations, too numerous to list here; furthermore, these degenerations have been linked to deficits in over 75 different genes. In one form of isolated retinitis pigmentosa, which follows an autosomal dominant pattern of inheritance and is linked to chromosome 3, the gene for rhodopsin (a combination of vitamin A and the rod-cell protein opsin) produces a defective opsin. This results in a diminution of rhodopsin in rod cells, a diminished response to light, and eventual degeneration of the rod cells (Dryja et al). Retinitis pigmentosa may also be associated with the Laurence-Moon-Biedl syndrome, with certain mitochondrial diseases (Kearns-Sayre syndrome, Chap. 38) and with a number of degenerative and metabolic diseases (e.g., Refsum disease) of the nervous system. Another early-life hereditary retinal degeneration, characterized by massive central retinal lesions, is the autosomal recessive Stargardt form of juvenile tapetoretinal degeneration. Like retinitis pigmentosa, Stargardt disease may be accompanied by progressive spastic paraparesis or ataxia. *Nonpigmentary retinal degeneration* is a familiar feature of a number of other rare syndromes and diseases, such as neuronal ceroid lipofuscinosis, Bassen-Kornzweig disease, Refsum disease, Batten-Mayou disease, and others (see Chap. 37).

Phenothiazine derivatives may conjugate with the melanin of the pigment layer, resulting in degeneration of the outer layers of the retina and a characteristic “bull’s-eye retinopathy,” demonstrated by fluorescein angiography. If these drugs are administered in high dosages for protracted periods, the patient should be tested frequently for defects in visual fields and color vision. Among the drugs used to treat neurologic disease, *vigabatrin* is notable for causing retinal degeneration and a concentric restriction of the visual fields in almost half of the patients. Elevated levels of GABA in the retina are presumably the cause of toxicity.

Retinal degeneration may also occur in patients with an oat-cell carcinoma of the lung as a so-called paraneoplastic illness (see Chap. 31). Antiretinal ganglion cell antibodies, presumably produced by the tumor cells, have been demonstrated in the serum of such patients by several investigators (Grunwald et al; Kornguth et al; Jacobson et al).

Certain lysosomal diseases of infancy and early childhood are characterized by an abnormal accumulation of undegraded proteins, polysaccharides, and lipids in cerebral neurons as well as in the macula and other parts of the retina (hence the terms *storage*

diseases and *cerebromacular degenerations*). Corneal clouding, cherry-red spot and graying of the retina, and later optic atrophy are the observed ocular abnormalities. These diseases are discussed in Chap. 37.

In some of these retinal diseases, minimal changes in the pigment epithelium or other layers of the retina that reduce visual acuity may not be readily detected by ophthalmoscopy. In these circumstances, it is helpful to estimate the time required for recovery of visual acuity following light stimulation (macular photo-stress test). This test consists of shining a strong light through the pupil of an affected eye for 10 s and measuring the time necessary for the acuity to return to the pretest level (normally 50 s or less). With macular lesions, recovery time is prolonged, but with lesions of the optic nerve, it is not affected. This phenomenon may be observed in the eye on the side of a carotid occlusion, in essence an ischemic retinopathy. Retinal diseases reduce or abolish the electrical activity generated by the outer layers of the retina, and this can be measured in the electroretinogram. Fluorescein retinography may also be helpful.

Age-Related Macular Degeneration (ARMD) This is perhaps the most important cause of visual loss in the elderly. As macular degeneration begins to disturb vision, the straight lines on the Amsler grid are observed by the patient to be distorted. Examination discloses central scotomata and an alteration of the retina around the macula. Central vision is at first distorted, then gradually diminishes, impairing reading, but these patients can still get about because of retained peripheral vision. The two most common types of macular degeneration are an atrophic “dry” type, which is a true pigmentary degeneration causing gradual visual loss, and an exudative “wet” type, which is the result of choroidal vascularization and secondary macular damage. The latter form is amenable to laser treatment.

Diabetic Retinopathy Although not strictly speaking a problem taken up by neurologists, this is such an important cause of reduced vision and blindness that the basic facts should be known to all physicians. The earliest changes are of microaneurysms and tiny intraretinal hemorrhages; these are present in almost all diabetics who have had type 1 disease for more than 20 years. Cotton-wool spots and small hemorrhages appear as the retina becomes ischemic. Subsequently, there is a more threatening proliferative retinopathy that consists of the formation of new blood vessels and consequent leakage of proteins and blood. The proliferative feature occurs in half of type 1 diabetics and 10 percent of those who have had type 2 disease for 15 to 20 years. The new vessels can grow into the vitreous and hemorrhage and may cause traction on the retina, which results in detachment. Serous visual loss may also be the result of macular edema. Reabsorption of the edema leads to the deposition of lipid “hard exudates.” The maintenance of glucose control reduces the frequency and severity of retinopathy. The recent review by Frank is recommended. Elevated levels of vascular endothelial growth factor have been shown to be the cause of retinal neovascularization in diabetic retinopathy.

Papilledema and Raised Intracranial Pressure

Of the various abnormalities of the optic disc, *papilledema* or *optic disc swelling* has the greatest neurologic implication, for it signifies the presence of increased intracranial pressure. It must be made clear, however, that an ophthalmoscopic appearance identical to that of papilledema can be produced by infarction of the optic nerve

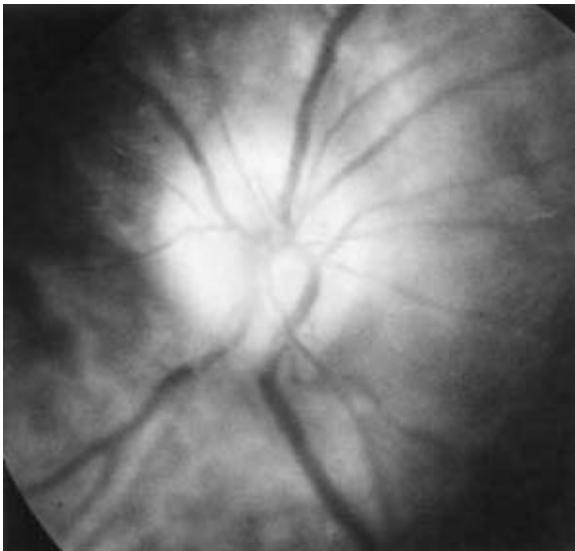

Figure 13-8. Mild papilledema with hyperemia of the disc and slight blurring of the disc margins.

head (anterior ischemic optic neuropathy) and by inflammatory changes in the intraorbital portion of the optic nerve ("papillitis" or optic neuritis). Certain clinical and funduscopic findings, listed in Table 13-1 and described below, assist in distinguishing these processes, although all share the basic feature of conspicuous disc swelling.

In its mildest form, papilledema may take the form of only slight elevation of the disc and blurring of the disc margins, especially of the superior and inferior aspects, and a mild fullness of

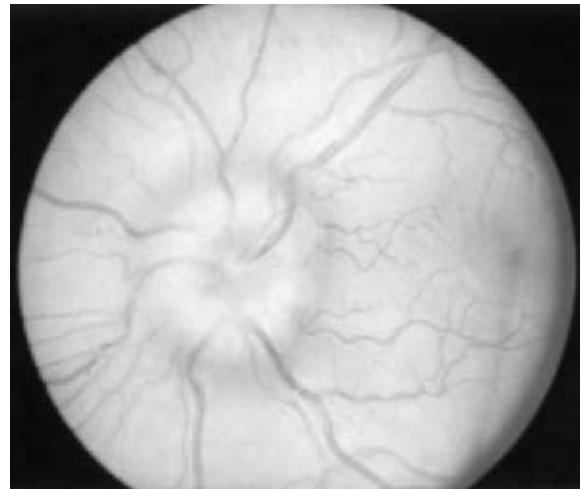

Figure 13-10. Chronic papilledema with beginning optic atrophy, in which the disc stands out like a champagne cork. The hemorrhages and exudates have been absorbed, leaving a glistening residue around the disc.

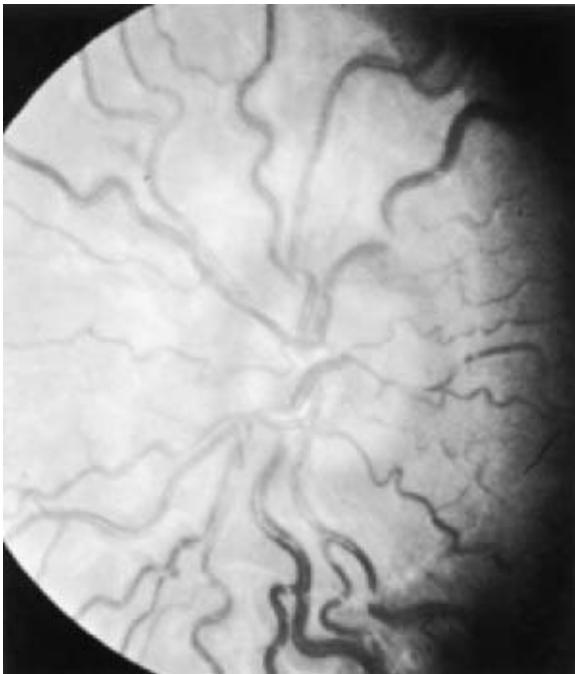

Figure 13-9. Fully developed papilledema. The main characteristics are marked swelling and enlargement of the disc, vascular engorgement, obscuration of small vessels at the disc margin as a result of nerve fiber edema, and white "cotton-wool spots" that represent superficial infarcts of the nerve fiber layer.

the veins in the disc. Subtle disc elevation is also indicated by a loss of definition of the vessels overlying the disc as they approach the disc margin from the periphery; this appearance is produced by edema in the adjacent retina. Since many normal individuals, especially those with hypermetropia, have ill-defined disc margins, this early stage of papilledema may be difficult to detect (Fig. 13-8). Pulsations of the retinal veins, best seen where the veins turn to enter the disc, will have disappeared by the time intracranial pressure is raised, but this criterion is not absolute, since venous pulsations are not present in 10 to 15 percent of normal individuals. On the other hand, the presence of spontaneous venous pulsations is a reliable indicator of an intracranial pressure below 180 to 190 mmH₂O and thus usually excludes the presence of early papilledema (Levin). Fluorescein angiography, red-free fundus photos (which highlight the retinal nerve fibers), and stereoscopic fundus photography may be helpful in detecting early edema of the optic discs.

More severe degrees of papilledema appear as further elevation, or a "mushrooming" of the entire disc and surrounding retina, with edema and obscuration of vessels at the disc margins and, in some instances, peripapillary hemorrhages (Fig. 13-9). When advanced, papilledema is almost always bilateral, although it may be more pronounced on the side of an intracranial tumor. A purely unilateral edema of the optic disc is usually associated with perioptic meningioma or other tumor involving the optic nerve, but it can also occur at an early stage of increased intracranial pressure. As the papilledema becomes chronic, elevation of the disc margin becomes less prominent and pallor of the optic nerve head, representing a dropout of nerve fibers (atrophy), becomes more evident (Fig. 13-10). Varying degrees of secondary optic atrophy are left in the wake of papilledema that has persisted for more than several days or weeks, leaving the disc pale and shrunken. A constriction in one quadrant of the nasal field is an early sign of the loss of nerve fibers. Unlike the case in primary optic atrophy, the disc margins are irregular, often with peripapillary pigment deposits.

A point to be emphasized is that *acute papilledema*, while it may enlarge the blind spot slightly, does not greatly affect visual acuity (except transiently during spontaneous waves of increased intracranial pressure). Therefore optic disc swelling in a patient

with severely reduced vision should not be attributed to papilledema; instead, intraorbital optic neuritis (papillitis) or infarction of the nerve head (ischemic optic neuropathy), both of which are described further on, are then the cause of disc edema. The examiner is also aided by the fact that *papilledema due to raised intracranial pressure is generally bilateral*, although, as mentioned earlier, the degree of disc swelling tends not to be symmetrical. In contrast, papillitis and infarction of the nerve head usually affect one eye, but there are exceptions to both of these statements. Also, the pupillary reaction to light is muted only with infarction and optic neuritis, not with papilledema. The occurrence of papilledema on one side and optic atrophy on the other is referred to as the Foster Kennedy syndrome and is attributable to a frontal lobe tumor or an olfactory meningioma on the side of the atrophic disc. In its complete form, which is seen only rarely, there is also anosmia on the side of the optic atrophy.

Papilledema due to increased intracranial pressure must also be distinguished from combined edema of the optic nerve and retina, which typifies both malignant hypertension and from posterior uveitis. Papilledema due to infarction of the nerve head is characterized by extension of the swelling beyond the nerve head, as described below, whereas the papilledema of increased pressure is associated with peripapillary hemorrhages. Often these distinctions cannot be made on the basis of the fundoscopic appearance alone, in which case the most reliable distinguishing feature is again the presence or absence of visual loss (Table 13-1).

Chronic papilledema, as occurs in pseudotumor cerebri (see Chap. 31), presents a special problem in diagnosis and represents a risk for permanent reduction in visual acuity and, eventually, optic atrophy. In addition to testing visual acuity at regular intervals, our colleagues advise serial evaluation of the visual fields; a constriction of the nasal field, detectable by automated perimetry and tangent screen testing, is an early and ominous sign.

The essential element in the pathogenesis of papilledema is an increase in pressure in the sheaths of the optic nerve, which communicate directly with the subarachnoid space of the brain. This was demonstrated convincingly by Hayreh (1964), who produced bilateral chronic papilledema in monkeys by inflating balloons in the temporal subarachnoid space and then opening the sheath of one optic nerve; the papilledema promptly subsided on the operated side but not on the opposite side. The pathogenesis of papilledema has also been ascribed to a blockage of axoplasmic flow in the optic nerve fibers (Minckler et al; Tso and Hayreh). It was found that compression of the optic nerve fibers by elevated cerebrospinal fluid (CSF) pressure resulted in swelling of axons behind the optic nerve head and leakage of their contents into the extracellular spaces of the disc. In our opinion, the block in axonal flow alone could not account for the marked congestion of vessels and hemorrhages that accompany papilledema.

The mechanism of papilledema that on rare occasions accompanies spinal tumors, particularly oligodendrogiomas, and the Guillain-Barré syndrome is not entirely clear. Usually the CSF protein is more than 1000 mg/100 mL, but this cannot be the entire explanation, since instances occur in which the protein concentration is only slightly elevated (also the concentration of protein in the ventricular and cerebral subarachnoid spaces is considerably lower than in the lumbar sac, where it is usually sampled; see Chap. 30). In other diseases that at times give rise to papilledema—e.g., chronic lung disease with hypercarbia, cancer with meningeal infiltration, or dural arteriovenous malformation—the mechanism is most often one of a generalized increase of intracranial pressure.

Puzzling are cases of papilledema without raised intracranial pressure, as may occur in children with cyanotic congenital heart disease and other forms of polycythemia and possibly with hypocalcemia.

Diseases of the Optic Nerves

The optic nerves, which constitute the axonic projections of the retinal ganglion cells to the lateral geniculate bodies and superior colliculi (the third visual neurons), can be inspected in the optic nerve head. Observable changes in the optic disc are therefore of particular importance. They may reflect the presence of raised intracranial pressure (papilledema or “choked disc”), as already described; optic neuritis (“papillitis”); infarction of the optic nerve head; congenital defects of the optic nerves (optic pits and colobomas); hypoplasia and atrophy of the optic nerves; and glaucoma. Illustrations of these and other abnormalities of the disc and ocular fundus can be found in the atlas by E. M. Chester and in the text by Glaser, listed in the References.

The main causes of visual loss from optic neuropathy are listed in Table 13-2 and discussed in the following portions of this chapter.

Optic Neuritis (Papillitis; Retrobulbar Neuritis) (See also page 777.) Acute impairment of vision in one or both eyes (the eyes being affected either simultaneously or successively) develops in a number of clinical settings, particularly with multiple sclerosis. The most frequent situation is one in which an adolescent or young adult (rarely a child) notes a rapid diminution of vision in one eye (as though a veil had covered the eye), sometimes progressing within hours or days to complete blindness. The optic disc and retina may appear normal (retrobulbar neuritis), but if the inflammation is near the nerve head, there is swelling of the disc, i.e., papillitis (Fig. 13-11); the disc margins are then seen to be elevated, blurred, and, rarely, surrounded by hemorrhages. As indicated above, papillitis is associated with marked impairment of vision and a scotoma, thus distinguishing it from the papilledema of increased intracranial pressure. Pain on movement and tenderness on pressure of the globe and a difference between the two eyes in the perception of brightness of light are other fairly consistent findings (Table 13-1). The pupil on the affected side may have a muted response to direct light. The patient may report an increase in blurring of vision with exertion or following a hot bath (Uthoff phenomenon). If there is papillitis, examination may disclose variable haziness of the vitreous that causes difficulty in visualizing the retina. Inflammatory sheathing of the retinal veins, as described by Rucker, is known to occur but has been an uncommon finding in our patients. In extreme cases, edema may suffuse from the disc to cause a rippling in the adjacent retina. However, as just noted, most cases of optic neuritis are retrobulbar and little is to be seen when examining the optic nerve head. In about 10 percent of cases, both eyes are involved, either simultaneously or in rapid succession.

In a proportion of such patients no cause of the optic neuropathy can be found, but a first bout of multiple sclerosis is always suspected, as discussed in Chap. 36. After several weeks there is spontaneous recovery; vision returns to normal in more than two-thirds of instances. Regression of symptoms may occur spontaneously or may be hastened by the intravenous administration of high doses of corticosteroids, but in one study the oral administration of the same drugs increased the frequency of a relapse of optic neuritis (page 788). Occasionally, diminution of brightness, dyschroma-

Table 13-2
Causes of optic disc swelling

OPHTHALMIC ABNORMALITY	UNDERLYING CAUSE	VISUAL LOSS	ASSOCIATED SYMPTOMS	PUPILS
Papilledema	Increased intracranial pressure	None or transient blurring; constriction of visual fields and enlargement of blind spot; findings almost always binocular	Headache; signs of intracranial mass	Normal unless succeeded by optic atrophy
Anterior ischemic optic neuropathy (AION)	Infarction of disc and intraorbital optic nerve due to atherosclerosis or temporal arteritis	Acute visual loss, monocular (usually); may be an altitudinal defect	Headache with temporal arteritis	Afferent pupillary defect
Optic neuritis ^a ("papillitis")	Inflammatory changes in disc and intraorbital part of optic nerve—usually due to MS, sometimes to ADEM	Rapidly progressive visual loss; usually monocular	Tender globe, pain on ocular movement	Afferent pupillary defect
Hyaline bodies ^b (drusen)	Congenital, familial	Usually none; may be slowly progressive Enlargement of blind spot or arcuate inferior nasal defect	Usually none; rarely transient visual obscurations	Normal

Key: MS, multiple sclerosis; ADEM, acute disseminated encephalomyelopathy.

^a Optic neuritis affecting the retrobulbar portion of the nerve shows no fundoscopic changes.

^b May be mistaken for papilledema (pseudopapilledema).

topsia, or a scotoma is left; rarely, the patient is left blind. The optic disc later becomes slightly pale, especially on the temporal side, and the pallor extends beyond the margins of the disc into the peripapillary retinal nerve fiber layer. The CSF may be normal or may contain from 10 to 100 lymphocytes, an elevated total protein and gamma globulin, and oligoclonal bands.

As time progresses, approximately half of such patients will develop other symptoms and signs of multiple sclerosis, usually within 5 years, and probably even more do so when they are observed for longer periods. In approximately 15 percent of patients with multiple sclerosis, the history discloses that retrobulbar neuritis was the first symptom. Postinfectious demyelinative disease is a probable cause in the minority of cases that do not later show signs of multiple sclerosis. Less is known about children with retrobulbar neuropathy, in whom the disorder is more often bilateral and frequently related to a preceding viral infection ("neuroretinitis," see below). Their prognosis is better than that of adults. Formerly, optic neuritis was often blamed on paranasal sinus disease, but this rarely affects vision and this diagnosis should be accepted only in the face of other evidence of infection, such as fever, purulent nasal discharge, leukocytosis, etc.; even then, the association is tenuous, as discussed further on.

Despite the return of visual acuity in the majority of patients, a degree of optic atrophy almost always follows an attack of optic neuritis. The disc then appears shrunken and pale, particularly in its temporal half (temporal pallor). The pattern-shift visual evoked potential becomes delayed as a result; this test is also a useful indicator of previous, even asymptomatic, episodes of optic neuritis.

The treatment of optic neuritis is taken up with multiple sclerosis in Chap. 36.

Leber hereditary optic atrophy may simulate retrobulbar neuropathy, even at times in causing a relatively abrupt onset of visual loss and some degree of recovery (page 949). Certain nutritional and toxic states may do the same, as well as sarcoidosis and the other causes of optic neuropathy discussed further on.

In *neuroretinitis*, which is related to optic neuritis, papillitis

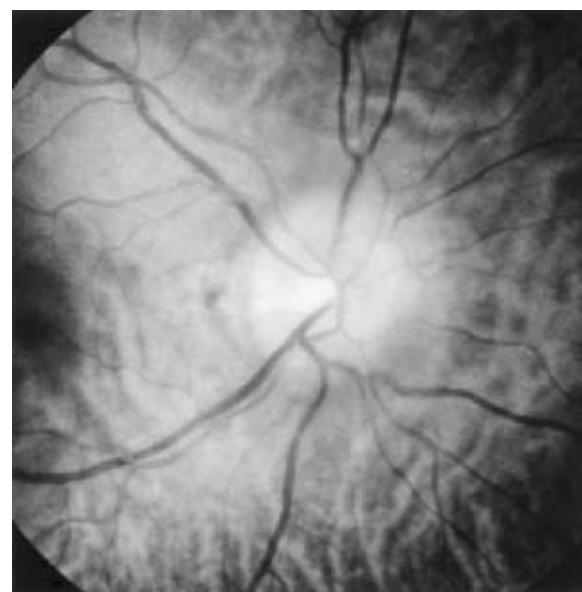

Figure 13-11. Acute optic neuritis in a patient with multiple sclerosis. The disc is swollen from an inflammatory process near the nerve head (papillitis) and the patient is virtually blind in the affected eye.

is accompanied by macular edema and exudates—a “macular star” appearance. This is a rare post- or parainfectious process seen mostly in children and young adults. Also, a type of chronic relapsing optic neuritis has been described by Kidd and colleagues; they did not view it as a variant of multiple sclerosis but instead related it to an idiopathic granulomatous disease of the optic nerve that is known to occur as an isolated illness or may be part of sarcoidosis.

Anterior Ischemic Optic Neuropathy (AION) In persons over 50 years of age, *ischemic infarction of the optic nerve head* is the most common cause of a persistent monocular loss of vision (Fig. 13-12). The onset is abrupt and painless, but on occasion the visual loss is progressive for several days. The field defect is often altitudinal and involves the area of central fixation, accounting for a severe loss of acuity. Swelling of the optic disc, extending for a short distance beyond the disc margin, and associated small, flame-shaped hemorrhages, is typical; less often, if the infarction is situated behind the optic nerve head, the disc appears entirely normal. As the disc edema subsides, optic atrophy becomes evident. The second eye may be similarly affected at a later date, particularly in those patients with hypertension and diabetes mellitus, but this has occurred in less than one-third of our patients. Usually there are no premonitory symptoms or episodes of transient visual loss. Despite these distinctive features, ischemic optic neuropathy can sometimes be difficult to differentiate from optic neuritis, as pointed out by Rizzo and Lessell. This proves particularly difficult when visual loss evolves over days, the disc is swollen, and pain accompanies the ischemic condition. However, the age of the patient and nature of the field defect (central in optic neuritis and altitudinal in ischemic neuropathy) often serve to clarify the situation.

As to the pathogenesis of ischemic optic neuropathy, the usual (anterior) form has been attributed by Hayreh to ischemia in the posterior ciliary artery circulation and more specifically to occlusion of the branches of the peripapillary choroidal arterial system. Infarction of the more posterior portions of the optic nerve(s) is uncommon. Most cases occur on a background of hypertensive vascular disease and diabetes, but not necessarily in relation to carotid artery atherosclerotic stenosis, which in our experience has accounted for only a few cases. The retina and retinal vessels are

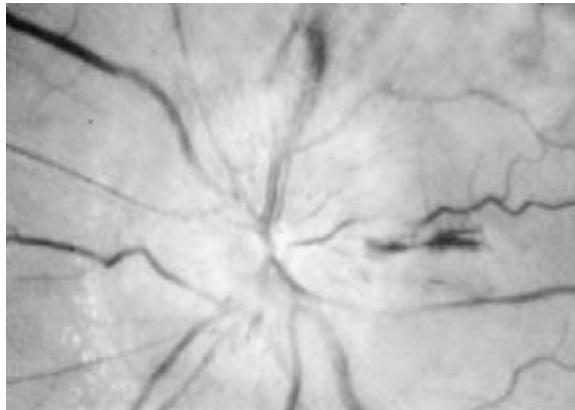

Figure 13-12. Anterior ischemic optic neuropathy (AION) related to hypertension and diabetes. There is diffuse disc swelling from infarction that extends into the retina as a milky edema. The veins are engorged. “Cotton-wool” infarcts can be seen to the left of the disc and a “flame” hemorrhage extends from the right disc margin.

not affected, as they are in cases of embolic occlusion of the central retinal artery. AION may also complicate intraocular surgery or follow an episode of severe blood loss or other causes of hypotension, particularly open-heart surgery.

Cranial or giant-cell arteritis (pages 159 and 731) is the other important cause of AION. In some of the arteritic cases, fleeting premonitory symptoms of visual loss (*amaurosis fugax*) may precede infarction of the nerve. Unlike the common atherosclerotic type of AION, infarction due to cranial arteritis may affect both optic nerves in close succession and, less often, ocular motor function. Also, the arteritis may present with the picture of central retinal artery occlusion. Systemic lupus erythematosus, diabetes, Lyme disease, neurosyphilis, and AIDS rarely give rise to the syndrome of retrobulbar neuropathy but should be considered as diagnoses only after the possibility of optic nerve compression has been excluded. Little is known about the idiopathic granulomatous type of optic neuropathy mentioned earlier in the section on optic neuritis, but it is similar to optic nerve infiltration in sarcoidosis.

Optic Neuropathy due to Acute Cavernous and Paranasal Sinus Disease A number of disease processes adjacent to the orbit and optic nerve can cause blindness, usually with signs of compression or infarction of the optic and oculomotor nerves. They are seen far less frequently than ischemic optic neuropathy and optic neuritis. Septic cavernous sinus thrombosis (see page 735) may be accompanied by blindness of one eye or both eyes in succession or asymmetrically. In our experience with three patients, the visual loss has appeared days after the characteristic chemosis and oculomotor palsies. The mechanism of visual loss, sometimes without swelling of the optic nerve head, is unclear but most likely relates to a retrobulbar ischemia of the nerve.

Similarly, optic and oculomotor disorders may rarely complicate ethmoid or sphenoid sinus infections. Severe diabetes with mucormycosis or other invasive fungal or bacterial infection is the usual setting for these complications. Although the formerly held notion that uncomplicated sinus disease is a common cause of optic neuropathy is no longer tenable, there are still a few instances in which such an association occurs, but the nature of the visual loss is unclear. Slavin and Glaser describe one such case of loss of vision from a sphenoethmoidal sinusitis with cellulitis at the orbital apex. Visual symptoms in these circumstances can occur prior to overt signs of local inflammation. An otherwise benign sphenoidal mucocele may cause an optic neuropathy, usually with accompanying ophthalmoparesis and slight proptosis.

Toxic and Nutritional Optic Neuropathies Simultaneous impairment of vision in the two eyes, with central or centrocecal scotomas, is caused not by a demyelinative process but usually by a toxic or nutritional process. The condition is observed most often in the chronically alcoholic, malnourished patient. Impairment of visual acuity evolves over several days or a week or two, and examination discloses bilateral, roughly symmetrical central or centrocecal scotomas, the peripheral fields being intact. With appropriate treatment (nutritious diet and B vitamins) instituted soon after the onset of amblyopia, complete recovery is possible; if treatment is delayed, patients are left with varying degrees of permanent defect in central vision and pallor of the temporal portions of the optic discs. This disorder has commonly been referred to as “tobacco-alcohol amblyopia,” the implication being that it is due to the toxic effects of tobacco or alcohol, or both. In fact, the disorder is one of nutritional deficiency and is more properly design-

nated as *deficiency amblyopia* or *nutritional optic neuropathy* (Chap. 41). The same disorder may be seen under conditions of severe dietary deprivation (Strachan syndrome, page 992) and in patients with vitamin B₁₂ deficiency (page 994). Another cause is Leber hereditary optic atrophy, an inherited disorder of mitochondria, a subject that is reviewed by Newman and discussed in Chap. 37.

Subacute optic neuropathy of possible toxic origin has been described in Jamaican natives. It is characterized by a bilaterally symmetrical central visual loss and may have additional features of nerve deafness, ataxia, and spasticity. A similar condition has been described in other Caribbean countries, most recently in Cuba, where an optic neuropathy of epidemic proportions was associated with a sensory polyneuropathy. A nutritional etiology, rather than tobacco use (putatively, cigars in the Cuban epidemic), is likely but has not been proved conclusively (see Sadun et al and the Cuba Neuropathy Field Investigation report).

Impairment of vision due to *methyl alcohol intoxication* (methanol) is abrupt in onset and characterized by large symmetrical central scotomas as well as symptoms of systemic disease and acidosis. Treatment is directed mainly to correction of the acidosis. The subacute development of central field defects has also been attributed to other toxins and to the chronic administration of certain therapeutic agents: halogenated hydroxyquinolines (clioquinol), chloramphenicol, ethambutol, isoniazid, streptomycin, chlorpropamide (Diabinese), infliximab, and various ergot preparations. The main drugs reported to have a toxic effect on the optic nerves are listed in Table 13-3 and have been catalogued by Grant.

Developmental Abnormalities Congenital cavitary defects due to defective closure of the optic fissure may be a cause of impaired vision because of failure of development of the papillomacular bundle. Usually the optic pit or a larger coloboma is unilateral and unassociated with developmental abnormalities of the brain (optic disc dysplasia and dysplastic coloboma). A hereditary form is known (Brown and Tasman). Vision may also be impaired as a result of developmental anomalies of the optic nerves; the discs are of small diameter (hypoplasia of the optic disc or micropapilla).

Other Optic Neuropathies

Optic nerve and chiasmal involvement by gliomas, meningiomas, craniopharyngiomas, and metastatic tumors (most often from lung or breast) may cause scotomas and optic atrophy (Chap. 31). Pituitary tumors characteristically cause bitemporal hemianopia, but very large adenomas, in particular if there is pituitary apoplexy, can cause blindness in one or both eyes (see page 577). Infiltration of an optic nerve may occur in sarcoidosis (Fig. 32-4, bottom panel), Wegener granulomatosis, and with certain neoplasms, notably leukemia and lymphoma.

Of particular importance is the optic nerve glioma that occurs in 15 percent of patients with type I von Recklinghausen neurofibromatosis. Usually it develops in children, often before the fourth year, causing a mass within the orbit and progressive loss of vision. If the eye is blind, the recommended therapy is surgical removal to prevent extension into the optic chiasm and hypothalamus. If vision is retained, radiation and chemotherapy are the recommended forms of treatment.

Thyroid ophthalmopathy with orbital edema, exophthalmos, and usually a swelling of extraocular muscles is an occasional cause of optic nerve compression.

Table 13-3
Causes of unilateral and bilateral optic neuropathy

I. Demyelinative (optic neuritis)	
	Multiple sclerosis
	Postinfectious and viral neuroretinitis
II. Ischemic	
	Arteriosclerotic (usually in-situ occlusion; occasionally carotid artery disease)
	Granulomatous (giant cell) arteritis
	Syphilitic arteritis
III. Parainfectious	
	Cavernous sinus thrombosis
	Paranasal sinus infection
IV. Toxins and drugs	
	Methanol
	Ethambutol
	Chloroquine
	Streptomycin
	Chlorpropamide
	Chloramphenicol
	Infliximab
	Ergot compounds, etc.
V. Deficiency states	
	Vitamin B ₁₂
	Thiamine or possibly several B vitamins ("tobacco-alcohol" amblyopia)
	Epidemic nutritional types (Cuban, Jamaican)
VI. Heredofamilial and developmental	
	Dominant juvenile optic atrophy
	Leber optic atrophy
	Developmental failure of disc or papillomacular bundle
	Progressive hyaline body encroachment
VII. Compressive and infiltrative	
	Meningioma of sphenoid wing or olfactory groove
	Metastasis to optic nerve or chiasm
	Glioma of optic nerve (neurofibromatosis type I)
	Optic atrophy following long-standing papilledema
	Pituitary tumor and apoplexy
	Thyroid ophthalmopathy
	Sarcoidosis
	Lymphoma
	Wegener granulomatosis
VIII. Radiation-induced optic neuropathy	

Radiation-induced damage of the optic nerves and chiasm has been well documented. In a series of 219 patients at the M. D. Anderson Cancer Center who received radiotherapy for carcinomas of the nasal or paranasal region, retinopathy occurred in 7, optic neuropathy with blindness in 8, and chiasmatic damage with bilateral visual impairment in 1. These complications followed the use of more than 50 Gy (5000 rad) of radiation (see Jiang et al).

Finally, it should be mentioned again that long-standing papilledema from any cause may eventually lead to optic atrophy and blindness. In the case of pseudotumor cerebri, the visual loss may be unexpectedly abrupt, appearing in a day or less and even sequentially in both eyes. This seems to happen most often in patients with constitutionally small optic nerves, no optic cup of the nerve head, and, presumably, a small aperture of the lamina cribrosa.

NEUROLOGY OF THE CENTRAL VISUAL PATHWAYS

From the retina there is a point-to-point projection to the lateral geniculate ganglion and from the latter to the calcarine cortex of the occipital lobe. Thus the visual cortex receives a spatial pattern of stimulation that corresponds with the retinal image of the visual field. Visual impairments due to lesions of the central pathways usually involve only a part of the visual fields, and a plotting of the fields provides fairly specific information as to the site of the lesion.

For purposes of description of the visual fields, each retina and macula are divided into a temporal and nasal half by a vertical line passing through the fovea centralis. A horizontal line represented roughly by the junction of the superior and inferior retinal vascular arcades also passes through the fovea and divides each half of the retina and macula into upper and lower quadrants. Visual field defects are always described in terms of the field defect from the patient's view (nasal, temporal, superior, inferior) rather than the retinal defect or the examiner's perspective. The retinal image of an object in the visual field is inverted and reversed from right to left, like the image on the film of a camera. Thus the left visual field of each eye is represented in the opposite half of each retina, with the upper part of the field represented in the lower part of the retina (see Fig. 13-2). The retinal projections to the geniculate nuclei and occipital cortex are illustrated in Fig. 13-4.

Testing for Abnormalities of the Visual Fields

Visual field defects caused by lesions of the retina, optic nerve and tract, lateral geniculate body, geniculocalcarine pathway, and striate cortex of the occipital lobe are illustrated in Fig. 13-2. In the alert, cooperative patient, the visual fields can be plotted accurately at the bedside. With one of the patient's eyes covered and the other fixed on the corresponding eye of the examiner (patient's right with examiner's left), a target—such as a moving finger, a cotton pledge, or a white disc mounted on a stick—is brought from the periphery toward the center of the visual field (confrontational testing). With the target at an equal distance between the eye of the examiner and that of the patient, the fields of the patient and examiner are then compared. Similarly, the patient's blind spot can be aligned with the examiner's and its size determined by moving the target outward from the blind spot until it is seen. Central and paracentral defects in the field can be outlined the same way. For reasons not known, red-green test objects are more sensitive than white ones in detecting defects of the visual pathways.

It should be emphasized that movement of the visual target provides the coarsest stimulus to the retina, so that a perception of its motion may be preserved while a stationary target of the same size may not be seen. In other words, moving targets are less useful than static ones in confrontational testing of visual fields. Finger counting and comparison of color intensity of a red object or the clarity of the examiner's hand from quadrant to quadrant are simple confrontation tests that will disclose most field defects. Glaser recommends presenting the examiner's hands simultaneously, one on each side of the vertical meridian; the hand in the hemianopic field appears blurred or darker than the other. Similarly, a scotoma may be defined by asking the patient to report changes in color or brightness of a red test object as it is moved toward or away from the point of fixation. We have taught that these confrontation tech-

niques are quite sensitive if performed carefully, but we are chastened by the article from Pandit and colleagues, who found false-negative tests in up to 42 percent of examinations. They found that testing of the central field with a 5-mm red target was less likely to give misleading results when compared to the standard of automated perimetry.

Similarly, a central scotoma may be identified by having the patient fixate with one eye on the examiner's nose, on which the examiner places the index finger of one hand or a white-headed pin and has the patient compare it for brightness, clarity, and color with a finger or pin held in the periphery. If any defect is found or suspected by confrontational testing, the fields should be charted and scotomas outlined on a tangent screen or perimeter. Highly accurate computer-assisted perimetry is now available in most ophthalmology clinics. Although the commonly used automated techniques encompass only the central visual field, this is more than adequate to detect most clinically important defects.

The method of testing by double simultaneous stimulation may elicit defects in the central processing of vision that are undetected by conventional perimetry. Movement of one finger in all parts of each temporal field may disclose no abnormality, but if movement is simultaneous in analogous parts of both temporal fields, the patient with a parietal lobe lesion, especially on the right, may see only the one in the normal right hemifield. In young children or uncooperative patients, the integrity of the fields may be roughly estimated by observing whether the patient is attracted to objects in the peripheral field or blinks in response to sudden threatening gestures in half of the visual field.

A common abnormality disclosed by visual field examination is *concentric constriction*. This may be due to severe papilledema, in which case it is usually accompanied by an enlargement of the blind spot. A progressive constriction of the visual fields, at first unilateral and later bilateral, associated with pallor of the optic discs (optic atrophy), should suggest a chronic meningeal process involving the optic nerves (syphilis, cryptococcosis, sarcoid, lymphoma). Long-standing, untreated glaucoma and retinitis pigmentosa are other causes of concentric constriction. Marked constriction of the visual fields of unvarying degree, regardless of the distance of the visual stimulus from the eye ("gun-barrel" or "tunnel" vision), is a sign of hysteria. With organic disease, the constricted visual field naturally enlarges as the distance between the patient and the test object increases.

A regional constriction of the field, especially in a nasal quadrant, usually signifies early optic atrophy, as mentioned earlier; it is the first sign that chronic papilledema is threatening the patient's vision.

Prechiasmal Lesions

Lesions of the macula, retina, or optic nerve cause a *scotoma* (an island of impaired vision surrounded by normal vision) rather than a defect that extends to the periphery of one visual field ("field cut"). Scotomas are named according to their position (central, cecocentral) or their shape (ring, arcuate). A small scotoma that is situated in the macular part of the visual field may seriously impair visual acuity.

Scotomas are the main features of optic neuropathy, the causes of which have been mentioned earlier. Demyelinative disease (optic neuritis), Leber hereditary optic atrophy, toxins (methyl alcohol, quinine, chloroquine, and certain phenothiazine drugs), nutritional deficiency (so-called tobacco-alcohol amblyopia), and vascular dis-

ease (ischemic optic neuropathy or occlusion of a branch of the retinal artery) are the usual ones. Orbital or retro-orbital tumors and infectious or granulomatous processes (e.g., sarcoid, retinal toxoplasmosis in AIDS) are other common causes. Certain toxic and malnutritional states are characterized by more or less symmetrical bilateral central scotomas (involving the fixation point) or cecocentral ones (involving both the fixation point and the blind spot). The cecocentral scotoma, which tends to have an arcuate border, represents a lesion that is predominantly in the distribution of the papillomacular bundle. However, the presence of this visual field abnormality does not establish whether the primary defect is in the cells of the origin of the bundle, i.e., the retinal ganglion cells, or in their fibers. Demyelinative disease is characterized by unilateral or asymmetrical bilateral scotomas. Vascular lesions that take the form of retinal hemorrhages or infarctions of the nerve-fiber layer (cotton-wool patches) give rise to unilateral scotomas; occlusion of the central retinal artery or its branches causes infarction of the retina and, as a rule, a loss of central vision. As pointed out earlier, anterior ischemic optic neuropathy causes sudden monocular blindness or an altitudinal field defect. Since the optic nerve also contains the afferent fibers for the pupillary light reflex, extensive lesions of the nerve will cause a so-called afferent pupillary defect, which has been mentioned earlier and is considered further in Chap. 14.

With most diseases of the optic nerve, as alluded to above, the optic disc will eventually become pale (atrophic). This usually requires 4 to 6 weeks to develop. If the optic nerve degenerates (e.g., in multiple sclerosis, Leber hereditary optic atrophy, traumatic transection, tumor of nerve, or syphilitic optic atrophy), the disc becomes chalk-white, with sharp, clean margins. If the atrophy is secondary to papillitis or papilledema, the disc margins are indistinct and irregular; the disc has a pallid, yellow-gray appearance, like candle tallow; the vessels are partially obscured; and the adjacent retina is altered because of the outfall of fibers.

As in the case of optic neuritis, visual evoked potentials from the stimulation of one eye may be slowed even if the optic disc appears normal and there is no perimetric abnormality.

Lesions of the Chiasm, Optic Tract, and Geniculocalcarine Pathway

Hemianopia (hemianopsia) means blindness in half of the visual field. *Bitemporal hemianopia* indicates a lesion of the decussating fibers of the optic chiasm and is caused most often by the suprasellar extension of a tumor of the pituitary gland (Fig. 13-2C). It may also be the result of a craniopharyngioma, a saccular aneurysm of the circle of Willis, and a meningioma of the tuberculum sellae; less often, it may be due to sarcoidosis, metastatic carcinoma, ectopic pinealoma or dysgerminoma, Hand-Schüller-Christian disease, or hydrocephalus with dilation and downward herniation of the posterior part of the third ventricle (Corbett). In some instances a tumor pushing upward presses the medial parts of the optic nerves, just anterior to the chiasm, against the anterior cerebral arteries. Heteronymous field defects, i.e., scotomas or field defects that differ in the two eyes, are also a sign of involvement of the optic chiasm or the adjoining optic nerves or tracts; they are caused by craniopharyngiomas or other suprasellar tumors and rarely by mucoceles, angiomas, giant carotid aneurysms, and opticochiasmic arachnoiditis.

The visual field pattern created by a lesion in the optic nerve as it joins the chiasm typically includes a scotomatous defect on

the affected side coupled with a contralateral superior quadrantanopia ("junctional field defect"). As noted previously, the latter is caused by interruption of nasal retinal fibers which, after crossing in the chiasm, project into the base of the affected optic nerve (Wilbrand's knee, see Fig. 13-2B). A sharply defined pattern of this type is relatively uncommon. Variations in the pattern of visual loss are frequent, in part accounted for by the location of the chiasm in an individual patient—a prefixed chiasm making unilateral eye findings more common.

Homonymous hemianopia (a loss of vision in corresponding halves of the visual fields) signifies a lesion of the visual pathway behind the chiasm and, if complete, gives no more information than that. *Incomplete homonymous hemianopia* has more localizing value. As a general rule, if the field defects in the two eyes are identical (congruous), the lesion is likely to be in the calcarine cortex and subcortical white matter of the occipital lobe; if they are *incongruous*, the visual fibers in the optic tract or in the parietal or temporal lobe are more likely to be implicated. Actually, absolute congruity of field defects is rare, even with occipital lesions.

The lower fibers of the geniculocalcarine pathway (from the inferior retinas) swing in a wide arc over the temporal horn of the lateral ventricle and then proceed posteriorly to join the upper fibers of the pathway on their way to the calcarine cortex (Fig. 13-2). This arc of fibers is known variously as the Flechsig, Meyer, or Archambault loop, and a lesion that interrupts these fibers will produce a *superior homonymous quadrantanopia* (contralateral upper temporal and ipsilateral upper nasal quadrants; Fig. 13-2E). This clinical effect was first described by Harvey Cushing, so that his name also has been applied to the loop of temporal visual fibers. Parietal lobe lesions are said to affect the inferior quadrants of the visual fields more than the superior ones, but this is difficult to document; with a lesion of the right parietal lobe, the patient ignores the left half of space; with a left parietal lesion, the patient is often aphasic. As to the localizing value of *quadrantic defects*, the report of Jacobson is of interest; he found, in reviewing the imaging studies of 41 patients with inferior quadrantanopia and 30 with superior quadrantanopia, that in 76 percent of the former and 83 percent of the latter the lesions were confined to the occipital lobe.

If the entire optic tract or calcarine cortex on one side is destroyed, the homonymous hemianopia is complete. But often that part of the field subserved by the macula is spared, i.e., there is a 5- to 10-degree island of vision around the fixation point on the side of the hemianopia (sparing of fixation, or *macular sparing*). With infarction of the occipital lobe due to occlusion of the posterior cerebral artery, the macular region, represented in the most posterior part of the striate cortex, may be spared by virtue of collateral circulation from branches of the middle cerebral artery. Incomplete lesions of the optic tract and radiation usually spare central (macular) vision. We have nevertheless observed a lesion of the tip of one occipital lobe that produced central homonymous hemianopic scotomata, bisecting the maculae. Lesions of both occipital poles (as in embolization of the posterior cerebral arteries) result in bilateral central scotomas; if all the calcarine cortex or all the subcortical geniculocalcarine fibers on both sides are completely destroyed, there is cerebral or "*cortical*" blindness (see below and Chap. 22).

An *altitudinal defect* is one that is confined to the upper or lower half of the visual field but crosses the vertical meridian. *Homonymous altitudinal hemianopia* is usually due to lesions of both occipital lobes below or above the calcarine sulcus and rarely to a

lesion of the optic chiasm or nerves. The most common cause is occlusion of both posterior cerebral arteries at their origin at the termination of the basilar artery. By contrast, the cause of a monocular altitudinal hemianopia is almost invariably an ischemic optic neuropathy that arises from occlusion of the posterior ciliary vessels.

In certain instances of homonymous hemianopia, the patient is capable of some visual perception in the hemianopic fields, a circumstance that permits the study of the vulnerability of different visual functions. Colored targets may be detected in the hemianopic fields, whereas achromatic ones cannot. But even in seemingly complete hemianopic defects, in which the patient admits to being blind, it has been shown that he may still react to visual stimuli when forced-choice techniques are used. Blythe and coworkers found that 20 percent of their patients with no ability to discriminate patterns in the hemianopic field nonetheless could still reach accurately and look at a moving light in the “blind” field. This type of residual visual function has been called “blindsight” by Weiskrantz and colleagues. These residual visual functions are generally attributed to the preserved function of retinocollicular or geniculoprestriate cortical connections, but they may as likely be due to sparing of small islands of calcarine neurons. In yet other instances of complete homonymous hemianopia, the patient may be little disabled by visual field loss (Benton et al; Meienberg). This is due to preservation of vision in a small monocular part of the visual field known as the *temporal crescent*. The latter is a peripheral unpaired portion of the visual field, between 60 and 100 degrees from the fixation point, and is represented in the most anterior part of the visual striate cortex. In particular, the temporal crescent is sensitive to moving stimuli, allowing the patient to avoid collisions with people and objects.

Blindness in the Hysterical or Malingering Patient *Hysterical blindness* is described on page 1299, along with other features of hysteria, but a few comments are in order here. Feigned or hysterical visual loss is usually detected by attending to the patient’s activities when he thinks he is unobserved and it can be confirmed by a number of simple tests. Complete feigned blindness is exposed by observing the normal ocular jerk movements in response to a rotating optokinetic drum or strip or by noting that the patient’s eyes follow their own image in a moving mirror. The hysterical nature of *monocular blindness* is exposed by noting the presence of a normal pupillary response to light. An optokinetic response in the nonseeing eye (with the good eye covered) is an even more convincing test; also, the visual evoked potential from the allegedly blind eye is normal. *Hysterical homonymous hemianopia* is exceedingly rare and is only displayed by practiced malingerers and psychopaths. Lateral hemianopias of every variety are common (Keane). The uniformly constricted tubular field defect of hysteria has already been mentioned.

Cerebral Forms of Blindness and Visual Agnosia (See also Chap. 22.) The ability to recognize visually presented objects and words depends on the integrity not only of the visual pathways and primary visual area of the cerebral cortex (area 17 of Brodmann) but also of those cortical areas that lie just anterior to area 17 (areas 18 and 19 of the occipital lobe and area 39—the angular gyrus of the dominant hemisphere). Blindness that is the result of destruction of both visual and adjacent regions of the occipital lobes is termed *cortical* or *cerebral blindness*. Another remarkable condi-

tion exists in which the patient denies or is oblivious to blindness despite overt manifestations of the defect (Anton syndrome).

In distinction to these forms of blindness, there is a less common category of visual impairment in which the patient cannot understand the meaning of what he sees, i.e., *visual agnosia*. Primary visual perception is more or less intact, and the patient may accurately describe the shape, color, and size of objects and draw copies of them. Despite this, he cannot identify the objects unless he hears, smells, tastes, or palpates them. The failure of visual recognition of words alone is called *visual verbal agnosia* or *alexia*. Visual-object agnosia rarely occurs as an isolated finding: as a rule, it is combined with visual verbal agnosia, homonymous hemianopia, or both. These abnormalities arise from lesions of the dominant occipital cortex and adjacent temporal and parietal cortex (angular gyrus) or from a lesion of the left calcarine cortex combined with one that interrupts the fibers crossing from the right occipital lobe (see Fig. 22-6).

Failure to understand the meaning of an entire picture even though some of its parts are recognized is referred to as *simultanagnosia*, and a failure to recognize familiar faces is called *prosopagnosia*. These and other variants of visual agnosia (including visual neglect) and their pathologic bases are dealt with more fully in Chap. 22.

Other cerebral disturbances of vision include various types of distortion in which images seem to recede into the distance (*teleopsia*), appear too small (*micropsia*), or, less frequently, seem too large (*macropsia*). If such distortions are perceived with only one eye, a local retinal lesion should be suspected. If perceived with both eyes, they usually signify disease of the temporal lobes, in which case the visual disturbances tend to occur in attacks and are accompanied by other manifestations of temporal lobe seizures (Chap. 16). *Palinopsia*, a persistence of repetitive afterimages, similar to the appearance of a celluloid movie strip, occurs with right parieto-occipital lesions; it has been a consequence of seizures in the cases we have encountered, but instances associated with static disorders (tumor, infarction) have been described as well. Patients describe the images as “trailing” or “echoing.” With parietal lobe lesions, objects may appear to be askew or even turned upside down. More often, lesions of the vestibular nucleus or its immediate connections produce the illusion that objects are tilted or turned upside down (*tortopia*; page 236) or that straight lines are curved. Presumably this is due to a mismatch between the visual image and the otolithic or vestibular input to the visual system.

Abnormalities of Color Vision

Normal color vision depends on the integrity of cone cells, which are most numerous in the macular region. When activated, they convey information to special columns of cells in the striate cortex. Three different cone pigments with optimal sensitivities to blue, green, and orange-yellow wavelengths are said to characterize these cells; presumably each cone possesses only one of these pigments. Transmission to higher centers for the perception of color is believed to be effected by neurons and axons that encode at least two pairs of complementary colors: red-green in one system and yellow-blue in the other. In the optic nerves and tracts, the fibers for color are of small caliber and seem to be preferentially sensitive to certain noxious agents and to pressure. The geniculostriate fibers for color are separate from fibers that convey information about form and brightness but course along with them; hence there may

be a homonymous color hemianopia (hemiachromatopsia). The visual fields for blue-yellow are smaller than those for white light, and the red and green fields are smaller than those for blue-yellow.

Diseases may affect color vision by abolishing it completely (*achromatopsia*) or partially by quantitatively reducing one or more of the three attributes of color—brightness, hue, and saturation. Or, only one of the complementary pairs of colors may be lost, usually red-green. The disorder may be congenital and hereditary or acquired. The most common form, and the one to which the term *color-blindness* is usually applied, is a male sex-linked inability to see red and green while normal visual acuity is retained. The main problem arises in relation to traffic lights, but patients learn to use the position of the light as a guide. Several other genetic abnormalities of cone pigments and their phototransduction have been identified as causes of achromatopsia. The defect cannot be seen by inspecting the retina. A failure of the cones to develop or a degeneration of cones may cause a loss of color vision, but in these conditions visual acuity is often diminished, a central scotoma may be present, and, although the macula also appears to be normal ophthalmoscopically, fluorescein angiography shows the pigment epithelium to be defective. While congenital color vision defects are usually protan (red) or deutan (green), leaving yellow-blue color vision intact, most acquired lesions affect all colors, at times disparately. Lesions of the optic nerves usually affect red-green more than blue-yellow; the opposite is true of retinal lesions. An exception is a rare dominantly inherited optic atrophy, in which the scotoma mapped by a large blue target is larger than that for red.

Damasio has drawn attention to a group of acquired deficits of color perception with preservation of form vision, the result of focal damage (usually infarction) of the visual association cortex and subjacent white matter. Color vision may be lost in a quadrant, half of the visual field, or the entire field. The latter, or full-field achromatopsia, is the result of bilateral occipitotemporal lesions involving the fusiform and lingual gyri, a localization that accounts for its frequent association with visual agnosia (especially prosopagnosia; see page 407) and some degree of visual field defect. A lesion restricted to the inferior part of the right occipitotemporal region, sparing both the optic radiations and striate cortex, causes the purest form of achromatopsia (left hemiachromatopsia). With a similar left-sided lesion, alexia may be associated with the right hemiachromatopsia.

Other Visual Disorders In addition to the losses of perception of form, movement, and color, lesions of the visual system may

also give rise to a variety of positive sensory visual experiences. The simplest of these are called phosphenes, i.e., flashes of light and colored spots in the absence of luminous stimuli. Mechanical pressure on the normal eyeball may induce them at the retinal level, as every child discovers. Or they may occur with disease of the visual system at many different sites. As mentioned earlier, elderly patients commonly complain of flashes of light in the peripheral field of one eye, most evident in the dark (*Moore's lightning streaks*); these are related to vitreous tags that rest on the retinal equator and may be quite benign or may be residual evidence of retinal detachment. In patients with migraine, ischemia (or perhaps activation) of nerve cells in the occipital lobe gives rise to the bright zigzag lines of a fortification spectrum. Stimulation of the cortical terminations of the visual pathways accounts for the simple or unformed visual hallucinations in epilepsy. Formed or complex visual hallucinations (of people, animals, landscapes) are observed in a variety of conditions, notably in old age when vision fails (Bonnet syndrome, discussed on page 405), in the withdrawal state following chronic intoxication with alcohol and other sedative-hypnotic drugs (Chaps. 42 and 43), in Alzheimer disease, and in infarcts of the occipitoparietal or occipitotemporal regions (release hallucinations) or the diencephalon ("peduncular hallucinosis"). These disorders are discussed in Chap. 22.

Occasionally, patients in whom a hemianopia is evident only when tested by double simultaneous stimulation ("attention hemianopia") may displace an image to the nonaffected half of the field of vision (*visual allesthesia*), or a visual image may persist for minutes to hours or reappear episodically, after the exciting stimulus has been removed (*palinopsia* or *paliopsia*, mentioned earlier); the latter disorder also occurs in defective but not blind homonymous fields of vision. *Polyopia*, the perception of multiple images when a single stimulus is presented, is said to be associated predominantly with right occipital lesions and can occur with either eye. Usually there is one primary and a number of secondary images, and their relationships may be constant or changing. Bender and Krieger, who described several such patients, attributed the polyopia to unstable fixation. When this is monocular, there is either a defect in the lens or more often, hysteria. *Oscillopsia*, or illusory movement of the environment, is a perception caused by nystagmus and occurs mainly with lesions of the labyrinthine-vestibular apparatus; it is described with disorders of ocular movement (see page 237). A rare idiopathic myokymia of one superior oblique muscle may produce a monocular oscillopsia (see page 234).

The clinical effects and syndromes that result from occipital lobe lesions are discussed further in Chap. 22.

CHAPTER 14

DISORDERS OF OCULAR MOVEMENT AND PUPILLARY FUNCTION

Ocular movement and vision are virtually inseparable. A moving object evokes movement of the eyes and almost simultaneously arouses attention and initiates the perceptive process. To look searchingly, i.e., to peer, requires stable fixation of the visual image on the center of the two retinas. One might say that the ocular muscles are at the beck and call of our visual sense. This is the logic of juxtaposing Chaps. 13 and 14 and suggesting that they be read together.

Abnormalities of ocular movement are of three basic types. One category can be traced to a lesion of the extraocular muscles themselves, the neuromuscular junction, or to the cranial nerves that supply them (*nuclear* or *infranuclear palsy*). The second type, of particular neurologic interest, is a derangement in the highly specialized neural mechanisms that enable the eyes to move together (*supranuclear* and *internuclear palsies*). Such a distinction, in keeping with the general concept of upper and lower motor neuron paralysis, hardly portrays the complexity of the neural mechanisms governing ocular motility; nevertheless, it constitutes an essential step in the approach to the patient with defective eye movements. With regard to these disorders, a knowledge of the anatomic basis of normal movement is essential to an understanding of abnormal movement. Perhaps more common but not primarily neurologic is the third group, *concomitant strabismus*, in which there is a congenital imbalance of the yoked muscles of extraocular movement.

SUPRANUCLEAR CONTROL OF EYE MOVEMENT

Anatomic and Physiologic Considerations

In no aspect of human anatomy and physiology is the sensory guidance of muscle activity more instructively revealed than in the neural control of coordinated ocular movement. Moreover, the entirely predictable and “hard-wired” nature of the central and peripheral oculomotor apparatus allows for a very precise localization of lesions within these pathways. To focus the eyes voluntarily in searching the environment, to stabilize objects for scrutiny when one is moving, to maintain clear images of moving objects, to bring into sharp focus near and far objects—all require the perfect coordination of six sets of extraocular muscles and three sets of intrinsic muscles (ciliary muscles and sphincters and dilators of the iris). The neural mechanisms that govern these functions reside mainly in the midbrain and pons but are greatly influenced by centers in the medulla, cerebellum, basal ganglia, and the frontal, parietal, and occipital lobes of the brain. Most of the nuclear structures and pathways concerned with fixation and stable ocular movements are now known, and much has been learned of their physiology both from clinical-pathologic correlations in humans and from experiments in monkeys. Different diseases give rise to

particular defects in ocular movement and pupillary function, and these are of diagnostic importance.

Accurate binocular vision is achieved by the associated action of the ocular muscles, which allows a visual stimulus to fall on exactly corresponding parts of the two retinas. The symmetrical and synchronous movement of the eyes is termed *conjugate movement* or *gaze* (*conjugate*, meaning yoked or joined together). The simultaneous movement of the eyes in opposite directions, as in convergence, is termed *disconjugate* or *disjunctive*. These two forms of normal ocular movement—conjugate and disconjugate—are also referred to as *versional* and *vergence*, respectively. *Vergence movements* have two components—fusional and accommodative. Fusional movements are *convergence* and *divergence*, which maintain binocular single vision and depth perception (stereopsis); they are necessary at all times to prevent visual images from falling on noncorresponding parts of the retinas. *Convergent movements* are brought into action when one looks at a near object. The eyes turn inward (off their parallel axes) and at the same time the pupils constrict and the ciliary muscles relax to thicken the lens and allow near vision (*accommodation*). This synkinesis is called the *near reflex* or *accommodative triad*. Divergence is required for distant vision.

Rapid voluntary conjugate movements of the eyes to the opposite side are initiated in area 8 of the frontal lobe (see page 387) and relayed to the pons. These quick movements are termed *saccadic* (peak velocity may exceed 700 degrees per second). Their purpose is to quickly change ocular fixation to bring images of new objects of interest onto the foveas. Saccades are so rapid that there is no subjective awareness of movement during the change in eye position, essentially resulting in a momentary blindness. Saccadic movements can be elicited by instructing the individual to look to the right or left (commanded saccades) or to move the eyes to a target (refixation saccades). Saccades may also be elicited reflexively, as when a sudden sound or the appearance of an object in the peripheral field of vision attracts attention and triggers an automatic movement of the eyes in the direction of the stimulus. Saccadic latency, the interval between the appearance of a target and the initiation of a saccade, is approximately 200 ms.

The neuronal firing pattern of pontine neurons that produces a saccade has been characterized as “pulse-step” in type. This refers to the sudden increase in neuronal firing (the pulse) that is necessary to overcome the inertia and viscous drag of the eyes and to move them into their new position; its is followed by a return to a new baseline firing level (the step), which maintains the eyes in their new position by constant tonic contraction of the extraocular muscles (*gaze holding*).

Saccades are distinguished from the slower and smoother, largely involuntary *pursuit* or *following movements*, for which the major stimulus is a moving target upon which the eyes are fixated. The function of pursuit movements is to stabilize the image of a moving object on the foveas as the object is tracked by the eyes

(“smooth tracking”) and thus to maintain a continuous clear image of the object as it changes position in the environment. Unlike saccades, pursuit movements to each side are generated in the *ipsilateral* parieto-occipital cortex, with modulation by the ipsilateral cerebellum, especially the vestibulocerebellum (flocculus and nodulus). Another portion of the cerebellum, the posterior vermis, modulates saccadic movements (see further on).

When following a moving target, as the visual image slips off the foveas, the firing rate of the governing motor neurons increases in proportion to the speed of the target, so that eye velocity matches target velocity. If, during pursuit, the eyes fall behind the target, supplementary catch-up saccades are required for refixation. The pursuit movement is then not smooth but becomes jerky (“cogwheel” or “saccadic” pursuit). A lesion of one cerebral hemisphere may cause pursuit movements to that side to break up into saccades. This is often associated with, but not dependent on, a homonymous hemianopia. Also, diseases of the basal ganglia are a common cause of a disruption of normally smooth pursuit into a ratchet-like saccadic pursuit in all directions.

If a series of visual targets enters the visual field, as when one is watching trees from a moving car or the stripes on a rotating drum, repeated quick saccades refocus the eyes centrally; the resulting repeated cycles of pursuit and refixation are termed *optokinetic nystagmus*. The main value of this test is in revealing a lesion of the posterior parietal lobe, which causes visual pursuit to be lost in the direction of the side of the lesion; it may also be found that a frontal lobe lesion eliminates the quick nystagmoid refixation phase away from the side of the lesion, causing the eyes to continue to follow the target until it is out of view. This phenomenon is described more fully further on, in the section on nystagmus.

Vestibular influences are of particular importance in stabilizing images on the retina. By means of the *vestibulo-ocular reflex* (VOR), a movement of the eyes is produced that is equal and opposite to movement of the head. The VOR generates a prompt short latency response to rapid transient head movements. During sustained rotation of the head, the VOR is supplemented by the optokinetic system, which enables one to maintain compensatory eye movements for a more prolonged period. If the VOR is lost, as occurs with disease of the vestibular apparatus or eighth nerve, the slightest movements of the head, especially those occurring during locomotion, cause a movement of images across the retina large enough to impair vision. When objects are tracked using both eye and head movements, the vestibulo-ocular movements induced by head turning must be suppressed, otherwise the eyes would remain stabilized in space; it appears likely that the smooth pursuit signals cancel the unwanted vestibular ones (Leigh and Zee).

Horizontal Gaze

Saccades As already mentioned, the signals for volitional horizontal gaze saccades originate in the eye field of the opposite frontal lobe (area 8 of Brodmann, see page 387) and are modulated by the adjacent supplementary motor eye field and by the posterior visual cortical areas. The cortical-to-pontine pathways for saccadic horizontal gaze have been traced in the monkey by Leichnetz. He found that these fibers traverse the internal capsule and separate at the level of the rostral diencephalon into two bundles, the first being a primary but indirect ventral “capsular-peduncular” bundle, which descends through the most medial part of the cerebral peduncle. This more ventral pathway undergoes a partial decussation in the

low midbrain, at the level of the trochlear nucleus, and terminates mainly in the vaguely defined paramedian pontine reticular formation (PPRF) of the opposite side, which in turn projects to the adjacent sixth nerve nucleus (Fig. 14-1). A second, more dorsal “transthalamic” bundle is predominantly uncrossed and courses through the internal medullary lamina and paralaminar parts of the thalamus to terminate diffusely in the pretectum, superior colliculus, and periaqueductal gray matter. An offshoot of these fibers (the prefrontal oculomotor bundle) projects to the rostral part of the oculomotor nucleus and to the ipsilateral rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) and to the interstitial nucleus of Cajal (INC), which are involved in vertical eye movements, as discussed in the next section.

Pursuit The pathways for smooth pursuit movements are less well defined. One probably originates in the posterior parietal cortex and the adjacent temporal and anterior occipital cortex (area MT of the monkey), and descends to the ipsilateral dorsolateral pontine nuclei. Also contributing to smooth pursuit movements are projections from the frontal eye fields to the ipsilateral dorsolateral pontine nuclei. The latter, in turn, project to the flocculus and dorsal vermis of the cerebellum, which provide stability for the pursuit movements. However, for the purposes of clinical work, lesions of the posterior parietal cortex are known to impair pursuit toward the damaged side, and lesions of the frontal eyefields impede pursuit to the opposite side.

Brainstem (Internuclear) Pathways and Oculomotor Nuclei Ultimately, all the pathways mediating saccadic and pursuit movements in the horizontal plane as well as vestibular and optokinetic movements converge on the pontine centers for horizontal gaze. These comprise the PPRF, the nuclei prepositus hypoglossi and commissure, the abducens and medial vestibular nuclei, and pathways in the pontine and tegmentum of the brainstem that interconnect the oculomotor nuclei (Fig. 14-1). (Conventionally, the term *oculomotor nuclei* refers to the nuclei of the third, fourth, and sixth cranial nerves; the term *oculomotor nucleus* refers to the third nerve nucleus alone.) The pathway connecting the third and sixth nerve nuclei and connecting both these nuclei with the vestibular nuclei lies in the medial tegmentum of the brainstem; this pathway is termed the *medial longitudinal fasciculus* (MLF).

The PPRF and the prepositus and medial vestibular nuclei function as a “neural integrator” and relay station for horizontal saccade pathways. However, it is apparent from animal experiments that the neural signals that encode smooth pursuit and vestibular and optokinetic movements bypass the PPRF and project independently to the abducens nuclei (Hanson et al).

The abducens nucleus contains two groups of neurons, each with distinctive morphologic and physiologic properties: (1) abducens motor neurons, which innervate the ipsilateral lateral rectus muscle, and (2) abducens internuclear neurons, which project via the contralateral medial longitudinal fasciculus (MLF) to the medial rectus neurons of the oculomotor nucleus. Conjugate lateral gaze is accomplished by the simultaneous innervation of the ipsilateral lateral rectus and the contralateral medial rectus, the latter through fibers that run in the medial portion of the MLF. Interruption of the MLF results in a discrete impairment or loss of adduction of the eye ipsilateral to the MLF lesion, a phenomenon referred to as *internuclear ophthalmoplegia*, the details of which are discussed further on (see Fig. 14-1). Two other ascending pathways between the pontine centers and the mesencephalic reticular for-

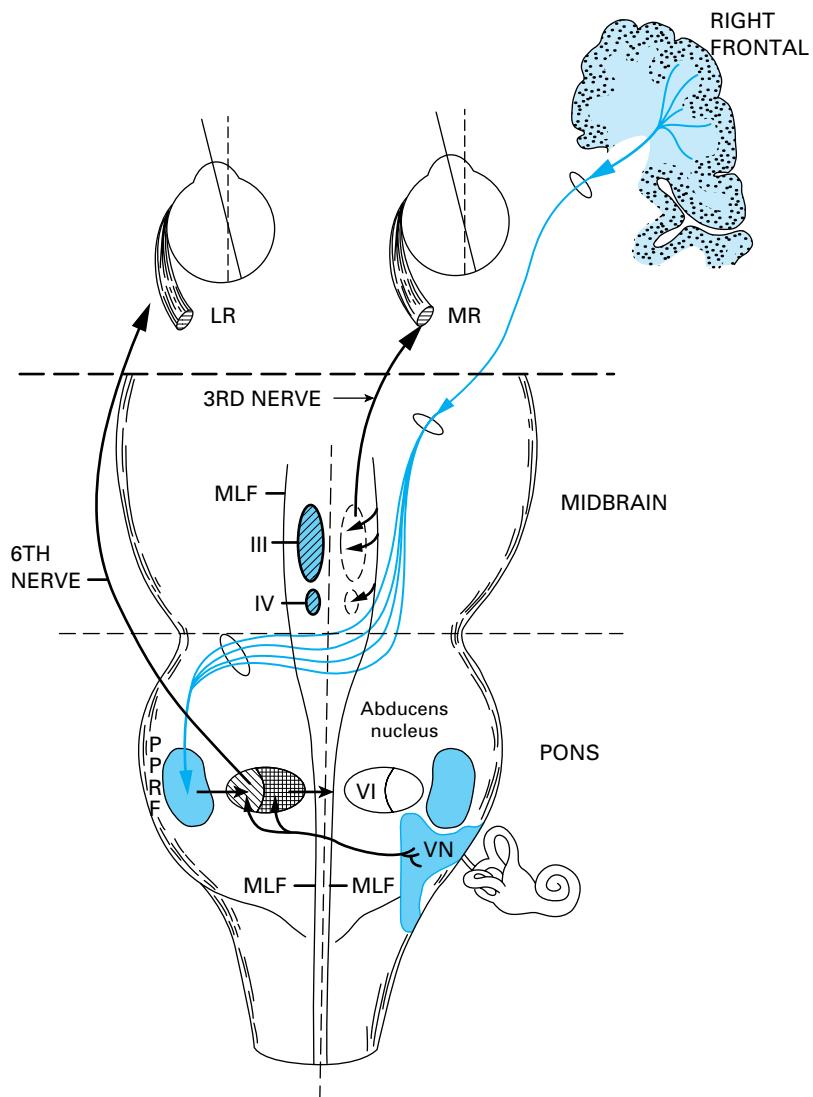

Figure 14-1. The supranuclear pathways subserving saccadic horizontal gaze to the left. The pathway originates in the right frontal cortex, descends in the internal capsule, decussates at the level of the rostral pons, and descends to synapse in the left pontine paramedian reticular formation (PPRF). Further connections with the ipsilateral sixth nerve nucleus and contralateral medial longitudinal fasciculus are also indicated. Cranial nerve nuclei III and IV are labeled on left; nucleus of VI and vestibular nuclei (VN) are labeled on right. LR, lateral rectus; MR, medial rectus; MLF, medial longitudinal fasciculus.

mation have been traced: one traverses the central tegmental tract and terminates in the pretectum, in the nucleus of the posterior commissure; the other is a bundle separate from the MLF that passes around the nuclei of Cajal and Darkschewitz to the rostral interstitial nucleus of the MLF (riMLF). These nuclei are involved more in vertical gaze and are described below. In addition, each vestibular nucleus projects onto the abducens nucleus and the MLF of the opposite side; the functional significance of the latter pathways is not entirely clear.

Although projections from the frontal eye fields to the oculomotor nuclei, as described above, undoubtedly exist, indirect projections are probably as important in the voluntary control of conjugate eye movements. According to Leigh and Zee, a more accurate conceptualization of these voluntary influences is one of a hierarchy of cell stations and parallel pathways that do not project

directly to oculomotor nuclei but to adjacent *premotor* or *burst neurons*, which discharge at high frequencies immediately preceding a saccade. The pre-motor or burst neurons for horizontal saccades lie within the PPRF and those for vertical saccades in the riMLF (see below). Yet a third class of neurons (pause cells), lying in the midline of the pons, is involved in the inhibition of unwanted saccadic discharges. Nonetheless, in clinical work, the circuit that comprises in sequence (1) frontal lobe eye fields, (2) contralateral pontine PPRF, (3) abducens nucleus, (3) MLF, and (4) oculomotor nucleus is exposed by a number of highly characteristic defects of horizontal ocular motion, as detailed further on.

Vertical Gaze

In contrast to horizontal gaze, which is generated by unilateral aggregates of cerebral and pontine neurons, vertical eye movements, with few exceptions, are under bilateral control of the cerebral cortex and upper brainstem. The groups of nerve cells and fibers that govern upward and downward gaze as well as torsional saccades are situated in the pretectal areas of the midbrain and involve three integrated structures—the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), the interstitial nucleus of Cajal (INC), and the nucleus and fibers of the posterior commissure (Fig. 14-2).

The riMLF lies at the junction of the midbrain and thalamus, at the rostral end of the medial longitudinal fasciculus, just dorsomedial to the rostral pole of the red nucleus. The riMLF functions as the “premotor” nucleus with “burst cells” for the production of fast (saccadic) vertical versional and torsional movements. Input to the riMLF arises both from the PPRF and the vestibular nuclei. Each riMLF projects mainly ipsilaterally to the oculomotor and trochlear nuclei, but each riMLF is connected to its counterpart by fibers that traverse the posterior commissure. Bilateral lesions of the riMLF or of their interconnections in the posterior commissure (see below) are more common than unilateral ones and cause a loss either of downward saccades or of all vertical saccades.

The *interstitial nucleus of Cajal (INC)* is a small collection of cells that lies just caudal to the riMLF on each side. Each nucleus projects to the motor neurons of the elevator muscles (superior rectus and inferior oblique) by fibers that cross through the posterior commissure and project ipsilaterally to the depressor muscles (inferior rectus and superior oblique). The functional role of the INC appears to be in holding eccentric vertical gaze, especially after a saccade; it is also integral to the vestibulo-ocular reflex. Lesions of the INC produce a vertical gaze–evoked and torsional nystagmus and an ocular tilt reaction (page 227) and probably impair all conjugate eye movements, mainly vertical ones, to some extent.

Lesions of the *posterior commissure* are common; they interrupt signals crossing to and from the INC and the riMLF. A lesion here characteristically produces a paralysis of upward gaze and of convergence, often associated with mydriasis and lid retraction

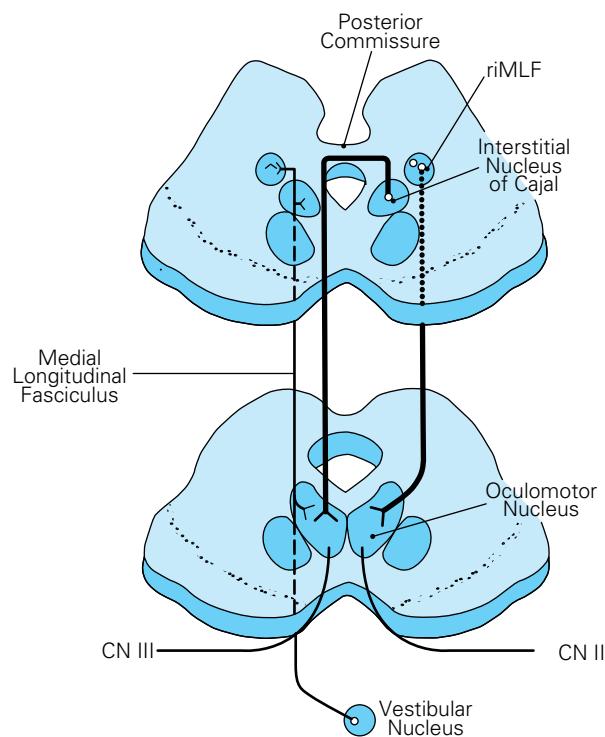

Figure 14-2. Pathways for the control of vertical eye movements. The main structures are the interstitial nucleus of Cajal (INC), the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), and the subnuclei of the third nerve, all located in the dorsal midbrain. Voluntary vertical movements are initiated by the simultaneous activity of both frontal cortical eye fields. The riMLF serves as the generator of vertical saccades and the INC acts tonically to hold eccentric vertical gaze. The INC and riMLF connect with their contralateral nuclei via the posterior commissure, where fibers are subject to damage. Projections for upgaze cross through the commissure before descending to innervate the third nerve nucleus, while those for downgaze may travel directly to the third nerve, thus accounting for the frequency of selective upgaze palsies (see text). The MLF carries signals from the vestibular nuclei, mainly ipsilaterally, to stabilize the eyes in the vertical plane (VOR) and maintain tonic vertical position.

(Collier's “tucked lid” sign) and less commonly with ptosis. This constellation comprises the *Parinaud syndrome*, also referred to as the pretectal, dorsal midbrain, or sylvian aqueduct syndrome (see page 227). The same syndrome may be produced by unilateral lesions of the posterior commissure, presumably by interrupting connections in both directions. With acute lesions of the commissure, there may be a tonic downward deviation of the eyes and lid retraction (“setting-sun sign”).

The MLF is the main conduit of vertical gaze signals from the vestibular nuclei in the medulla to the midbrain centers. For this reason, along with the characteristic adductor paresis on the affected side, vertical pursuit and the VOR are impaired with internuclear ophthalmoplegia (INO), particularly when the lesion is bilateral, and a vertical deviation of the ipsilateral globe (*skew*) may be seen in cases of unilateral INO, as discussed in a later section.

Vestibulocerebellar Influences on Eye Movements

There are important vestibulocerebellar influences on both smooth pursuit and saccadic movements, as mentioned earlier (see also

Chap. 5). The flocculus and posterior vermis of the cerebellum receive abundant sensory projections from proprioceptors of the cervical musculature (responsive to head velocity), the retinas (sensitive to target velocity), proprioceptors of eye muscles (eye position and eye velocity), auditory and tactile receptors, and the superior colliculi and PPRF. Cerebellar efferents concerned with ocular movement project onto the vestibular nuclei, and the latter, in turn, influence gaze mechanisms through several projection systems: one, for horizontal movements, consists of direct projections from the vestibular nuclei to the contralateral sixth nerve nucleus; another, for vertical movements, projects via the contralateral MLF to third and fourth nerve nuclei (Figs. 14-1 and 14-2).

Lesions of the flocculus and posterior vermis (lobules VI and VII) are consistently associated with deficits in smooth pursuit movements and an inability to suppress the vestibulo-ocular reflex by fixation (Baloh et al). Floccular lesions are also an important cause of downbeat nystagmus. As indicated in Chap. 5, patients with cerebellar (floccular) lesions are unable to hold eccentric positions of gaze and must make repeated saccades to look at a target that is away from the neutral position (*gaze-paretic nystagmus*, a term also applied to nystagmus arising from a lesion in the PPRF). This phenomenon is explained by the fact that with acute, one-sided lesions of the vestibulocerebellum, the inhibitory discharges of the Purkinje cells onto the ipsilateral medial vestibular nucleus are removed and the eyes deviate away from the lesion. When gaze to the side of the lesion is attempted, the eyes drift back to the midline and can be corrected only by a saccadic jerk. The head and neck may also turn away from the lesion (the occiput toward the lesion and the face away). In addition, the vestibulo-ocular reflexes, which coordinate eye movements with head movements, are improperly adjusted (Thach and Montgomery). The interested reader will find further details concerning cerebellar influences on ocular movements in the monograph by Leigh and Zee and the review by Lewis and Zee.

Testing of Conjugate Gaze

It is apparent from the foregoing remarks that there is considerable clinical information to be obtained from an analysis of ocular movements. To examine the eye movements, the patient may be asked to look quickly to each side as well as up and down (saccades) and to follow a moving target (pursuit of a light, the examiner's or the patient's finger, or an optokinetic drum). A patient with stupor and coma can be examined by passively turning the head and irrigating the external auditory canals—these being vestibular stimuli.

Most individuals make accurate saccades to a target. Persistent alterations of saccadic movements, particularly overshooting of the eyes (*hypermetria*), is characteristic of a cerebellar lesion. *Slowness of saccadic movements* is mainly the result of disease of the basal ganglia such as Huntington and Wilson diseases, ataxia-telangiectasia, progressive supranuclear palsy, olivopontocerebellar degeneration, and certain lipid storage diseases. Lesions involving the PPRF may be accompanied by slow saccadic movements to the affected side. Hypometric, slow saccades, occurring only in the abducting eye, indicate an incomplete internuclear ophthalmoplegia due to a lesion of the ipsilateral MLF. When slow saccades are first observed in the vertical plane, the likeliest diagnosis is progressive supranuclear palsy, but the same condition may occur in advanced Parkinson disease and several rarer diseases of the basal ganglia (Table 14-1). Slow up-and-down saccades are also found in Niemann-Pick disease type C (page 821).

Table 14-1**Diseases exhibiting upgaze or vertical gaze palsy**

Midbrain infarction and hemorrhage
Tumor in the region of the dorsal midbrain (e.g., pinealoma)
Advanced hydrocephalus with enlargement of third ventricle
Progressive supranuclear palsy
Parkinson disease
Lewy body disease
Cortical basal ganglionic degeneration
Whipple disease
Metabolic diseases of childhood (Niemann-Pick type C, Gaucher, Tay-Sachs)
Any cause of bilateral internuclear ophthalmoplegia (e.g., multiple sclerosis)

Yet another saccadic disorder takes the form of an *inability to initiate voluntary movements*, either vertically or horizontally. This abnormality may be congenital in nature, as in the ocular “apraxia” of childhood (Cogain syndrome, see below) and ataxia-telangiectasia; an acquired difficulty in the initiation of saccadic movements may be seen in patients with Huntington disease or with a lesion of the contralateral frontal lobe or ipsilateral pontine tegmentum.

In addition to abnormalities of the saccades themselves, saccadic latency or reaction time (the interval between the impulse to move and movement) is prolonged in Huntington chorea and Parkinson disease. Saccadic latency is also increased in corticobasal ganglionic degeneration (see Chap. 39), in which case it seems to correlate with the degree of apraxia.

Fragmentation of smooth pursuit movement, a frequent neuroophthalmic finding, is a nystagmoid irregularity of tracking. Drug intoxication—with phenytoin, barbiturates, diazepam, and other sedative drugs—is probably the most common cause. As a manifestation of structural disease, it points to a lesion of the vestibulocerebellum. A similar-appearing but distinct phenomenon occurs in certain extrapyramidal diseases, as mentioned earlier, such as Parkinson disease, Huntington disease, and progressive supranuclear palsy. In these diseases there is often a ratchet-like impairment of smooth pursuit movements in association with slow, hypometric saccades (“saccadic pursuit”). Indeed, according to Vidailhet and colleagues, smooth pursuit movements are found to be impaired in all types of basal ganglionic degenerations. Asymmetrical impairment of smooth pursuit movements is indicative of a parietal or a frontal lobe lesion. Pursuit is impaired toward the side of a parietal lesion and away from a frontal lesion, as described earlier. The evaluation of visual pursuit by optokinetic testing is explained further on.

Evaluation of the VOR can provide considerable information and is simply performed in the cooperative patient by rapidly turning his head to one side by 5 to 10 degrees and requesting that he fixate on a distant target (see page 259 in Chap 15). Slippage of fixation (impaired VOR) is then appreciated indirectly by observing a small corrective saccade in the direction opposite head turning. Zee has described another means of testing the VOR. In a dimly lit room, the patient is instructed to fixate on a distant target with one eye while the examiner observes the optic nerve head of the other eye with an ophthalmoscope. The subject is then instructed to rotate the head back and forth at a rate of one to two cycles per second. In a normal subject, the optic nerve head remains stationary; if the VOR is impaired, the optic nerve head appears to oscillate.

late. Normally, movement of the head at this rate does not cause blurring of vision because of the rapidity with which the VOR accomplishes compensatory eye movements. By contrast with the head in a fixed position, to-and-fro movement of the environment will cause blurring of vision because normal tracking movements are too slow to fixate the object in space. As a rule, the patient with impairment of smooth pursuit movements will have a commensurate inability to suppress the VOR, thereby causing a feeling of instability.

Combined convergence and accommodative movements are tested by asking the patient to look at his thumbnail, the examiner’s finger, or another object as it is brought toward the eyes. However, these fusional movements are frequently impaired in the elderly and in confused or inattentive patients and should not, in these circumstances, be interpreted as the direct result of disease in the oculomotor pathways. Otherwise, the absence or impairment of these movements should suggest the presence of basal ganglionic disease, more particularly progressive supranuclear palsy, Parkinson disease, or a lesion in the rostral midbrain. *Convergence spasms* and *retraction nystagmus* may accompany paralysis of vertical gaze. But when such spasms occur alone, they are characteristic of hysteria, in which full horizontal movement can usually be obtained if each eye is tested separately. Also, a cycloplegic (homatropine eyedrops) will abolish the accommodation and pupillary miosis; but as a diagnostic test for hysteria its effect on the convergence spasm is less predictable.

Paralysis of Conjugate Gaze

Horizontal Gaze Palsy

Cerebral Origin An acute lesion of one frontal lobe, such as an infarct, usually causes impersistence or paresis of contralateral gaze, and the eyes may for a limited time turn involuntarily toward the side of the cerebral lesion. In most cases of frontal lobe infarction, the gaze palsy is incomplete and temporary, lasting for a day or two or for as long as a week. Almost invariably, it is accompanied by hemiparesis. In this circumstance, forced closure of the eyelids may cause the eyes to move paradoxically to the side of the hemiparesis rather than their deviating upward (Bell phenomenon), as would be expected. During sleep, the eyes may deviate conjugately from the side of the lesion to the side of the hemiplegia. Also as indicated above, pursuit movements away from the side of the lesion tend to be fragmented or lost. (Posterior parietal lesions reduce pursuit movements but do not cause a gaze palsy.) With bilateral frontal lesions, the patient may be unable to turn his eyes voluntarily in any direction but retains fixation and following movements, probably because pursuit movements are initiated in the parieto-occipital cortex. Occasionally, a deep cerebral lesion, particularly a thalamic hemorrhage extending into the midbrain, will cause the eyes to deviate conjugately to the side opposite the lesion (“wrong-way” gaze); the basis for this anomalous phenomenon is not established, but interference with descending oculomotor tracts in the midbrain has been postulated by Tijssen. It should be emphasized that cerebral gaze paralysis is not attended by strabismus or diplopia, i.e., the eyes move conjugately. The usual causes are vascular occlusion with infarction, hemorrhage, and abscess or tumor of the frontal lobe.

Brainstem Origin With regard to conjugate and horizontal gaze palsy, a *unilateral lesion in the rostral midbrain tegmentum*, by interrupting the cerebral pathways for horizontal conjugate gaze

before their decussation, will cause a gaze palsy to the opposite side. More common is a lesion in the pontine horizontal gaze complex (PPRF) also involving the abducens nucleus, which causes ipsilateral gaze palsy and deviation of the eyes to the opposite side.

As a rule, the horizontal gaze palsies of cerebral and pontine origin are readily distinguished. Both may be accompanied by hemiparesis, particularly cerebral lesions, in which case gaze toward the side as the hemiparesis is impaired. When there is a tonic deviation of the eyes from a cerebral lesion, this relationship is expressed as “*the eyes look toward the brain lesion and away from the hemiparesis*.” The opposite pertains to brainstem gaze palsies, that is, gaze is impaired toward the side opposite the lesion, and if there is gaze deviation, the eyes are turned toward a hemiparesis. Palsies of pontine origin need not have an accompanying hemiparesis but are associated with other signs of pontine disease, particularly peripheral facial and external rectus palsies and internuclear ophthalmoplegia on the same side as the paralysis of gaze. Gaze palsies due to cerebral lesions tend not to be as long-lasting as those due to pontine lesions. If there is a tonic gaze deviation away from the lesion, it too tends to be transient in the case of a cerebral paralysis of gaze and longer-lasting with a brainstem lesion. Also, in the case of a cerebral lesion (but not a pontine lesion), the eyes can be turned to the paralyzed side if they are fixated on the target and the head is rotated passively to the opposite side (i.e., by utilizing the VOR).

Vertical Gaze Palsy Midbrain lesions affecting the pretectum and the region of the posterior commissure interfere with conjugate movements in the vertical plane. Paralysis of vertical gaze is a prominent feature of the *Parinaud or dorsal midbrain syndrome*. Upward gaze in general is affected far more frequently than downward gaze because, as already explained, some of the fibers subserving upgaze cross rostrally and posteriorly between the riMLF and INC and are subject to interruption before descending to the oculomotor nuclei, whereas the pathways for downgaze apparently project directly downward from the two controlling nuclei. Optokinetic nystagmus in the vertical plane is usually lost in association with any interruption of vertical gaze.

The range of upward gaze is frequently restricted by a number of extraneous factors, such as drowsiness, increased intracranial pressure, and particularly aging. In a patient who cannot elevate the eyes voluntarily, the presence of reflex upward deviation of the eyes in response to flexion of the head (“doll’s-head maneuver”) or to voluntary forceful closure of the eyelids (*Bell’s phenomenon*) usually indicates that the nuclear and infranuclear mechanisms for upward gaze are intact and that the defect is supranuclear. However useful this rule may be, in some instances of disease of the peripheral neuromuscular apparatus—such as Guillain-Barré syndrome and myasthenia gravis—in which voluntary upgaze may be limited, the strong stimulus of eye closure causes upward deviation, whereas voluntary attempts at upgaze are unsuccessful, thereby spuriously suggesting a lesion of the upper brainstem. However, about 15 percent of normal adults do not show a Bell’s phenomenon; in others, deviation of the eyes is paradoxically downward.

In several patients who during life had shown an isolated palsy of downward gaze, autopsy has disclosed bilateral lesions of the rostral midbrain tegmentum (just medial and dorsal to the red nuclei.) In monkeys, a defect in downward gaze has been produced by bilateral circumscribed lesions centered in these regions (Kompf et al.). An unusual case, described by Bogousslavsky and colleagues, suggests that a paralysis of vertical gaze may follow a

strictly unilateral infarction in the posterior commissure, riMLF, and INC. Hommel and Bogousslavsky have summarized the location of strokes that cause monocular and binocular vertical gaze palsies.

Several *degenerative* and related processes exhibit selective or prominent upgaze or vertical gaze palsies, as mentioned earlier (Table 14-1). In progressive supranuclear palsy, a highly characteristic feature is a selective paralysis of upward and then downward gaze, initially evident as difficulty with vertical saccades (page 926). Parkinson and Lewy body diseases (Chap. 39), corticobasal ganglionic degeneration (Chap. 39), and Whipple disease of the brain (Chap. 40) may also produce vertical gaze palsies as these diseases progress.

Other Gaze Palsies *Skew deviation* is a poorly understood disorder in which there is vertical deviation of one eye above the other. The deviation may be the same (comitant) in all fields of gaze, or it may vary with different directions of gaze. The patient complains of vertical diplopia in all gaze positions (i.e., it is comitant). A noncomitant vertical deviation of the eyes, most pronounced when the affected eye is turned down, is characteristic of fourth nerve palsy, described further on. Skew deviation does not have precise localizing value but is associated with a variety of lesions of the cerebellum and the brainstem, particularly those involving the MLF. With skew deviation due to cerebellar disease, the eye on the side of the lesion usually rests lower, but sometimes it is higher than the other eye (in a ratio of 2:1 in Keane’s series), particularly in an internuclear ophthalmoplegia. (The corresponding image, of course, rests higher in the first instance and lower with INO).

Skew deviation has been known to alternate from one side to the other (“alternating skew”) and has also been seen with the condition known as *periodic alternating nystagmus*. Ford and coworkers described a rare form of skew deviation due to a monocular palsy of elevation stemming from a lesion immediately rostral to the ipsilateral oculomotor nucleus; a lesion of upgaze efferents from the ipsilateral riMLF was postulated, but an abnormality of the vertical gaze holding mechanism related to the function of the INC is an alternative explanation.

The *ocular tilt reaction*, in which skew deviation is combined with ocular torsion and head tilt, is attributed to an imbalance in otolith-ocular and otolith-collic reflexes. In unilateral lesions involving the vestibular nuclei, as in lateral medullary infarction, the eye is lower on the side of the lesion. With lesions of the MLF or INC, which can also cause an ocular tilt reaction, the eye is higher on the side of the lesion.

Another unusual and now almost vanished disturbance of gaze is the *oculogyric crisis*, or *spasm*, which consists of a tonic spasm of conjugate deviation of the eyes, usually upward and less frequently laterally or downward. Recurrent attacks, sometimes associated with spasms of the neck, mouth, and tongue muscles and lasting from a few seconds to an hour or two, were pathognomonic of postencephalitic parkinsonism. Now this phenomenon is observed rarely as an acute reaction in patients being given phenothiazine drugs (page 1025) and in Niemann-Pick disease. The pathogenesis of these ocular spasms is not known. In the drug-induced form, upward deviation of the eyes is associated with peculiar obsessional thoughts; it can be terminated by the administration of an atropinic medication.

Congenital oculomotor apraxia (Cogan syndrome) is a disorder characterized by abnormal eye and head movements during attempts to change the position of the eyes. The patient is unable

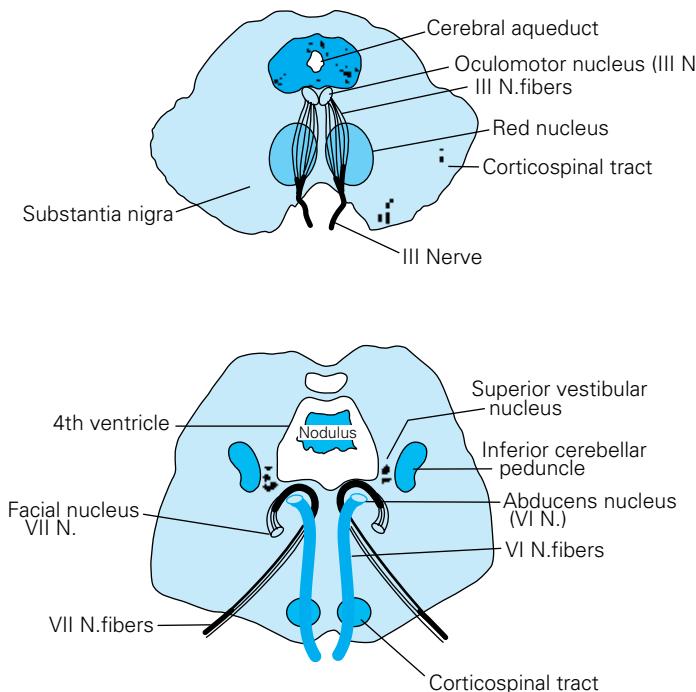

Figure 14-3. A. Midbrain in horizontal section, indicating the effects of lesions at different points along the intramedullary course of the third nerve fibers. A lesion at the level of oculomotor nucleus results in homolateral third nerve paralysis and homolateral anesthesia of the cornea. A lesion at the level of red nucleus results in homolateral third nerve paralysis and contralateral ataxic tremor (Benedikt and Claude syndromes). A lesion near the point of exit of third nerve fibers results in homolateral third nerve paralysis and crossed corticospinal tract signs (Weber syndrome; see Table 47-2). B. Brainstem at the level of the sixth nerve nuclei, indicating effects of lesions at different loci. A lesion at the level of the nucleus results in homolateral sixth and seventh nerve paralyses with varying degrees of nystagmus and weakness of conjugate gaze to the homolateral side. A lesion at the level of corticospinal tract results in homolateral sixth nerve paralysis and crossed hemiplegia (Millard-Gubler syndrome).

to make normal voluntary horizontal saccades when the head is stationary. If the head is free to move and the patient is asked to look at an object to either side, the head is thrust to one side and the eyes turn in the opposite direction; the head overshoots the target, and the eyes, as they return to the central position, fixate on the target. Both voluntary saccades and the quick phase of vestibular nystagmus are defective. The pathologic anatomy has never been studied. This phenomenon is also seen in ataxia-telangiectasia (page 819) and in association with agenesis of the corpus callosum, in which both horizontal and vertical saccades may be affected.

NUCLEAR AND INFRANUCLEAR DISORDERS OF EYE MOVEMENT

Anatomic Considerations

The third (oculomotor), fourth (trochlear), and sixth (abducens) cranial nerves innervate the extrinsic muscles of the eye. Since their actions are closely integrated and many diseases involve all of them at once, they are suitably considered together.

The *oculomotor* (*third-nerve*) nuclei consist of several paired groups of nerve cells, adjacent to the midline and ventral to the

aqueduct of Sylvius, at the level of the superior colliculi. A centrally located group of nerve cells that innervate the pupillary sphincters and ciliary bodies (muscles of accommodation) is situated dorsally in the Edinger-Westphal nucleus; this is the parasympathetic portion of the oculomotor nucleus. Ventral to this nuclear group are cells that mediate the actions of the levator of the lid, superior and inferior recti, inferior oblique, and medial rectus in this dorsal-ventral order. This functional arrangement has been determined in cats and monkeys by extirpating individual extrinsic ocular muscles and observing the retrograde cellular changes (Warwick). Subsequent studies, utilizing radioactive tracer techniques, have shown that the medial rectus neurons occupy three disparate locations within the oculomotor nucleus rather than being confined to its ventral tip (Büttner-Ennever and Akert). These experiments also indicated that the medial and inferior recti and the inferior oblique have a strictly homolateral representation in the oculomotor nuclei, whereas the superior rectus receives only crossed fibers and the levator palpebrae superioris has a bilateral innervation. Whether this precise arrangement is reproduced in humans is not known. Vergence movements are under the control of medial rectus neurons and not an unpaired medial group of cells ("nucleus of Perlia"), as was once supposed.

The fibers of the third nerve nucleus course ventrally in the brainstem, crossing the medial longitudinal fasciculus, red nucleus, substantia nigra, and medial part of the cerebral peduncle; lesions involving these structures may therefore interrupt oculomotor fibers in their intramedullary course and give rise to crossed syndromes of hemiplegia and ocular palsies.

The *sixth nerve (abducens)* arises at the level of the lower pons, from a paired group of cells in the floor of the fourth ventricle, adjacent to the midline. The intrapontine portion of the facial nerve loops around the sixth nerve nucleus before it turns anterolaterally to make its exit; a lesion in this locality therefore causes a homolateral paralysis of the lateral rectus and facial muscles. It is also important to note that the efferent fibers of the oculomotor and abducens nuclei have a considerable intramedullary extent (Fig. 14-3A and B).

The cells of origin of the *trochlear nerves* are just caudal to those of the oculomotor nerves. Unlike the third and sixth nerves, the fourth nerve courses posteriorly and decussates a short distance from its origin before emerging from the dorsal surface of the brainstem, just caudal to the inferior colliculi. Each nucleus therefore innervates the *contralateral* superior oblique muscle. The long extra-axial course is thought to be an explanation for the common complication of fourth nerve palsy in head injury. The superior oblique muscle forms a tendon that passes through a pulley structure (the trochlea) and inserts on the upper aspect of the globe. When the eye is adducted, the muscle exerts an upward pull, but being attached to the globe behind the axis of rotation, it causes depression of the globe; in abduction, it pulls the ocular meridian toward the nose, thereby causing intorsion (i.e., clockwise in the right eye and counterclockwise in the left).

The oculomotor nerve, soon after it emerges from the brainstem, passes between the superior cerebellar and posterior cerebral arteries. The nerve (and sometimes the posterior cerebral artery) may be compressed at this point by herniation of the uncal gyrus of the temporal lobe through the tentorial opening (see Chap. 17). The sixth nerve, after leaving the brainstem, sweeps upward and runs alongside the third and fourth cranial nerves; together they course anteriorly, pierce the dura just lateral to the posterior clinoid

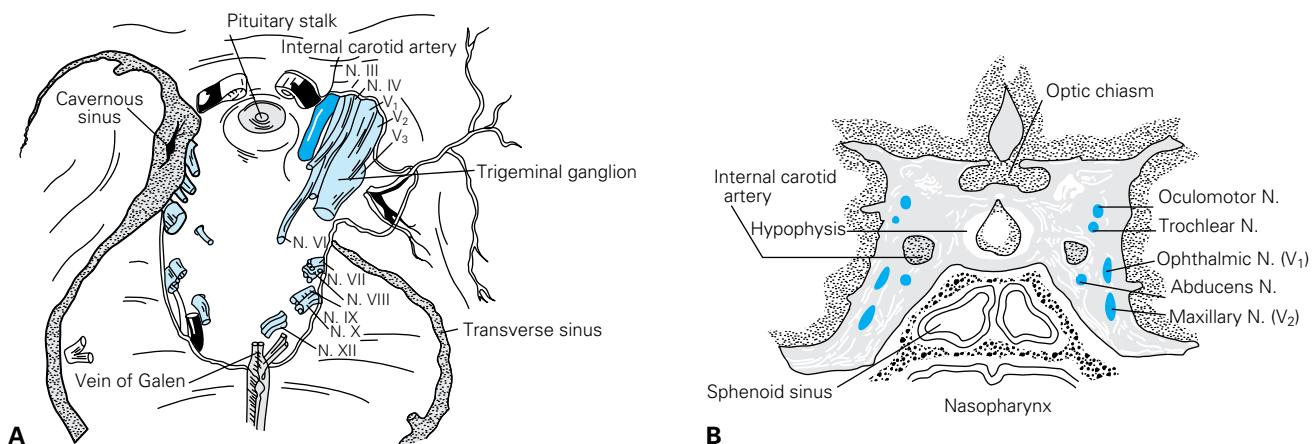

Figure 14-4 (See also Fig. 34-29). The cavernous sinus and its relation to the cranial nerves. *A*. Base of the skull; the cavernous sinus has been removed on the right. *B*. The cavernous sinus and its contents viewed in the coronal plane.

process, and run in the lateral wall of the cavernous sinus, where they are closely applied to the cavernous portion of the internal carotid artery and first and second divisions of the fifth nerve (Fig. 14-4 and Fig. 34-32, page 735).

Retrocavernous compressive lesions, notably infracavernous aneurysms and tumors, tend to involve all three sensory divisions of the trigeminal nerve together with the oculomotor nerves. In the posterior portion of the cavernous sinus, the first and second trigeminal divisions tend to be involved along with the oculomotor nerves; in the anterior portion, only the ophthalmic division is affected. Just posterior and superior to the cavernous sinus, the oculomotor nerve crosses the terminal portion of the internal carotid artery at its junction with the posterior communicating artery. An aneurysm at this site frequently damages the third nerve; this serves to localize the site of compression or bleeding.

Together with the first division of the fifth nerve, the third, fourth, and sixth nerves enter the orbit through the superior orbital fissure. The oculomotor nerve, as it enters the orbit, divides into superior and inferior branches, although a functional division occurs well before the anatomic bifurcation. The superior branch supplies the superior rectus and the voluntary (striated) part of the levator palpebrae (the involuntary part is under the control of sympathetic fibers of Müller); the inferior branch supplies the pupillary and ciliary muscles and all the other extrinsic ocular muscles except two—the superior oblique and the external rectus—which are innervated by the trochlear and abducens nerves, respectively. Superior branch lesions of the oculomotor nerve caused by an aneurysm or associated with diabetes or a viral infection cause ptosis and uniocular upgaze paresis.

Under normal conditions, all the extraocular muscles participate in every movement of the eyes; for proper movement, the contraction of any muscle requires relaxation of its antagonist. Clinically, however, an eye movement should be thought of in terms of the one muscle that is predominantly responsible for an agonist movement in that direction: e.g., outward rotation of the eye requires the action of the lateral rectus; inward rotation, action of the medial rectus. The action of the superior and inferior recti and the oblique muscles varies according to the position of the eye. When the eye is turned outward, the elevator is the superior rectus and the depressor is the inferior rectus. When the eye is turned inward, the elevator and depressor are the inferior and superior

oblique muscles, respectively. The actions of the ocular muscles in different positions of gaze are illustrated in Fig. 14-5 and Table 14-2. The clinical implications of deficiencies in these muscle actions are discussed below.

Strabismus (Squint)

This term refers to a muscle imbalance that results in misalignment of the visual axes of the two eyes. It may be caused by weakness of an individual eye muscle (*paralytic strabismus*) or by an imbalance of muscular tone, presumably due to a faulty “central” mechanism that normally maintains a proper angle between the two visual axes (*nonparalytic strabismus*). It is in the latter sense that the term is generally used. Almost everyone has a slight tendency to strabismus, i.e., to misalign the visual axes when a target is viewed with one eye. This tendency is referred to as a *phoria* and is normally overcome by the fusion mechanisms. A misalignment

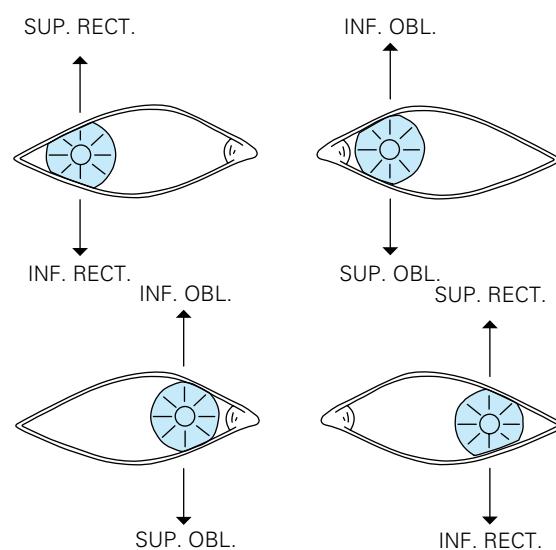

Figure 14-5. Muscles chiefly responsible for vertical movements of the eyes in different positions of gaze. (Adapted by permission from Cogan DG: Neurology of the Ocular Muscles, 2nd ed. Springfield, IL, Charles C Thomas, 1956.)

Table 14-2

Actions of the extraocular muscles (see also Fig. 14-5)

MUSCLE	PRIMARY ACTION	SECONDARY ACTION	OCULOMOTOR NERVE
Medial rectus	Adduction	—	III
Lateral rectus	Abduction	—	VI
Superior rectus	Elevation	Intorsion	III
Inferior rectus	Depression	Extorsion	III
Superior oblique	Intorsion	Depression	IV
Inferior oblique	Extorsion	Elevation	III

that is manifest during binocular viewing of a target and cannot be overcome, even when the patient is forced to fixate with the deviant eye, is called a *tropia*. The prefixes *eso-* and *exo-* indicate that the phoria or tropia is directed inward or outward, respectively, and the prefixes *hyper-* and *hypo-*, that the deviation is upward or downward. Paralytic strabismus is primarily a neurologic problem; nonparalytic strabismus (referred to as *comitant strabismus* if the angle between the visual axes is the same in all fields of gaze) is more strictly an ophthalmologic problem, although it is associated with a number of congenital cerebral diseases and various forms of mental retardation.

Once binocular fusion is established, usually by 6 months of age, any type of ocular muscle imbalance will cause diplopia, since images then fall on disparate or noncorresponding parts of the two functionally active retinas. After a time, however, the child eliminates the diplopia by suppressing the image from one eye. After a variable period, the suppression becomes permanent, and the individual grows up with a diminished visual acuity in that eye, the result of prolonged disuse (*amblyopia ex anopsia*). With proper early treatment, the amblyopia can be reversed; but if it persists beyond the age of 5 or 6 years, recovery of vision rarely occurs. Occasionally, when the eyes are used alternately for fixation (*alternating strabismus*), visual acuity remains good in each eye.

Nonparalytic strabismus may pose a problem for neurologists. It has a way of appearing in early childhood for unclear reasons and conjures up possibilities of serious neurologic disease. Sometimes it is first noticed after a head injury or an infection, or it may be exposed by some other neurologic disorder or drug intoxication that impairs fusional mechanisms (vergence). In a cooperative patient, nonparalytic strabismus may be demonstrated by showing that each eye can be moved fully when the other eye is covered. Tropias and phorias can readily be detected by means of the simple “cover” and “cover-uncover” tests. In the case of a tropia, in which one eye is not aligned with the target (for example when viewing the large E at 20 ft), covering the fixating eye will force the uncovered (deviating) eye to change its position abruptly and focus on the target (movement of redress). Similarly, the cover-uncover test can detect latent phorias that are suppressed by the fusion mechanism as long as both eyes are used. When fusion is disrupted by covering one eye, the covered eye will deviate as just noted; uncovering the eye results in a quick corrective movement designed to re-establish the fusion mechanism.

Clinical Effects of Lesions of the Third, Fourth, and Sixth Ocular Nerves

Third (Oculomotor) Nerve A complete *third nerve lesion* causes ptosis, or drooping of the upper eyelid (since the levator palpebrae

is supplied mainly by the third nerve), and an inability to rotate the eye upward, downward, or inward. This corresponds to a combined weakness of the medial, superior, and inferior recti and the inferior oblique muscles. The remaining actions of the fourth and sixth nerves give rise to the mnemonic “down and out” to describe the position of the eye in third nerve palsy (Fig. 14-5B). When the lid is passively elevated, *the eye is found to be deviated outward and slightly downward* because of the unopposed actions of the intact lateral rectus and superior oblique muscles. In addition, one finds a dilated nonreactive pupil (iridoplegia) and paralysis of accommodation (cycloplegia) due to interruption of the parasympathetic fibers in the third nerve. However, the extrinsic and intrinsic eye muscles may be affected separately. For example, infarction of the central portion of the oculomotor nerve, as occurs in diabetic ophthalmoplegia, typically spares the pupil, since the parasympathetic preganglionic pupilloconstrictor fibers lie near the surface. Conversely, compressive lesions of the nerve usually dilate the pupil as an early manifestation. After injury, regeneration of the third nerve fibers may be aberrant, in which case some of the fibers that originally moved the eye in a particular direction now reach another muscle or the iris; in the latter instance the pupil, which is unreactive to light, may constrict when the eye is turned up and in.

Fourth (Trochlear) Nerve A lesion of the *fourth nerve*, which innervates the superior oblique muscle, is the most common cause of isolated symptomatic vertical diplopia. Although oculomotor palsy was a more common cause of vertical diplopia in Keane’s series, as stated earlier, in instances where this is the sole complaint, trochlear palsy (and brainstem lesions) predominate. Paralysis of the superior oblique muscle results in weakness of downward movement of the affected eye, most marked when the eye is turned inward, so that the patient complains of special difficulty in reading or going down stairs. The affected eye tends to deviate slightly upward. This defect may be overlooked in the presence of a third nerve palsy if the examiner fails to note the absence of an expected intorsion as the patient tries to move the paretic eye downward. Head tilting to the opposite shoulder (Bieschowsky sign) is especially characteristic of fourth nerve lesions; this maneuver causes a compensatory intorsion of the unaffected eye and ameliorates the double vision. Bilateral trochlear palsies, as may occur rarely after head trauma, give a characteristic alternating hyperdeviation depending on the direction of gaze (unilateral traumatic trochlear paresis is more common). A detailed review of the clinical approach to vertical diplopia is given by Palla and Straumann.

Sixth (Abducens) Nerve Lesions of the *sixth nerve* result in a palsy of the abducens muscle and a resultant weakness of lateral or outward movement as well as a crossing of the visual axes. The affected eye *deviates medially*, i.e., in the direction of the opposing muscle. With incomplete sixth nerve palsies, turning the head toward the side of the paretic muscle overcomes the diplopia. The main causes of individual oculomotor palsies and of combined palsies are listed in Table 14-3 and are illustrated in Fig. 14-6 and below.

The Analysis of Diplopia Almost all instances of diplopia (i.e., seeing a single object as double) are the result of an acquired palsy or paresis of one or more extraocular muscles. The signs of the oculomotor palsies, as described above, are manifest in various degrees of completeness. Noting the relative positions of the corneal light reflections and having the patient perform common versional movements will usually disclose the faulty muscle(s) as the eyes are turned into the field of action of the paretic muscle. The

muscle weakness may be so slight, however, that no strabismus or defect in ocular movement is obvious, yet the patient experiences diplopia. It is then necessary to utilize the patient's report of the relative positions of the images of the two eyes as a means of determining which muscle might be involved. Several tests are useful for this purpose.

Two rules are applied sequentially to identify the affected ocular muscle in the analysis of diplopia:

1. The direction in which the images are maximally separated indicates the direction of action of a pair of muscles at fault. For example, if the greatest horizontal separation is in looking to the right, either the right abductor (lateral rectus) or the left adductor (medial rectus) muscle is weak; when looking to the left, either the left lateral rectus and right medial rectus are implicated (Fig. 14-6A and B). Restated, if the separation is mainly horizontal, the paresis will be found in one

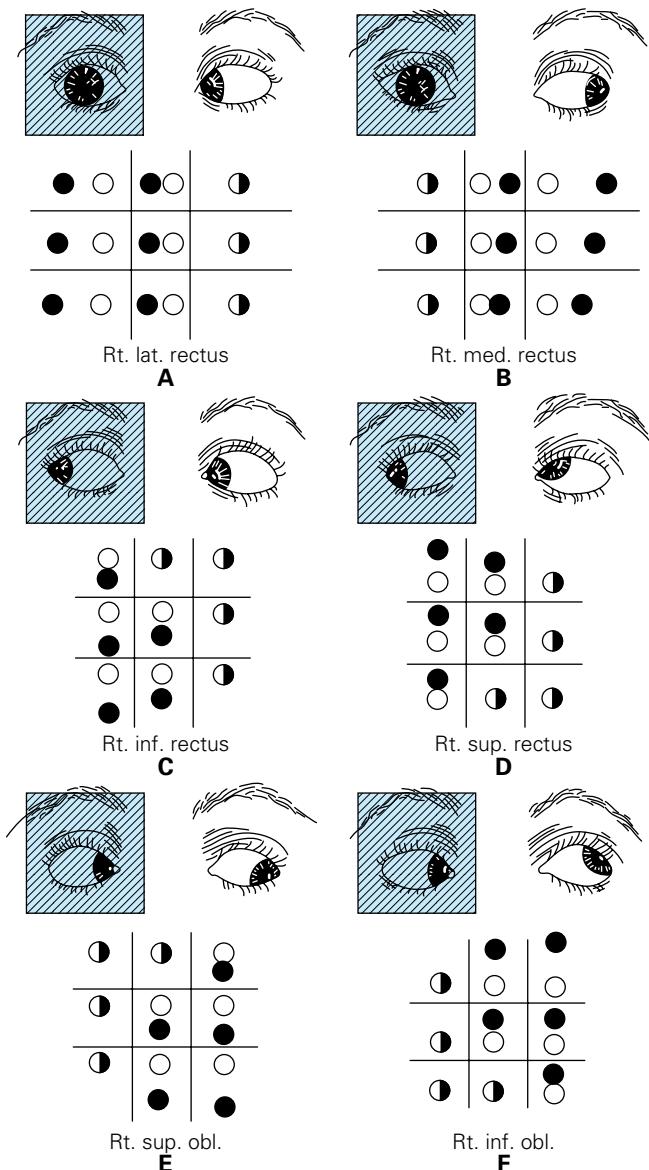

Figure 14-6. Diplopia fields with individual muscle paralysis. The dark glass is in front of the right eye, and the fields are projected as the patient sees the images. *A.* Paralysis of right lateral rectus. Characteristic: right eye does not move to the right. Field: horizontal homonymous diplopia increasing on looking to the right. *B.* Paralysis of right medial rectus. Characteristic: right eye does not move to the left. Field: horizontal crossed diplopia increasing on looking to the left. *C.* Paralysis of right inferior rectus. Characteristic: right eye does not move downward when eyes are turned to the right. Field: vertical diplopia (image of right eye lowermost) increasing on looking to the right and down. *D.* Paralysis of right superior rectus. Characteristic: right eye does not move upward when eyes are turned to the right. Field: vertical diplopia (image of right eye uppermost) increasing on looking to the right and up. *E.* Paralysis of right superior oblique. Characteristic: right eye does not move downward when eyes are turned to the left. Field: vertical diplopia (image of right eye lowermost) increasing on looking to left and down. *F.* Paralysis of right inferior oblique. Characteristic: right eye does not move upward when eyes are turned to the left. Field: vertical diplopia (image of right eye uppermost) increasing on looking to left and up. (Adapted by permission from Cogan DG: Neurology of the Ocular Muscles, 2nd ed.. Springfield, IL, Charles C. Thomas, 1956.)

of the horizontally acting recti (a small vertical disparity should be disregarded); if the separation is mainly vertical, the paresis will be found in the vertically acting muscles, and a small horizontal deviation should be disregarded.

2. *In the position of maximal separation, the image projected farther from the center is attributable to the paretic muscle of the implicated pair that is identified in the first step above. The patient may be aided in identifying which image is diverted most by having her several times momentarily uncover one eye and observe which image is most peripheral.*

The simplest maneuver for the analysis of diplopia consists of asking the patient to follow an object or penlight into the six cardinal positions of gaze. When the position of maximal separation of images is identified, one eye is covered and the patient is asked to identify which image disappears. The *red-glass* test is a more reliable enhancement of this technique. A red glass is placed in front of the patient's right eye (the choice of the right eye is arbitrary, but if the test is always done in the same way, interpretation is simplified). The patient is then asked to look at a flashlight (held at a distance of 1 m), to turn the eyes sequentially to the six cardinal points in the visual fields, and to indicate the positions of the red and white images and the relative distances between them. The positions of the two images are plotted as the patient indicates them to the examiner (i.e., from the patient's perspective) (Fig. 14-6). Two similar methods of examination are described below.

It must be remembered that the red-glass test distinguishes *one of two* muscles responsible for the movement in the direction of maximal separation of images. If the white image on right lateral gaze is to the right of the red (i.e., the image from the left eye is projected outward), then the left medial rectus muscle is weak. In testing vertical movements, again, the image corresponding to the eye with the paretic muscle is the one projected most peripherally in the visual field. For example, if the maximum vertical separation of images occurs on looking downward and to the *left* and the white image is projected farther down than the red, the paretic muscle is the left inferior rectus; if the red image is lower than the white, the paretic muscle is the right superior oblique. As already mentioned for a supplementary test, correction of vertical diplopia by a tilting of the head implicates the superior oblique muscle of the opposite side. Separation of images on looking up and to the right or left will similarly distinguish paresis of the inferior oblique and superior rectus muscles. The examiner is aided by committing to memory the cardinal actions of the ocular muscles shown in Fig. 14-5 and Table 14-2.

There are several alternative methods for studying the relative positions of the images of the two eyes. One, a refinement of the red-glass test, is the *Maddox rod*, in which the occluder consists of a transparent red lens with series of parallel cylindrical bars that transform a point source of light into a red line perpendicular to the cylinder axes. The position of the red line is compared with the position of a white point source of light seen with the other eye. Another, the *alternate cover test*, requires less cooperation than the red-glass test and is, therefore, more useful in the examination of young and inattentive patients. It does, however, require sufficient visual function to permit central fixation with each eye. The test consists of rapidly alternating an occluder or the examiner's hand from one eye to another and observing the deviations from and return to the point of fixation, as described above in the discussion of tropias and phorias. Detailed descriptions of the Maddox rod and alternate cover tests, which are the ones favored by neuro-

ophthalmologists, can be found in the monographs of Leigh and Zee and of Glaser listed with the References.

Other Forms of Diplopia The red-glass and other similar tests are most useful when a single muscle is responsible for the diplopia. If testing suggests that more than one muscle is involved, one must be certain not to overlook myasthenia gravis and thyroid ophthalmopathy, which affect several muscles of ocular motility.

Monocular diplopia occurs most commonly in relation to diseases of the cornea and lens rather than the retina; usually the images are overlapping or superimposed rather than discrete. In most cases, monocular diplopia can be traced to a lenticular distortion or displacement, but in some no abnormality can be found. Monocular diplopia has been reported in association with cerebral disease (Safran et al), but this must be a very rare occurrence. Occasionally patients with homonymous scotomas due to a lesion of the occipital lobe will see multiple images (polyopia) in the defective field of vision, particularly when the target is moving.

Rarely, the acute onset of *convergence paralysis* may give rise to diplopia and blurred vision at all near points; most cases are due to head injury, some to encephalitis or multiple sclerosis. Many cases of convergence paralysis do not have a demonstrable neurologic basis; they are due to hysteria or remain unexplained. The acute onset of the ill-defined entity of *divergence paralysis* causes diplopia at a distance because of crossing of the visual axes; in such patients images fuse only at a near position. This disorder, the pathologic basis of which is unknown, is difficult to distinguish from mild bilateral sixth nerve palsies and from convergence spasm, which is common in malingerers and hysterics. A special type of divergence paralysis is seen not uncommonly in patients with strokes in the rostral midbrain; they display an asymmetrical incompleteness of ocular abduction on both sides ("pseudo-sixth palsy"). Based on scant clinical data, a center for active divergence has been postulated to reside in the rostral midbrain tegmentum.

Causes of Third, Fourth, and Sixth Nerve Palsies (Table 14-3) Ocular palsies may have a central cause—i.e., due to a lesion of the nucleus or the intramedullary (fascicular) portion of the cranial nerve—or they may be peripheral. Weakness of ocular muscles due to a lesion in the brainstem is usually accompanied by involvement of other cranial nerves and by signs referable to the "crossed" brainstem syndromes of a cranial nerve palsy on one side and a hemiparesis on the opposite side (Table 34-3). Peripheral lesions, which may or may not be solitary, have a great variety of causes. Rucker (1958, 1966), who analyzed 2000 cases of paralysis of the oculomotor nerves, found that the most common causes were tumors at the base of the brain (primary, metastatic, meningeal carcinomatosis), head trauma, ischemic infarction of a nerve (generally associated with diabetes), and aneurysms of the circle of Willis, in that order. The sixth nerve was affected in about half of the cases; third nerve palsies were about half as common as those of the sixth nerve; and the fourth nerve was involved in less than 10 percent. In a series of 1000 unselected cases reported subsequently by Rush and Younge, trauma was a more frequent cause than neoplasm and the frequency of aneurysm-related cases was fewer than in the aforementioned series; otherwise the findings were little changed from those of the earlier studies. Less common causes of paralysis of the oculomotor nerves include variants of Guillain-Barré syndrome, herpes zoster, giant-cell arteritis, ophthalmoplegic migraine, carcinomatous or lymphomatous meningitis, and sarcoidosis as well as fungal, tuberculous, syphilitic, and other chronic

forms of meningitis. *Myasthenia gravis* must always be considered in cases of ocular muscle palsy, particularly if several muscles are involved and if ptosis is a prominent feature. Thyroid ophthalmopathy, discussed further on, presents in the similar fashion but without ptosis and is less common than myasthenia. Actually, in the single largest group (20 to 30 percent) in each of the above series, no cause could be assigned, although more cases are now being resolved with magnetic resonance imaging (MRI) and newly available serologic tests of the cerebrospinal fluid (CSF). Fortunately, in many cases of undetermined cause, the palsy disappears in a few weeks or months.

Sixth Nerve Palsy Infarction of the sixth nerve is a common cause of sixth nerve palsy in diabetics, in which case there is usually pain near the outer canthus of the eye. An idiopathic form that occurs in the absence of diabetes—possibly atherosclerotic, arteritic, or phlebitic—is also well known. An isolated sixth nerve palsy with global headache, and more specifically when the palsy is bilateral, as mentioned below, frequently proves to be caused by neoplasm. In children, the most common tumor involving the sixth nerve is a pontine glioma; in adults, it is a metastatic tumor arising from the nasopharynx. Thus it is essential that the nasopharynx be examined carefully in every case of unexplained sixth nerve palsy, particularly if it is accompanied by sensory symptoms on the side of the face. As the abducens nerve passes near the apex of the petrous bone, it is in close relation to the trigeminal nerve. Both may be implicated by petrositis, manifest by facial pain and diplopia (Gradenigo syndrome). Fractures at the base of the skull and petrous clivus tumors may have a similar effect, and sometimes head injury alone is the only assignable cause, even in the absence of a fracture (as mentioned, fourth nerve palsy is a more common complication of closed cranial injury).

Unilateral or bilateral abducens weakness may be a nonspecific sign of increased intracranial pressure from any source—including brain tumor, meningitis, and pseudotumor cerebri; rarely, it may appear after lumbar puncture, epidural injections, or insertion of a ventricular shunt. The type that arises with infarction of the rostral midbrain (pseudo-sixth) was described above. Occasionally the nerve is compressed by a congenitally persistent trigeminal artery.

Fourth Nerve Palsy The fourth nerve is particularly vulnerable to head trauma (this was the cause in 43 percent of 323 cases of trochlear nerve lesions collected by Wray from the literature). The reason for this vulnerability has been speculated to be the long crossed course of the nerves. A fair number of cases remain idiopathic even after careful investigation. The fourth and sixth nerves are practically never involved by aneurysm. This reflects the relative infrequency of carotid artery aneurysms in the infraclinoid portion of the cavernous sinus, where they could impinge on the sixth nerve. (In contrast, supraclinoid aneurysms commonly involve the third nerve.) Herpes zoster ophthalmicus may affect any of the oculomotor nerves but particularly the trochlear, which shares a common sheath with the ophthalmic division of the trigeminal nerve. Diabetic infarction of the fourth nerve occurs, but far less frequently than infarction of the third or sixth nerves. Trochlear nerve palsy may also be a false localizing sign in cases of increased intracranial pressure, but again not nearly as often as abducens palsy. Entrapment of the superior oblique tendon is a rare cause (Brown syndrome) in which, in addition to diplopia, there is focal pain at the corner of the orbit; hence it may be mistaken for the Tolosa-Hunt syndrome, discussed further on. Most cases are idiopathic. Trochlear nerve palsies have been described in patients with

lupus erythematosus and with Sjögren syndrome, but their basic pathology is not known.

Superior oblique myokymia is an unusual but easily identifiable condition, characterized by recurrent episodes of vertical diplopia, monocular blurring of vision, and a tremulous sensation in the affected eye. The affected globe is observed to make small arrhythmic torsional movements. The problem is usually benign and responds to carbamazepine, but rare instances presage pontine glioma or demyelinating disease. Compression of the fourth nerve by a small looped branch of the basilar artery has been suggested as the cause of the idiopathic variety, analogous to several other better documented vascular compression syndromes affecting cranial nerves. This notion is supported by findings of vascular compression on MRI reported by Yousry and colleagues.

Third Nerve Palsy The third nerve is commonly compressed by aneurysm, tumor, or temporal lobe herniation. In a series of 206 cases of third nerve palsy collected by Wray and Taylor, neoplastic diseases accounted for 25 percent and aneurysms for 18 percent. Of the neoplasms, 25 percent were parasellar meningiomas and 4 percent pituitary adenomas. The palsy is usually chronic, progressive, and painless. As emphasized earlier, enlargement of the pupil is a sign of extramedullary third nerve compression because of the peripheral location in the nerve of the pupilloconstrictor fibers. By contrast, as indicated above, infarction of the nerve in diabetics usually spares the pupil, since the damage is situated in the central portion of the nerve. The oculomotor palsy that complicates diabetes (this was the cause in 11 percent of the Wray and Taylor series) develops over a few hours and is accompanied by pain, usually severe, in the forehead and around the eye. The prognosis for recovery (as in other nonprogressive lesions of the oculomotor nerves) is usually good because of the potential of the nerve to regenerate. Infarction of the third nerve may occur in nondiabetics as well.

In chronic compressive lesions of the third nerve (distal carotid, basilar, or, most commonly, posterior communicating artery aneurysm; pituitary tumor, meningioma, cholesteatoma) the pupil is almost always affected by way of dilation or reduced light response. However, the chronicity of the lesion may permit aberrant nerve regeneration. This is manifest by pupillary constriction on adduction of the eye or by retraction of the upper lid on downward gaze or adduction.

Rarely, children or young adults may have one or more attacks of ocular palsy in conjunction with an otherwise typical migraine (ophthalmoplegic migraine). The muscles (both extrinsic and intrinsic) innervated by the oculomotor or, very rarely, by the abducens nerve are affected. Presumably, intense spasm of the vessels supplying these nerves or compression by edematous arteries causes a transitory ischemic paralysis. Arteriograms done after the onset of the palsy usually disclose no abnormality. The oculomotor palsy of migraine tends to recover; after repeated attacks, however, there may be permanent paresis.

Painful Ophthalmoplegia, Tolosa-Hunt Syndrome, and Cavernous Sinus Syndrome (Table 14-4)

Some of the diseases discussed above are associated with a degree of pain, often at the epicenter of an affected nerve or muscle. But the development over days or longer of a *painful unilateral ophthalmoplegia* constitutes a special syndrome that is traceable to an aneurysm, tumor, or inflammatory and granulomatous process in

Table 14-4
Causes of painful ophthalmoplegia

Vascular

- Intracavernous carotid artery aneurysm
- Posterior communicating or posterior cerebral artery aneurysm
- Cavernous sinus thrombosis (septic and aseptic)
- Carotid-cavernous fistula
- Diabetic oculomotor mononeuroopathy (may be multiple)
- Temporal arteritis
- Ophthalmoplegic migraine

Neoplastic

- Pituitary adenoma
- Pituitary apoplexy
- Pericavernous meningioma
- Metastatic nodules to dura of cavernous sinus
- Giant-cell tumor of orbital bone
- Nasopharyngeal tumor invading cavernous sinus or orbit

Inflammatory and infectious

- Tolosa-Hunt syndrome
- Orbital pseudotumor
- Sinusitis
- Mucocele
- Herpes zoster
- Mucormycosis
- Sarcoidosis

the anterior portion of the cavernous sinus or at the adjacent superior orbital fissure. The idiopathic granulomatous condition has been termed *Tolosa-Hunt syndrome*; a similar but more extensive process is known as *orbital pseudotumor*. Although there is little pathologic material on which to base an understanding of these two diseases, they are both idiopathic orbital inflammations, in the case of Tolosa-Hunt syndrome involving the superior orbital fissure or the anterior cavernous sinus, and in orbital pseudotumor, inflammatory enlargement of the extraocular muscles, which often also encompasses the globe and other orbital contents.

Orbital pseudotumor is accompanied by injection of the conjunctiva and lid and slight proptosis; the Tolosa-Hunt syndrome lacks these features but is occasionally associated with additional signs of cavernous sinus disease, such as sensory loss in the peri-orbital branches of the trigeminal nerve. In pseudotumor of the orbit, a single muscle or several may be involved and there is a tendency to relapse and later to involve the opposite globe. Visual loss from compression of the optic nerve is a rare complication of either condition. Associations with connective tissue disease have been reported, but most cases in our experience have occurred in isolation. Ultrasound examination or CT scans of the orbit shows enlargement of the orbital contents in pseudotumor, mainly the muscles, similar to the findings in thyroid ophthalmopathy.

The inflammatory changes of Tolosa-Hunt syndrome are limited to the superior orbital fissure and can sometimes be detected by MRI; coronal views taken after gadolinium infusion show the lesion to best advantage. It should be noted, however, that sarcoidosis, lymphomatous infiltration, and a small meningioma may produce similar radiographic findings. The sedimentation rate in our patients has varied but is generally moderately elevated in reported cases, sometimes accompanied by a leukocytosis at the onset of symptoms.

Both the Tolosa-Hunt syndrome and orbital pseudotumor

should be treated with corticosteroids. A marked response with reduction in pain and improved ophthalmoplegia in 1 or 2 days is confirmatory of the diagnosis; however, as pointed out in the review by Kline and Hoyt, tumors of the parasellar region that cause ophthalmoplegia may also respond, albeit not to the same extent. We have generally given prednisone 60 mg and tapered the medication slowly, but there are no data to guide the proper dose. Treatment should be continued for several weeks or longer.

In the *cavernous sinus syndrome*, involvement of the oculomotor nerve on one or both sides is accompanied by periorbital pain and chemosis (Fig. 14-4B). In a series of 151 such cases reported by Keane, the third nerve (usually with pupillary abnormalities) and sixth nerve were affected in almost all and the fourth nerve in one-third of them; complete ophthalmoplegia, usually unilateral, was present in 28 percent. Sensory loss in the distribution of the ophthalmic division of the trigeminal nerve was often added, a finding that is helpful in the differentiation of cavernous sinus disease from other causes of orbital edema and ocular muscle weakness.

Trauma and neoplastic invasion are the most frequent causes of the cavernous sinus syndrome, whereas conditions that in the past were commonly responsible (thrombophlebitis, intracavernous carotid aneurysm or fistula, fungal infection, meningioma) now account for only a small proportion (see pages 605 and 735). A dural arteriovenous fistula is a rare cause. The diagnosis is confirmed and the disorder is distinguished from orbital pseudotumor by the finding of thrombosis in the sinus by imaging studies such as MRI, MRV, or MRA. This process is discussed in Chap. 34 with other disorders of the cerebral venous sinuses; the optic neuropathy that sometimes accompanies the syndrome is noted in Chap. 13.

The other important considerations in older patients with painful ophthalmoplegia are *temporal arteritis* (pages 159 and 731) and *thyroid ophthalmopathy* (although pain tends not to be prominent in the latter), which are discussed further on. When only the superior oblique muscle is involved and there is pain, the Brown syndrome, mentioned earlier, must be considered. The various intramedullary and extramedullary syndromes involving the oculomotor and other cranial nerves are summarized in Tables 34-3 and 47-2, respectively.

Acute Ophthalmoplegia (Table 14-5) When a total or nearly complete loss of eye movements evolves within a day or days, it raises a limited number of diagnostic possibilities. Keane, who analyzed 60 such cases, found the responsible lesion to lie within the brainstem in 18 (usually infarction and less often Wernicke disease), in the cranial nerves in 26 (Guillain-Barré syndrome or tuberculous meningitis), within the cavernous sinus in 8 (tumors or infection), and at the myoneural junction in 8 (myasthenia gravis and botulism). Our experience has tended toward the Guillain-Barré syndrome and, somewhat less frequently, myasthenia. The ophthalmoplegic form of Guillain-Barré syndrome is almost always associated with circulating antibodies to GQ1b ganglioside (see Chap. 46). There may be an accompanying paralysis of the dilator and constrictor of the pupil ("internal ophthalmoplegia") that is not seen in myasthenia. *Unilateral complete ophthalmoplegia* has an even more limited list of causes, largely related to local disease in the orbit and cavernous sinus, mainly infectious, neoplastic, or thrombotic.

Chronic and Progressive Bilateral Ophthalmoplegia This is most often due to an ocular myopathy [the mitochondrial disorder

Table 14-5

Causes of complete ophthalmoplegia (acute syndromes are noted by an asterisk)

Brainstem lesions

- Wernicke disease*
- Pontine infarction*
- Infiltrating glioma
- Acute disseminated encephalomyelitis and multiple sclerosis

Cranial nerve lesions

- Guillain-Barré syndrome*
- Neoplastic meningitis
- Granulomatous meningitis (tuberculous, sarcoid)
- Cavernous sinus thrombosis
- Tolosa-Hunt syndrome
- Orbital pseudotumor*

Neuromuscular junction syndromes

- Myasthenia gravis*
- Thyroid ophthalmopathy
- Lambert-Eaton syndrome
- Botulism*
- Congenital myasthenic syndromes ("slow-channel" disease)

Muscle disease

- Progressive external ophthalmoplegia (mitochondrial and dystrophic types)
- Oculopharyngeal dystrophy
- Congenital polymyopathies (myotubular, nemaline rod, central core)

known as progressive external ophthalmoplegia (pages 843 and page 1220), a restricted muscular dystrophy (page 1221), thyroid ophthalmopathy (see below and page 1235)] and, sometimes, myasthenia gravis and Lambert-Eaton syndrome. We have encountered instances of the Lambert-Eaton myasthenic syndrome that caused an almost complete ophthalmoplegia (but not as an initial sign, as it may be in myasthenia) and a patient with paraneoplastic brainstem encephalitis similar to the case reported by Crino and colleagues, but both of these are certainly rare as causes of complete loss of eye movements. Among the group of congenital myopathies, most of which are named for a morphologic characteristic of the affected limb musculature, a few—such as the central core, myotubular and nemaline types as well as the slow channel congenital myasthenic syndrome—may cause a generalized ophthalmoparesis (see Chaps. 52 and 53).

The *Duane retraction syndrome* (so called because of the retraction of the globe and narrowing of the palpebral fissure that are elicited by attempted adduction) is due to a congenital absence or hypoplasia of the abducens nucleus and nerve and aberrant innervation of the lateral rectus by branches of the third nerve. Cocontraction of the medial and lateral recti results in retraction of the globe in all directions of ocular movement.

Mechanical-Restrictive Ophthalmoparesis Several causes of a *pseudoparalysis of ocular muscles* are distinguished from the neuromuscular and brainstem diseases discussed above. In *thyroid disease*, a swollen and tight inferior or superior rectus muscle may limit upward and downward gaze; less frequently, involvement of the medial rectus limits abduction. The extraocular muscle enlargement can be demonstrated by computed tomography (CT) scans and ultrasonography, and their inelasticity may be confirmed by

forced duction tests (the insertions of the extraocular muscles are anesthetized and grasped by toothed forceps and attempts to move the globe are restricted). In most instances of thyroid ophthalmopathy, diagnosis is not difficult since there is an associated proptosis, but in the absence of the latter sign, and particularly if the ocular muscles are affected on one side predominantly, one may at first not be confident of thyroid disease as a cause. This disorder is discussed further on page 1235. In a significant number of cases (10 percent, according to Bahn and Heufelder), there are no signs of hyperthyroidism. However, most of these patients have laboratory evidence of thyroid autoimmune disease.

Mixed Gaze and Ocular Muscle Paralysis

We have already considered two types of neural paralysis of the extraocular muscles: paralysis of conjugate movements (gaze) and paralysis of individual ocular muscles. Here we discuss a third more complex one—namely, mixed gaze and ocular muscle paralysis. The mixed type is always a sign of an intrapontine or mesencephalic lesion due to a wide variety of pathologic changes.

Internuclear Ophthalmoplegia (INO) and Other Pontine Gaze Palsies These abnormalities have already been mentioned previously because they are components of numerous brainstem syndromes affecting both horizontal and vertical gaze. A lesion of the lower pons in or near the sixth nerve nucleus causes an ipsilateral paralysis of the lateral rectus muscle and a failure of adduction of the opposite eye—i.e., a combined paralysis of the sixth nerve and of conjugate lateral gaze, which is manifest simply as a gaze palsy. As already indicated, the pontine center accomplishes horizontal conjugate gaze by simultaneously innervating the ipsilateral lateral rectus (via the abducens neurons) and the contralateral medial rectus via fibers that originate in the internuclear neurons of the abducens nucleus and cross at the level of the nucleus to traverse the medial longitudinal fasciculus (MLF) of the opposite side (Fig. 14-1).

With a complete lesion of the left MLF, the left ipsilateral eye fails to adduct when the patient looks to the right; this condition is referred to as *internuclear ophthalmoplegia* (reciprocally, with a lesion of the right MLF, the right eye fails to adduct when the patient looks to the left—*right internuclear ophthalmoplegia*). Quite often, rather than a complete paralysis of adduction, there are slowed adducting saccades in the affected eye while its opposite quickly arrives at its fully abducted position upon commanded gaze or refixation. This can be brought out by having the patient make large side-to-side refixation movements between two targets or by observing the slowed corrective saccades induced by optokinetic stimulation. It should be pointed out that, typically, the affected eye at rest does not lie in an abducted position; there are exceptions, but this finding most dependably differentiates INO from a partial third nerve palsy and weakness of the medial rectus muscle. The two medial longitudinal fasciculi lie close together, each being situated adjacent to the midline, so that they are frequently affected together, yielding a bilateral internuclear ophthalmoplegia; this condition should be suspected when the predominant ocular finding is bilateral paresis of adduction.

A second component of INO is a nystagmus that is limited to or most prominent in the opposite (abducting) eye. The intensity of nystagmus varies greatly from case to case. Several explanations have been offered to account for this dissociated nystagmus, all of

them speculative. The favored one invokes Hering's law—that activated pairs of yoked muscles receive equal and simultaneous innervation; because of an adaptive increase in innervation of the weak adductor, a commensurate increase in innervation to the strong abductor occurs (manifest as nystagmus). Whatever the afferent stimulus for this overdrive, it is probably proprioceptive, since occlusion of the affected eye does not suppress the nystagmus. The MLF also contains axons that originate in the vestibular nuclei and govern vertical eye position, for which reason a lesion of the MLF may also cause a skew (vertical deviation of one eye) or vertical nystagmus with impairment of vertical fixation and pursuit.

Lesions involving the MLF in the high midbrain may be associated with a loss of convergence ("anterior" internuclear ophthalmoplegia); more commonly the MLF is involved by a lesion in the pons and convergence is spared, but there is then sometimes an additional slight degree of horizontal gaze or sixth nerve palsy as a result of disturbance of adjacent horizontal gaze centers ("posterior" internuclear ophthalmoplegia).

The main cause of *unilateral INO* is a small paramedian pontine infarction. Other common lesions are lateral medullary infarction (where skew deviation is often added), a demyelinating plaque of multiple sclerosis (more common as a cause of bilateral INO, as noted below), lupus erythematosus, and infiltrative tumors of the brainstem and fourth ventricular region. Occasionally, an INO is an unexplained finding after mild head injury or with subdural hematoma or hydrocephalus.

Bilateral INO is most often the result of a demyelinating lesion (multiple sclerosis) in the posterior part of the midpontine tegmentum. Pontine myelinolysis, pontine infarction from basilar artery occlusion, Wernicke disease, or infiltrating tumors are other causes. Brainstem damage following compression by a large cerebellar mass has on occasion produced the syndrome.

An ipsilateral gaze palsy is the simplest oculomotor disturbance that results from a lesion in the paramedian tegmentum. Another pontine disorder of ocular movement combines an internuclear ophthalmoplegia and a horizontal gaze palsy on the same side. One eye lies fixed in the midline for all horizontal movements; the other eye makes only abducting movements and may be engaged in horizontal nystagmus in the direction of abduction ("one-and-a-half syndrome" of Fisher; see also Wall and Wray). Unlike the situation of an INO alone, the mobile eye rests abducted because of the gaze palsy. The lesion in such cases involves the pontine center for gaze plus the adjacent ipsilateral MLF on one side only; it is usually of vascular or demyelinative causation. Caplan has summarized the features of other mixed oculomotor defects that occur with thrombotic occlusion of the upper part of the basilar artery ("top of the basilar" syndromes). These include upgaze or complete vertical gaze palsy and so-called pseudoabducens palsy, mentioned earlier. The latter is characterized by bilateral incomplete esotropia that simulates bilateral sixth nerve paresis but appears to be a type of sustained convergence or a paresis of divergence; it can be overcome by vestibular stimulation.

Among the most unusual of the complex ocular disturbances is a subjective tilting of the entire visual field that may produce any angle of divergence but most often creates an illusion of tilting of 45 to 90 degrees (*tortopia*) or of 180-degree vision (*upside-down vision*). Objects normally on the floor, such as chairs and tables, are perceived to be on the wall or ceiling. Although this symptom may arise as a result of a lesion of the parietal lobe or in the otolithic apparatus, it is most often associated with an internuclear ophthal-

moplegia and slight skew deviation and presumably with impaired function of the vestibular-otolithic nucleus or its central connections that maintain stable vertical position of the ipsilateral eye. Lateral medullary infarction has been the most common cause in our experience (Ropper).

Nystagmus

Nystagmus refers to involuntary rhythmic movements of the eyes and is of two general types. In the more common *jerk nystagmus*, the movements alternate between a slow component and a fast corrective component, or jerk, in the opposite direction. In *pendular nystagmus*, the oscillations are roughly equal in rate in both directions, although on lateral gaze the pendular type may be converted to the jerk type, with the fast component to the side of gaze. Nystagmus reflects an imbalance in one or more of the systems that maintain stability of gaze. The causes may therefore be viewed as originating in (1) structures that maintain steadiness of gaze in the primary position; (2) the system for holding eccentric gaze—the so-called neural integrator; or (3) the vestibulo-ocular reflex system (VOR), which maintains foveal fixation of images as the head moves. The theoretical aspects of nystagmus are reviewed by Adabi. For the purposes of clinical work, however, certain types of nystagmus are identified as corresponding to lesions in specific structures within each of these systems, and it is this approach that we take in the following pages. It follows that nystagmus can be classified as the result of a disturbance in the vestibular apparatus or its brainstem nuclei, the cerebellum, or a number of specific regions of the brainstem such as the MLF.

In testing for nystagmus, the eyes should be examined first in the central position and then during upward, downward, and lateral movements. *Jerk nystagmus* is the more common type. It may be horizontal or vertical and is elicited particularly on ocular movement in these planes, or it may be rotatory and, rarely, retractive or vergent. By custom the direction of the nystagmus is named according to the direction of the fast component. There are several varieties of jerk nystagmus. Some occur spontaneously; others are readily induced in normal persons by drugs or by labyrinthine or visual stimulation.

Drug intoxication is the most frequent cause of nystagmus. Alcohol, barbiturates, other sedative-hypnotic drugs, and phenytoin are the common ones. This form of nystagmus is most prominent on deviation of the eyes in the horizontal plane, but occasionally it may appear in the vertical plane as well. It rarely appears in the vertical plane alone, suggesting then a tegmental brainstem disorder or lithium intoxication. For no known reason, it may be asymmetrical in the two eyes.

Oscillopsia is the illusory movement of the environment in which stationary objects seem to move back and forth, up and down, or from side to side. It may be associated with ocular flutter or with coarse nystagmus of any type. With lesions of the labyrinths (as in aminoglycoside toxicity), oscillopsia is characteristically provoked by motion—e.g., walking or riding in an automobile—and indicates an impaired ability of the vestibular system to stabilize ocular fixation during body movement (i.e., impaired VOR function). In these circumstances cursory examination of the eyes may disclose no abnormalities; however, if the patient's head is rotated slowly from side to side or moved rapidly in one direction while attempting to fixate a target, impairment of smooth eye movements and their replacement by saccadic movements is evoked (see Chap. 15 for further discussion of these tests). If episodic and involving

only one eye, oscillopsia may be due to myokymia of an ocular muscle (usually the superior oblique).

Nystagmus of Labyrinthine Origin (See also Chap. 15.) This is predominantly a horizontal jerk nystagmus that is evident when the eyes are close to the central position; it is more prominent when visual fixation is eliminated (i.e., it is suppressed with fixation). The observation of suppression with visual fixation is facilitated by the use of Frenzel lenses, but most instances are evident without elaborate apparatus. Vestibular nystagmus of peripheral (labyrinthine) origin beats in most cases away from the side of the lesion and increases as the eyes are turned in the direction of the quick phase (Alexander's law). In contrast, as noted below, nystagmus of brainstem and cerebellar origin is most apparent when the patient fixates upon and follows a moving target and the direction of nystagmus changes with the direction of gaze as noted below and discussed in Chap. 15. Labyrinthine-vestibular nystagmus may be horizontal, vertical, or oblique, and that of purely labyrinthine origin characteristically has an additional torsional component. Tinnitus and hearing loss are often associated with disease of the peripheral labyrinthine mechanism; also, vertigo, nausea, vomiting, and staggering may accompany disease of any part of the labyrinthine-vestibular apparatus or its central connections. These points are elaborated in Chap. 15. As a characteristic example, the intense nystagmus or benign positional vertigo (described fully on page 261) is evoked by the action of moving from the sitting to the supine position, or the opposite, with the head turned to one side. In this condition, nystagmus of vertical-torsional type and vertigo develop in a few seconds and persist for another 10 to 15 s. When the patient sits up quickly, the nystagmus changes to beat in the opposite direction.

In many normal individuals, a few irregular jerks of the eyes are observed when the eyes are moved far to one side ("nystagmoid" jerks), but the movements cease once lateral fixation is attained. A fine rhythmic nystagmus may also occur in extreme lateral gaze, beyond the range of binocular vision; but if it is bilateral and disappears as the eyes move a few degrees toward the midline, it usually has no clinical significance. These movements are probably analogous to the tremulousness of skeletal muscles when maximally contracted.

Nystagmus Due to Brainstem and Cerebellar Disease Brainstem lesions often cause a coarse, unidirectional, *gaze-dependent nystagmus*, which may be horizontal or vertical, meaning that the nystagmus is exaggerated when the eyes sustain an eccentric position of gaze; vertical nystagmus, for example, is brought out usually on upward gaze, less often on downward gaze. Unlike the vestibular nystagmus discussed above, the central type usually changes direction depending on the direction of gaze. The presence of bidirectional vertical nystagmus usually indicates disease in the pontomedullary or mesencephalic tegmentum. Vertigo is less common or less intense than with labyrinthine nystagmus, but signs of disease of other nuclear structures and tracts in the brainstem are frequent. *Upbeat nystagmus* is observed frequently in patients with demyelinative or vascular disease, tumors, or Wernicke disease. There is still uncertainty about the anatomic basis of coarse upbeat nystagmus. According to some authors, it has been associated with lesions of the anterior cerebellar vermis, but we have not observed such an association. Kato and associates cite cases with a lesion at the pontomedullary junction, involving the nucleus prepositus hypoglossi, which receives vestibular connections and projects to all

brainstem and cerebellar regions concerned with oculomotor functions.

Downbeat nystagmus, which is always of central origin, is characteristic of lesions in the medullary-cervical region such as syringobulbia, Chiari malformation, basilar invagination, and demyelinative plaques. It has also been seen with Wernicke disease and may be an initial sign of either paraneoplastic brainstem encephalitis or cerebellar degeneration with opsoclonus. Downbeat nystagmus, usually in association with oscillopsia, has also been observed in patients with lithium intoxication or with profound magnesium depletion (Saul and Selhorst). Halmagyi and coworkers, who studied 62 patients with downbeat nystagmus, found that in half of them this abnormality was associated with the Chiari malformation and various forms of cerebellar degeneration; in most of the remainder, the cause could not be determined. However, a large proportion of cases of downbeating nystagmus remain unexplained by any of these mechanisms. Antonini and colleagues have reported a case associated with antibodies against glutamic acid decarboxylase (GAD), a substance that has a documented relationship to the “stiff-man” syndrome. Whether this may explain some idiopathic cases is unclear.

Nystagmus of several types—including gaze-evoked nystagmus, downbeat nystagmus, and “rebound nystagmus” (gaze-evoked nystagmus that changes direction with refixation to the primary position)—occurs with cerebellar disease (more specifically with lesions of the vestibulocerebellum) or with brainstem lesions that involve the nucleus prepositus hypoglossi and the medial vestibular nucleus (see above, in relation to upbeat nystagmus). Characteristic of cerebellar disease are several closely related disorders of saccadic movement (opsoclonus, flutter, dysmetria) described below. Tumors situated in the cerebellopontine angle may cause a coarse bilateral horizontal nystagmus, coarser to the side of the lesion.

Nystagmus that occurs only in the abducting eye is referred to as *dissociated nystagmus* and is a common sign of internuclear ophthalmoplegia, as discussed above.

Pendular Nystagmus This is found in a variety of conditions in which central vision is lost early in life, such as albinism and various other diseases of the retina and refractive media (congenital ocular nystagmus). Occasionally it is observed as a congenital abnormality, even without poor vision. The defect is postulated to be an instability of smooth pursuit or gaze-holding mechanisms. The nystagmus is always binocular and in one plane; i.e., it will remain horizontal even during vertical movement. It is purely or mainly pendular (sinusoidal) except in extremes of gaze, when it comes to resemble jerk nystagmus. Head oscillation may accompany the nystagmus and is probably compensatory. The formerly common syndrome of “miner’s nystagmus” is an associated condition that occurs in patients who have worked for many years in comparative darkness. The oscillations of the eyes are usually very rapid, increase on upward gaze, and may be associated with compensatory oscillations of the head and intolerance of light.

Indications as to the congenital nature of nystagmus are that it remains horizontal in all directions of gaze; it is suppressed during convergence and may be associated with odd head positions or with head oscillations and with strabismus. Also characteristic is a paradoxical response to optokinetic testing (see below), in which the quick phase is in the same direction as the drum rotation. A related *latent nystagmus* is the result of a lack of normal development of stereoscopic vision and may be detected by noting that

the nystagmus changes direction when the eyes are alternately covered.

In addition, severe visual loss or blindness of acquired type that eliminates the ability to accurately direct gaze, even in adulthood, produces nystagmus of pendular or jerk variety. Both horizontal and vertical components are evident and the characteristic feature is a fluctuation over several seconds of observation in the dominant direction of beating.

Spasmus mutans, a specific type of pendular nystagmus of infancy, is accompanied by head nodding and occasionally by wry positions of the neck. Most cases begin between the fourth and twelfth months of life, never after the third year. The nystagmus may be horizontal, vertical, or rotatory; it is usually more pronounced in one eye than the other (or limited to one eye) and can be intensified by immobilizing or straightening the head. Most infants recover within a few months or years. Most cases are idiopathic, but symptoms like those of spasmus mutans betray the presence of a chiasmal or third ventricular tumor (see also seesaw nystagmus below).

Optokinetic Nystagmus When one is watching a moving object (e.g., the passing landscape from a train window, a rotating drum with vertical stripes, or a strip of cloth with similar stripes), a rhythmic jerk nystagmus, *optokinetic nystagmus* (OKN), normally appears. The explanation of this phenomenon is that the slow component of the nystagmus represents an involuntary pursuit movement to the limit of comfortable conjugate gaze; the eyes then make a quick saccadic movement in the opposite direction in order to fixate a new target that is entering the visual field. With unilateral lesions of the parietal region, the slow pursuit phase of the OKN may be lost or diminished when a moving stimulus—e.g., the striped OKN drum—is rotated *toward the side of the lesion*, whereas rotation of the drum to the opposite side elicits a normal response. (A prominent neurologist of our acquaintance in past days correctly made the diagnosis of parietal lobe abscess on the basis of fever and absent pursuit to the side of the lesion.) It should be noted that patients with hemianopia due to an occipital lobe lesion usually show a normal optokinetic response. These observations indicate that an abnormal response does not depend on a lesion of the geniculocalcarine tract. Presumably the loss of the pursuit phase with a parietal lesion is due to interruption of efferent pathways from the parietal cortex to the brainstem centers for conjugate gaze. On the other hand, frontal lobe lesions allow the eyes to tonically follow in the direction of the target but with little or no fast-phase correction in the direction opposite the lesion.

An important additional fact about OKN is that its presence proves that the patient is not blind. Each eye can be tested separately to exclude monocular blindness. Thus it is of particular value in the examination of hysterical patients and malingeringers who claim that they cannot see and of neonates and infants (a nascent OKN is established within hours after birth and becomes more easily elicitable over the first few months of life).

Labyrinthine stimulation—e.g., irrigation of the external auditory canal with warm or cold water, or “caloric testing”—produces a marked nystagmus. Cold water induces a slow tonic deviation of the eyes toward the ear irrigated by a cold stimulus and a compensatory nystagmus in the opposite direction; warm water does the reverse. Thus the acronym taught to generations of medical students: “COWS,” or “cold opposite, warm same,” to refer to the direction of induced nystagmus. The slow component reflects the effect of impulses originating in the semicircular canals, and

the fast component is a corrective movement. The production of nystagmus by labyrinthine stimulation and other features of vestibular nystagmus are discussed further in Chap. 15.

Other Types of Nystagmus *Convergence nystagmus* refers to a rhythmic oscillation in which a slow abduction of the eyes in respect to each other is followed by a quick movement of adduction. It is usually accompanied by quick rhythmic retraction movements of the eyes (*nystagmus retractorius*) and by one or more features of the Parinaud–dorsal midbrain syndrome. There may also be rhythmic movements of the eyelids or a maintained spasm of convergence, best brought out on attempted elevation of the eyes to command or downward rotation of an OKN drum. These unusual phenomena all point to a lesion of the upper midbrain tegmentum and are usually manifestations of vascular disease, traumatic disease, or tumor, notably pinealoma that compresses this region.

Seesaw nystagmus is a torsional-vertical oscillation in which the intorting eye moves up and the opposite (extorting) eye moves down, then both move in the reverse direction. It is occasionally observed in conjunction with chiasmatic bitemporal hemianopia due to sellar or parasellar masses. Spasmus mutans has some similarities, as mentioned above.

Periodic alternating nystagmus is a remarkable horizontal jerking that periodically (every 90 seconds or so) changes direction, interposed with a brief neutral period during which the eyes show no nystagmus or jerk downward. Alternating nystagmus is seen with lesions in the lower brainstem but has also been reported with Creutzfeldt–Jakob disease, hepatic encephalopathy, lesions of the cerebellar nodulus, carcinomatous meningitis, and a large number of other processes. A congenital form is associated with albinism. It differs from *ping-pong gaze*, which is a saccadic variant with a more rapid alternating of gaze from side to side and usually the result of bilateral cerebral strokes.

So-called *palatal nystagmus*, which is really a tremor, is due to a lesion of the central tegmental tract and may be accompanied by a convergence-retraction nystagmus that has the same beat as the palatal and pharyngeal muscles, as discussed on page 85.

Other Spontaneous Ocular Movements

Roving conjugate eye movements are characteristic of light coma. Slow horizontal ocular deviations that shift every few seconds from side to side (“*ping-pong gaze*”) is a form of roving eye movement that occurs with bihemispheric infarctions or sometimes with posterior fossa lesions. C.M. Fisher has noted a similar slow, side-to-side pendular oscillation of the eyes (“windshield-wiper eyes”). This phenomenon has been associated with bilateral hemispheric lesions that have presumably released a brainstem pacemaker.

Ocular bobbing is a term coined by Fisher to describe a distinctive spontaneous fast downward jerk of the eyes followed by a slow upward drift to the midposition. It is observed in comatose patients in whom horizontal eye movements are absent and has been associated most often with large destructive lesions of the pons, less often of the cerebellum. The eye movements may be disconjugate in the vertical plane, especially if there is an associated third nerve palsy on one side.

Other spontaneous vertical eye movements have been given a variety of confusing names: *atypical bobbing*, *inverse bobbing*, *reverse bobbing*, and *ocular dipping*. For the most part, they are observed in coma of metabolic or anoxic origin and in the context of preserved horizontal eye movements (in distinction to ocular

bobbing). *Ocular dipping* is a term we have used to describe an arrhythmic slow conjugate downward movement followed in several seconds by a more rapid upward movement; it occurs spontaneously but may at times be elicited by moving the limbs or neck. Anoxic encephalopathy has been the most common cause, but a few cases have been attributed to drug overdose (Ropper 1981).

Oculogyric crisis, formerly associated with postencephalitic parkinsonism, is now most often due to phenothiazine drugs, as discussed earlier.

Opsoclonus is the term applied to rapid, conjugate oscillations of the eyes in horizontal, rotatory, and vertical directions, made worse by voluntary movement or the need to fixate the eyes. These movements are continuous and chaotic, without an intersaccadic pause (called by some by the colorful term *saccadomania*), and are almost unique among disorders of ocular movement in that they persist in sleep. Often, as indicated in Chap. 6, they are part of a widespread myoclonus associated with parainfectious disease, occasionally with AIDS, West Nile virus encephalitis, and rickettsial infections, but most characteristically as a paraneoplastic manifestation with severe ataxia (page 583). Opsoclonus may also be observed in patients who are intoxicated with antidepressants, anticonvulsants, organophosphates, cocaine, lithium, thallium, and haloperidol; in the nonketotic hyperosmolar state; and in cerebral Whipple disease, where it is coupled with rhythmic jaw movements (oculomasticatory myorhythmia, page 603). A childhood form, associated with limb ataxia and myoclonus that is responsive to adrenocorticotrophic hormone (ACTH), may persist for years without explanation, as in the “dancing eyes” of children (Kinsbourne syndrome), although neuroblastoma remains the main consideration in children with this ocular disorder. There is also a self-limited benign form in neonates. Similar movements have been produced in monkeys by creating bilateral lesions in the pretectum.

Ocular dysmetria, the analogue of limb dysmetria, consists of an overshoot of the eyes on attempted fixation followed by several cycles of oscillation of diminishing amplitude until fixation is attained. The overshoot may occur on eccentric fixation or on refixation to the primary position of gaze. It probably reflects dysfunction of the anterosuperior vermis and underlying deep cerebellar nuclei. *Ocular flutter* refers to occasional bursts of very rapid horizontal oscillations around the point of fixation; this abnormality is also associated with cerebellar disease. Flutter at the end of a saccade, called *flutter dysmetria (fish-tail nystagmus)* has the appearance of dysmetria, but careful analysis indicates that it is probably a different phenomenon. Whereas the inaccurate saccades of ataxia are separated by normal brief pause (intersaccadic interval), flutter dysmetria consists of consecutive saccades without an intersaccadic interval (Zee and Robinson).

Opsoclonus, ocular dysmetria, and flutter-like oscillations may occur together, or a patient may show only one or two of these ocular tremors, either simultaneously or in sequence. One hypothesis relates opsoclonus and ocular flutter to a disorder of the saccadic “pause neurons” (see above), but their exact anatomic basis has not been elucidated. Some normal individuals can voluntarily induce flutter.

Disorders of the Eyelids and Blinking

A consideration of oculomotor disorders would be incomplete without reference to the eyelids and blinking. In the normal individual, the eyelids on both sides are at the same level with respect

to the limbus of the cornea and there is a variable prominence of the eyes, depending on the width of the palpebral fissure. The function of the eyelids is to protect the delicate corneal surfaces against injury and the retinae against glare; this is done by blinking and lacrimation. Eyelid movement is normally coordinated with ocular movement—the upper lids elevate when looking up and descend when looking down. Turning the eyes quickly to the side is usually attended by a single blink, which is necessarily brief so as not to interfere with vision. When the blink duration is prolonged in this context, it is indicative of an abnormally intense effort required to initiate the saccade; usually this is due to frontal lobe or basal ganglionic disease.

Closure and opening of the eyelids is accomplished through the reciprocal action of the levator palpebrae and orbicularis oculi muscles. Relaxation of the levator and contraction of the orbicularis effect closure; the reverse action of these muscles effects opening of the closed eyelids. Opening of the lids is aided by the tonic sympathetic innervation of Müller's muscles, which is innervated by sympathetic fibers. The levator is innervated by the oculomotor nerve, and the orbicularis by the facial nerve. The trigeminal nerves provide sensation to the eyelids and are also the afferent limbs of corneal and palpebral reflexes. Central mechanisms for the control of blinking, in addition to the reflexive brainstem connections between the third, fifth, and seventh nerve nuclei, include the cerebrum, basal ganglia, and hypothalamus. Voluntary closure is initiated through frontobasal ganglionic connections.

The eyelids are kept open by the tonic contraction of the levator muscles, which overcomes the elastic properties of the periorbital muscles. The eyelids close during sleep and certain altered states of consciousness due to relaxation of the levator muscles. Facial paralysis causes the closure to be incomplete.

Blinking occurs irregularly at a rate of 12 to 20 times a minute, the frequency varying with the state of concentration and with emotion. The natural stimuli for the blink reflex (blinking is always bilateral) are corneal contact (corneal reflex), a tap on the brow or around the eye, visual threat, an unexpected loud sound, and, as indicated above, turning of the eyes to one side. There is normally a rapid adaptation of blink to visual and auditory stimuli but not to corneal stimulation.

Electromyography of the orbicularis oculi reveals two components of the blink response, an early and late one, a feature that is readily corroborated by clinical observation. The early response consists of only a slight movement of the upper lids; the immediately following response is more forceful and approximates the upper and lower lids. Whereas the early part of the blink reflex is beyond volitional control, the second part can be inhibited voluntarily.

Blepharospasm, an excessive and forceful closure of the lids, which is described on page 93, is a common disorder that occurs in isolation or as part of a number of dyskinesias and drug-induced movement disorders. Increased blink frequency occurs with corneal irritation, with sensitization of trigeminal nerve endings, and in oculofacial dyskinetic syndromes, such as blepharospasm. A reduced frequency of blinking (<10 per minute) is characteristic of progressive supranuclear palsy and Parkinson disease. In these cases, adaptation to repeated supraorbital tapping at a rate of about 1 per second is impaired; therefore the patient continues to blink with each tap on the forehead or glabella. The failure to inhibit this response is referred to as the glabellar or *Myerson sign*.

A lesion of the oculomotor nerve, by paralyzing the levator

muscle, causes *ptosis*, i.e., drooping of the upper eyelid. A lesion of the facial nerve, as in Bell's palsy, results in an inability to close the eyelids due to weakness of orbicularis oculi, a slight retraction of the upper lid (due to the unopposed action of the levator), and loss of the blink reflex on the affected side. In some instances of Bell's palsy, even after nearly full recovery of facial movements, the blink frequency may be reduced on the previously paralyzed side. Of neurologic importance is the fact that a trigeminal nerve lesion on one side, by reducing corneal sensation, interferes with the blink reflex on both sides, while a Bell's palsy does not abolish the contralateral blink. Aberrant regeneration of the third nerve after an injury may result in a condition wherein the upper lid retracts on lateral or downward gaze (pseudo-von Graefe sign). Aberrant regeneration of the facial nerve after Bell's palsy has an opposite effect—closure of the lid with jaw movements or speaking. The Gunn "jaw-winking" phenomenon is a synkinesis that may also occur after aberrant regeneration of the facial nerve but is otherwise a congenital and sometimes hereditary anomaly in which a ptotic eyelid retracts momentarily when the mouth is opened or the jaw is moved to one side. In other cases, inhibition of the levator muscle and ptosis occurs with opening of the mouth ("inverse Marcus Gunn phenomenon," or Marin Amat syndrome).

A useful clinical rule is that a combined paralysis of the levator and orbicularis oculi muscles (i.e., the muscles that open and close the lids) nearly always indicates a myopathic disease such as myasthenia gravis or myotonic dystrophy. This is because the third and seventh cranial nerves are rarely affected together in peripheral nerve or brainstem disease. An infrequent but overlooked cause of unilateral ptosis is a dehiscence of the tarsal muscle attachment; it can be identified by the loss of the upper lid fold just below the brow.

Bilateral ptosis is a characteristic feature of certain muscular dystrophies and myasthenia gravis; congenital ptosis and progressive sagging of the upper lids in the elderly are other common forms. An effective way of demonstrating that mild ptosis is in fact bilateral is to lift one side and observe that the opposite lid promptly droops. This reflects the enhanced effort required to maintain patency of the lids. The combination of bilateral ptosis and mild weakness of lid closure is particularly characteristic of myasthenia. Unilateral ptosis is a notable feature of third nerve lesions (see above) and of sympathetic paralysis, as in the Horner syndrome. It may be accompanied by an overaction (compensation) of the frontalis and the contralateral levator palpebrae muscles. In patients with myasthenia, Cogan has described a "lid twitch" phenomenon, in which there is a transient retraction of the upper lid when the patient moves visual fixation from the down position to straight ahead. Brief fluttering of the lid margins upon moving the eyes vertically is also characteristic of myasthenia.

The opposite of ptosis, i.e., *retraction of the upper lids*, often with a staring expression, is observed with orbital tumors and in thyroid disease, the latter being most common causes of unilateral and bilateral proptosis. A staring appearance alone is observed in Parkinson disease, progressive supranuclear palsy, and hydrocephalus, in which there may be downturning of the eyes ("sunset sign") and paralysis of upward gaze. The sunset sign is found mostly in children with hydrocephalus. Retraction of the eyelids (Collier sign), when part of a dorsal midbrain syndrome, is accompanied by a light-near pupillary dissociation; it is not accompanied by a lid lag (von Graefe sign) on downward gaze, in distinction to what is observed in thyroid ophthalmopathy. Slight lid retraction has been observed in a few patients with hepatic cirrhosis, Cushing

disease, chronic steroid myopathy, and hyperkalemic periodic paralysis; in these conditions, lid lag is also absent. Lid retraction can be a reaction to ptosis on the other side; this is clarified by lifting the ptotic lid manually and observing the disappearance of contralateral retraction.

In myotonic dystrophy, which features ptosis as a component of the myopathic facies, and in myotonia congenita, forceful closure of the eyelids may induce a strong aftercontraction. In certain progressive supranuclear palsy and Parkinson disease, even gentle closure may elicit blepharoclonus and blepharospasm on attempted opening of the lids; or there may be a delay in the opening of the tightly closed eyelids. Acute right parietal or bifrontal lesions often produce a peculiar disinclination to open the eyelids, even to the point of offering active resistance upon attempts at forced opening. The closed lids give the impression of diminished alertness when the patient is largely awake.

THE PUPILS

The testing of pupillary size and reactivity, which can be accomplished by the use of a flashlight and simple pupillometer (we favor the circular laminated card known as the *Iowa pupil gauge*) yields important, often vital clinical information. Essential, of course, is the proper interpretation of the pupillary reactions, and this requires some knowledge of their underlying neural mechanisms.

The diameter of the pupil is determined by the balance of innervation between the autonomically innervated sphincter and radially arranged dilator muscles of the iris, the sphincter muscle playing the major role. The *pupilloconstrictor* (*parasympathetic*) fibers arise in the Edinger-Westphal nucleus in the high midbrain, join the third cranial (oculomotor) nerve, and synapse in the ciliary ganglion, which lies in the posterior part of the orbit. The postganglionic fibers then enter the globe via the short ciliary nerves; approximately 3 percent of the fibers innervate the sphincter pupillae and 97 percent the ciliary body. The sphincter of the pupil comprises 50 motor units, according to Corbett and Thompson. The *pupillodilator* (*sympathetic*) fibers arise in the posterolateral part of the hypothalamus and descend, uncrossed, in the lateral tegmentum of the midbrain, pons, medulla, and cervical spinal cord to the eighth cervical and first and second thoracic segments, where they synapse with the lateral horn cells. The latter cells give rise to preganglionic fibers, most of which leave the cord by the second ventral thoracic root and proceed through the stellate ganglion to synapse in the superior cervical ganglion. The postganglionic fibers course along the internal carotid artery and traverse the cavernous sinus, where they join the first division of the trigeminal nerve, finally reaching the eye as the long ciliary nerve that innervates the dilator muscle of the iris. Some of the postganglionic sympathetic fibers also innervate the sweat glands and arterioles of the face and Müller's muscle in the eyelid.

The Pupillary Light Reflex

The most common stimulus for pupillary constriction is exposure of the retina to light. Reflex pupillary constriction is also part of the act of convergence and accommodation for near objects (near-synkinesis).

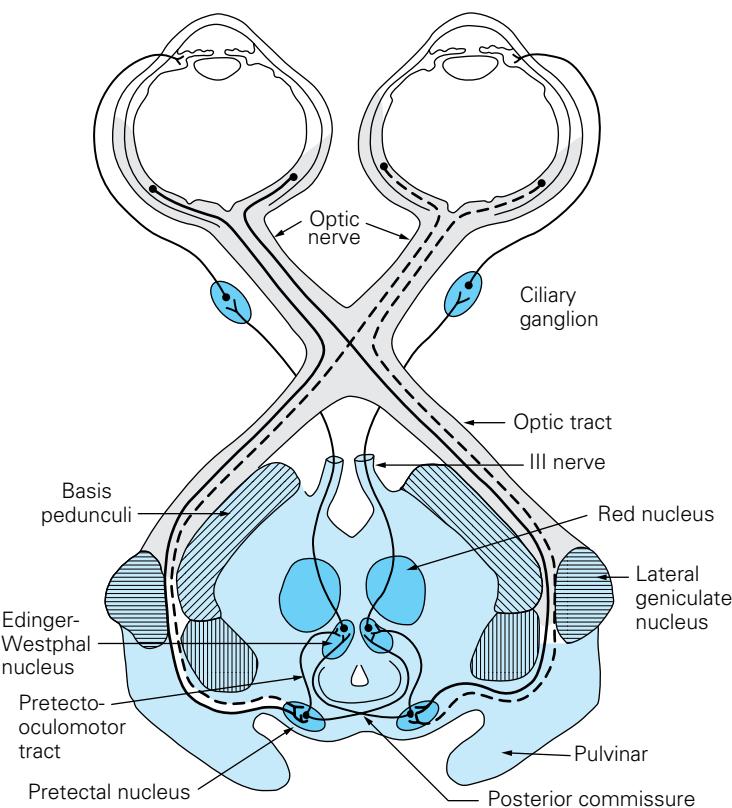

Figure 14-7. Diagram of the pathways subserving the pupillary light reflex. (Redrawn with permission from Walsh FB, Hoyt WF: Clinical Neuro-Ophthalmology, 3rd ed. Baltimore, Williams & Wilkins, 1969.)

The pathway for the pupillary light reflex consists of three parts (Fig. 14-7):

1. *An afferent limb*, whose fibers originate in the retinal receptor cells, pass through the bipolar cells, and synapse with the retinal ganglion cells; axons of these cells run in the optic nerve and tract. The light reflex fibers leave the optic tract just rostral to the lateral geniculate body and enter the high midbrain, where they synapse in the pretectal nucleus.
2. *Intercalated neurons* that give rise to the pupillomotor fibers, which pass ventrally to the ipsilateral Edinger-Westphal nucleus and, via fibers that cross in the posterior commissure, to the contralateral Edinger-Westphal nucleus (labeled "pretecto-oculomotor" tract in Fig. 14-7).
3. *An efferent two-neuron pathway from the Edinger-Westphal nucleus*, synapsing in the ciliary ganglion, by which all motor impulses reach the pupillary sphincter, as described above.

Alterations of the Pupils

The pupils tend to be large in children and small in the aged, sometimes markedly miotic but still reactive (senile miosis). An asymmetry of the pupils of 0.3 to 0.5 mm is found in 20 percent or more of normal individuals. A lesion that destroys only a small number of nerve cells in the Edinger-Westphal nucleus or ciliary ganglion will cause paralysis of a sector or sectors of the iris and deform the pupil to a pear or elliptical shape.

Normally the pupil constricts under a bright light (direct re-

flex), and the other unexposed pupil also constricts (consensual reflex). With complete or nearly complete interruption of the optic nerve, the pupil will fail to react to direct light stimulation; however, the pupil of the blind eye will still show a consensual reflex, i.e., it will constrict when light is shone in the healthy eye. Contrariwise, lack of direct and consensual light reflex with retention of the consensual reflex in the opposite eye places the lesion in the efferent limb of the reflex arc, i.e., in the homolateral oculomotor nerve or its nucleus. A lesion of the afferent limb of the light reflex pathway will not affect the near responses of the pupil, and lesions of the visual pathway caudal to the point where the light reflex fibers leave the optic tract will not alter the pupillary light reflex (Fig. 14-7).

Following initial constriction, the pupil may normally dilate slightly in spite of a light shining steadily in one or both eyes. Slowness of response along with failure to sustain pupillary constriction, or “pupillary escape,” is sometimes referred to as the *Marcus-Gunn pupillary sign* (not to be confused with the Gunn jaw synkinesis mentioned earlier); a mild degree of it may be observed in normal persons, but it is far more prominent in cases of damage to the retina or optic nerve. A variant of this pupillary response may be used to expose mild degrees of retrobulbar neuropathy (relative afferent pupillary defect). This is best tested in a dimly lighted room with the patient fixating on a distant target. If a light is shifted quickly from the normal to the impaired eye, the direct light stimulus is no longer sufficient to maintain the previously evoked consensual pupillary constriction and both pupils dilate. These abnormal pupillary responses form the basis of “the swinging-flashlight test,” in which each pupil is alternately exposed to light at 3-s intervals and the pupil on the side of an optic neuropathy displays a paradoxical dilation just as the light is brought to that side.

Hippus, a rapid alternation in pupillary size, is common in metabolic encephalopathy but has no particular significance.

Horner Syndrome Interruption of the sympathetic fibers—either centrally, between the hypothalamus and their points of exit from the spinal cord (C8 to T3, mainly T2), or peripherally (cervical sympathetic chain, superior cervical ganglion, or along the carotid artery)—results in miosis and ptosis (because of paralysis of the pupillary dilator muscle and of Müller’s muscle, respectively). To this may be added loss of sweating on the same side of the face and redness of the conjunctiva. The entire complex is called the *Horner syndrome*, *Bernard-Horner syndrome*, or *oculosympathetic palsy* (see also page 464). It may be due to ipsilateral lesions of the sympathetic tract in the medulla or cervical cord or to peripheral lesions. The pattern of sweating may be helpful in localizing the lesion in the following manner: with lesions at the level of the common carotid artery, loss of sweating involves the entire side of the face. With lesions distal to the bifurcation, loss of sweating is not found or is confined to the medial aspect of the forehead and side of the nose (see Morris et al). Retraction of the eyeball (enophthalmos), traditionally considered a component of the syndrome, is probably an illusion created by narrowing of the palpebral fissure. A hereditary form (autosomal dominant) of the Horner syndrome is known, usually but not always associated with a congenital absence of pigment in the affected iris (heterochromia iridis) (see Hageman et al). *Bilateral Horner syndrome* is a rare occurrence; usually it is found in autonomic neuropathies and in high cervical cord transection. Although difficult to appreciate, it may be detected (using pupillometry) by noting a lag in the redilation

of the initially small pupils when light is withdrawn (Smith and Smith).

Stimulation or irritation of the sympathetic fibers has the opposite effect, i.e., lid retraction, dilatation of the pupil, and apparent proptosis. Use is made of this phenomenon in the testing of the *ciliospinal pupillary reflex*, which is evoked by pinching the neck (afferent, C2, C3) and is effected through the efferent sympathetic fibers.

Extreme constriction of the pupils (miosis) is commonly observed with pontine lesions, presumably because of bilateral interruption of the pupillodilator fibers. Narcotic ingestion is the most common cause. Interruption of the parasympathetic fibers causes an abnormal dilatation of the pupils (mydriasis), often with loss of pupillary light reflexes; this is frequently the result of midbrain lesions and is a common finding in cases of deep coma (the “blown” or Hutchinson pupil, described in Chap. 17) and with direct compression of the oculomotor nerve, as by cerebral aneurysm, tumor, or temporal lobe herniation. Other signs of oculomotor palsy are usually conjoined.

As an ancillary test to determine the cause of changes in the size of the pupils, the functional integrity of the sympathetic and parasympathetic nerve endings in the iris may also be determined by the use of certain drugs. These are detailed in the next section. Atropinics dilate the pupils by paralyzing the parasympathetic nerve endings; physostigmine and pilocarpine constrict the pupils, the former by inhibiting cholinesterase activity at the neuromuscular junction and the latter by direct stimulation of the sphincter muscle of the iris. Epinephrine and phenylephrine dilate the pupils by direct stimulation of the dilator muscle. Cocaine dilates the pupils by preventing the reabsorption of norepinephrine into the nerve endings. Morphine and other narcotics act centrally to constrict the pupils.

In *diabetes mellitus*, where autonomic spinal and cranial nerves are often involved, the pupils are affected in the majority of cases. They are smaller than would be expected for age due to involvement of pupillodilator sympathetic fibers, and mydriasis is excessive upon instillation of sympathomimetic drugs. The light reflex, mediated by parasympathetic fibers (which are also damaged), is reduced, usually to a greater degree than constriction on accommodation (Smith and Smith). Some of these abnormalities require special methods of pupillometry for their demonstration.

Argyll-Robertson Pupil In the forms of late syphilis, particularly tabes dorsalis, the pupils are usually small, irregular, and unequal; they fail to react to light, although they do constrict on accommodation (light-near dissociation) and do not dilate properly in response to mydriatic drugs. Atrophy of the iris is associated in some cases. This is known as the *Argyll Robertson pupil*. The exact locality of the lesion is not certain; it is generally believed to be in the tectum of the midbrain proximal to the oculomotor nuclei where the descending pupillodilator fibers are in close proximity to the light reflex fibers (Fig. 14-7). The possibility of a partial third nerve lesion extending to the ciliary ganglion seems more plausible to us. A similar pupillary abnormality has been observed in the meningoradiculitis of Lyme disease and in diabetes. A dissociation of the light reflex from the accommodation-convergence reaction is also sometimes observed with a variety of midbrain lesions—e.g., pinealoma, multiple sclerosis; in these diseases, miosis, irregularity of pupils, and failure to respond to a mydriatic are usually not present. S. A. K. Wilson referred to this condition as the *Argyll*

Robertson pupillary phenomenon, in contrast to the Argyll Robertson pupil.

Adie Tonic Pupil (Holmes-Adie Syndrome) Another interesting pupillary abnormality is the tonic reaction, also referred to as the *Adie pupil*. This syndrome is due to a degeneration of the ciliary ganglia and the postganglionic parasympathetic fibers that normally constrict the pupil and effect accommodation. The patient may complain of unilateral blurring of vision or may have noticed that one pupil is larger than the other. The affected pupil is slightly enlarged in ambient light and the reaction to light is absent or greatly reduced if tested in the customary manner, although the size of the pupil will change slowly with prolonged light stimulation. Characteristically, there is a light-near dissociation, i.e., the Adie pupil responds better to near (accommodation) than it does to light. Once the pupil has constricted, it tends to remain tonically constricted and redilates very slowly. Once dilated, the pupil remains in this state for many seconds, up to a minute or longer. Light and near paralysis of a segment or segments of the pupillary sphincter is also characteristic of the syndrome; this segmental irregularity can be seen with the high plus lenses of an ophthalmoscope. The affected pupil constricts promptly in response to the common miotic drugs and is unusually sensitive to a 0.1% solution of pilocarpine, a concentration that has only minimal effect on a normal pupil (denervation supersensitivity).

The tonic pupil usually appears during the third or fourth decade of life and is much more common in women than in men; it may be associated with absence of knee or ankle jerks (*Holmes-Adie syndrome*) and hence be mistaken for tabes dorsalis. From all available data, it represents a special form of mild inherited polyneuropathy. There is a familial proclivity to the syndrome, in most cases attributable to a mutation in the myelin protein zero (MPZ) gene that is implicated in one of the less common forms of Charcot-Marie-Tooth inherited polyneuropathy (see Chap. 46).

An acquired type of tonic pupil has also been attributed, sometimes on uncertain grounds to diabetes, viral infection, and trauma. We have observed it following recovery from the Guillain-Barré syndrome.

Springing Pupil Finally, mention should be made of a rare pupillary phenomenon characterized by transient episodes of unilateral mydriasis for which no cause can be found (the “*springing pupil*”). These episodes of mydriasis, which are more common in women, last for minutes to days and may recur at random intervals. Oculomotor palsies and ptosis are notably lacking, but sometimes the pupil is distorted during the attack. Some patients complain of blurred vision and head pain on the side of the mydriasis, suggesting an atypical form of ophthalmoplegic migraine. In children, following a minor or major seizure, one pupil may remain dilated for a protracted period of time. The main consideration in an awake patient is that the cornea has inadvertently (or purposefully) been exposed to mydriatic solutions, among them vasopressor agents used in cardiac resuscitation.

Differential Diagnosis of Anisocoria

In regard to pupillary disorders, there are two main issues with which the neurologist has to contend. One is the problem of unequal pupils (anisocoria) and determining whether this abnormality is derived from sympathetic or parasympathetic denervation. The

second problem is the relative afferent pupillary defect and how to recognize it; this was discussed earlier.

As stated above, in dealing with anisocoria, it is worth noting that at any given examination, 20 percent of normal persons show an inequality of 0.3 to 0.5 mm or more. This is “simple” or physiologic anisocoria, and it may be a source of confusion in patients with small pupils. Its main characteristic is that the same degree of asymmetry in size is maintained in low, ambient, and bright light conditions. It is also variable from day to day and even from hour to hour and often will have disappeared at the time of the second examination (Loewenfeld; Lam et al.).

In first dealing with the problem of pupillary asymmetry, one has to determine which of the pupils is abnormal. If it is the larger one, the light reaction will be muted on that side; if it is the smaller pupil, it will fail to enlarge in response to shading both eyes. More simply stated, *light exaggerates the anisocoria due to a third-nerve lesion, and darkness accentuates the anisocoria in the case of a Horner syndrome*.

A persistently small pupil always raises the question of a Horner syndrome, a diagnosis that may be difficult if the ptosis is slight and facial anhidrosis undetectable. In darkness, the Horner pupil dilates more slowly and to a lesser degree than the normal one because it lacks the pull of the dilator muscle (dilation lag). The diagnosis can be confirmed by placing 1 or 2 drops of 2 to 10% cocaine in each eye; the Horner pupil dilates not at all or much less than the normal one—a response that can be documented by photos taken after 5 and 15 s of darkness. Such a response to cocaine will occur with a defect at any point along the sympathetic pathway (page 461) because lesions of the first- or second-order sympathetic neurons eventually deplete norepinephrine at the synapses with third-order neurons. The reduction of neurotransmitter at the nerve endings in the ciliary dilator muscle greatly reduces the reuptake blocking effects of cocaine. If the subsequent (24 h after cocaine) application of the adrenergic mydriatic hydroxyamphetamine (1%) has no effect, the lesion can be localized to the postganglionic portion of the pathway since this drug releases any norepinephrine that may remain in the third-order neuron. Localization of the lesion to the central or preganglionic parts of the sympathetic pathway depends upon the associated symptoms and signs (Chap. 26).

A variety of lesions, some of them purely ocular, such as uveitis, may give rise to a *dilated pupil*. Neurologically, there are three main diagnostic considerations:

1. An interruption of the parasympathetic preganglionic pupilloconstrictor fibers in the third nerve. It is a safe clinical rule that the interruption of these fibers is practically always associated with ptosis, palsies of the extraocular muscles, or signs of other brainstem or cerebral disease. The importance of unilateral pupillary enlargements in the diagnosis of coma is discussed in Chap. 17. Often in this circumstance the pupil goes through an early phase of miosis followed by irregularly shaped enlargement.
2. The presence of a tonic or *Adie* pupil. Here one requires that the pupillary abnormalities conform to the diagnostic criteria for this disorder, enumerated above.
3. Drug-induced iridoplegia. Not infrequently, particularly among nurses and pharmacists, a mydriatic fixed pupil is the result of accidental or deliberate application of an atropinic or sympathomimetic drug. Failure of 1% pilocarpine drops to contract the pupil provides proof that the iris sphincter has

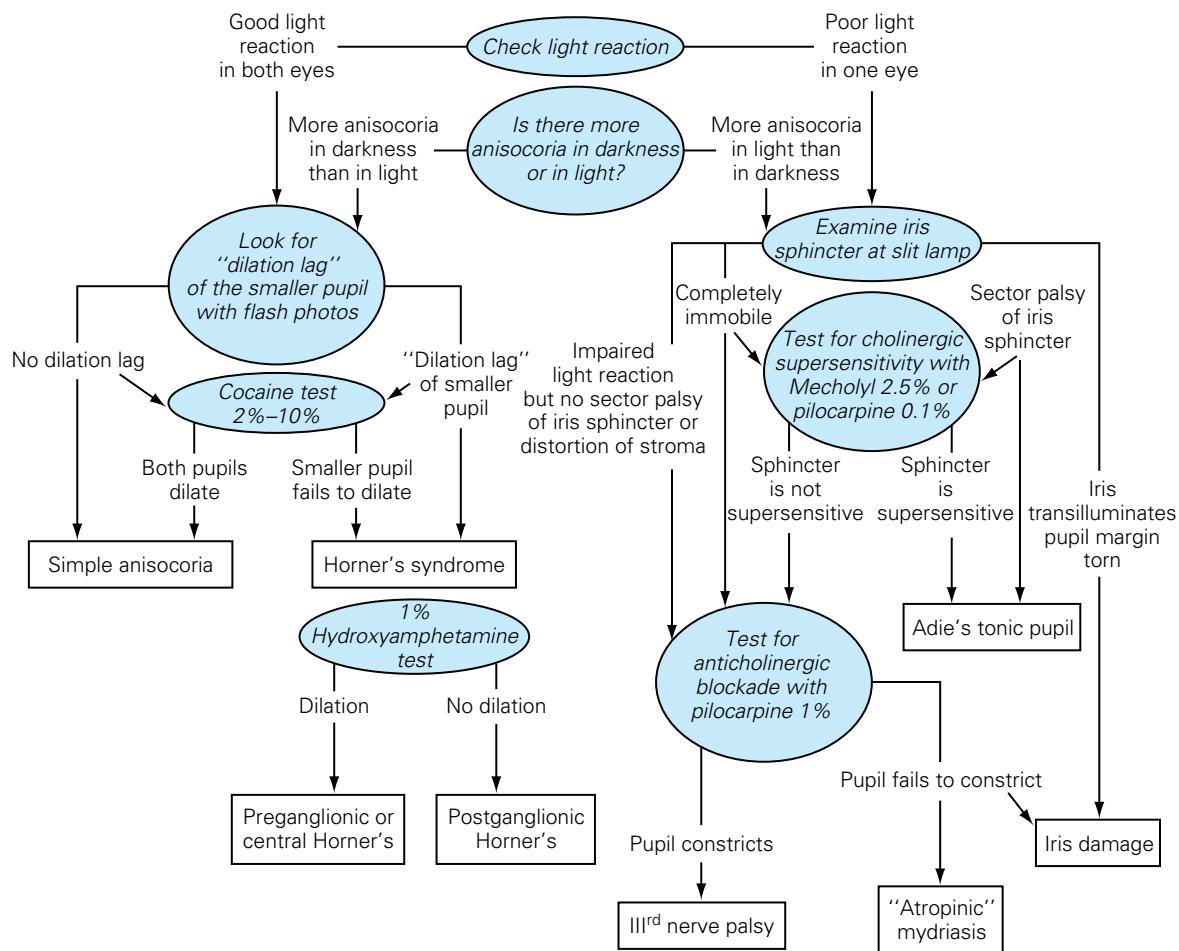

Figure 14-8. A schematic approach for sorting out the nature of anisocoria. (Reprinted by permission from Thompson and Pilley.)

been blocked by atropine or some other anticholinergic agent.

As a rule, bilateral smallness of pupils does not pose a difficult diagnostic problem. The clinical associations, acute and chronic, have already been discussed. Long-standing bilateral Adie pupils

tend to be small and show tonic near responses. They can be readily distinguished from Argyll-Robertson pupils, which constrict quickly to near (accommodation) and dilate quickly on release from the near stimulus.

Figure 14-8 is a useful schematic, devised by Thompson and Pilley, for sorting out the various types of anisocoria.

CHAPTER 15

DEAFNESS, DIZZINESS, AND DISORDERS OF EQUILIBRIUM

Hearing is one of our most precious possessions. Sounds alert us to danger; spoken words are the universal means of communication; music is one of our most exalted esthetic pleasures. The loss of this sense excludes the individual from much of what is going on, and adjustment to this deprivation imposes a profound reorientation. Prevention of deafness is a goal toward which medicine strives. Likewise, vestibular function assures one's ability to stand steadily, stabilize eye position during head movement, and move about gracefully. Hence an understanding of the functions of the eighth cranial nerves and their derangements by disease is as much the legitimate concern of the neurologist as the otologist. As a general rule, the association of vertigo and deafness signifies a disease process of the end organ or eighth nerve. The precise locus of the disease is determined by tests of labyrinthine and auditory function, described below, and by findings on neurologic examination and imaging studies that implicate the primary and secondary connections of the eighth cranial nerve.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The vestibulocochlear or eighth cranial nerve has two separate components: the cochlear nerve, which subserves hearing or acoustic function, and the vestibular nerve, which is concerned with equilibrium, or balance, and orientation of the body to the surrounding world.

The acoustic division has its cell bodies in the spiral ganglion of the cochlea. This ganglion is composed of bipolar cells, the peripheral processes of which convey auditory impulses from the specialized neuroepithelium of the inner ear, the spiral organ of Corti. This is the end organ of hearing, wherein sound is transduced into nerve impulses. It consists of approximately 15,000 neuroepithelial (hair) cells that rest on the basilar membrane, which extends along the entire 2 1/2 turns of the cochlea. Projecting from the inner surface of each hair cell are approximately 60 very fine filaments, or stereocilia, which are embedded in the tectorial membrane, a gelatinous structure overlying the organ of Corti (Fig. 15-1). Sound causes the basilar membrane to vibrate; upward displacement of the basilar membrane bends the relatively fixed stereocilia and provides a stimulus adequate for activating the hair cells. The stimulus is then transmitted to the sensory fibers of the cochlear nerve, which end synaptically at the base of each hair cell. Each afferent auditory fiber and the hair cell with which it is connected has a minimum threshold at one frequency ("characteristic" or "best" frequency). The basilar membrane vibrates at different frequencies throughout its length, according to the frequency of the sound stimulus. In this way the fibers of the cochlear nerve respond to the full range of audible sound and can differentiate and resolve complexes of sounds.

The so-called inner hair cells, numbering about 3500, are of particular importance, since they synapse with about 90 percent of the 30,000 afferent cochlear neurons. The central processes of the primary auditory neurons constitute the cochlear division of the eighth cranial nerve. In addition, the nerve contains approximately

500 efferent fibers, which arise from the superior olfactory nuclei (80 percent from the contralateral nucleus and 20 percent from the ipsilateral one) and synapse with the afferent neurons from the hair cells (Rasmussen). The function of this efferent pathway is not clear. It is thought to play some part in the auditory processing generated in the ear itself, possibly to enhance the sharpness of sound perception by some feedback mechanism (Kemp). The eighth nerve also contains adrenergic postganglionic fibers that are derived from the cervical autonomic chain and innervate the cochlea and labyrinth.

The vestibular division of the eighth nerve arises from cells in the vestibular, or Scarpa's, ganglion, which is situated in the internal auditory meatus. This ganglion is also composed of bipolar cells, the peripheral processes of which terminate in hair cells of the specialized sensory epithelium of the labyrinth (semicircular canals, saccule, and utricle). The sensory epithelium is located on hillocks (cristae) in the dilated openings or ampullae of the semicircular canals, where they are called the *cristae ampullaris*, and in the utricle and saccule, where they are called *maculae acusticae*. The hair cells of the maculae are covered by the *otolithic membrane*, or *otolith*, which is composed of calcium carbonate crystals embedded in a gelatinous matrix. The sensory cells of the cristae are covered by a sail-shaped gelatinous mass called a *cupula* (Fig. 15-1). The labyrinthine semicircular canals transduce angular movements of the head, and the otoliths transduce linear movement.

The central fibers from the cells of the spiral and vestibular ganglia are united in a common trunk, which enters the cranial cavity through the internal auditory meatus (accompanied by the facial and intermediate nerves). They traverse the cerebellopontine angle and enter the brainstem at the junction of the pons and medulla. Here the cochlear and vestibular fibers become separated. The cochlear fibers bifurcate and terminate almost at once in the dorsal and ventral cochlear nuclei. The fibers from each cochlear nucleus pursue separate crossing and ascending pathways; they pass to both inferior colliculi (mainly to the opposite side) via the lateral lemnisci. Secondary acoustic fibers project via the trapezoid body and lateral lemniscus to the medial geniculate bodies, a special component of the thalamic sensory system (Fig. 15-2). Some fibers terminate in the trapezoid body and superior olfactory complex and subserve such reflex functions as auditory attention, sound localization, auditory startle, and oculopostural orientation to sound. Both excitatory and inhibitory neurons are located at every level of these pathways. At all levels there are strong commissural connections through which auditory signals come to be represented bilaterally in the cerebrum. From the medial geniculate bodies, fibers project to the cortex via the auditory radiations—relatively compact bundles that course ventrolaterally through the posterior parts of the putamen before dispersing and ending in the *transverse gyri of Heschl* and other auditory cortical areas (Tanaka et al).

The auditory cortical field comprises the superior temporal gyrus and the upper bank of the sylvian fissure (Brodmann area 41; see page 387), or *primary auditory cortex*, and the surrounding secondary and tertiary cortices in the adjacent temporal lobe. The

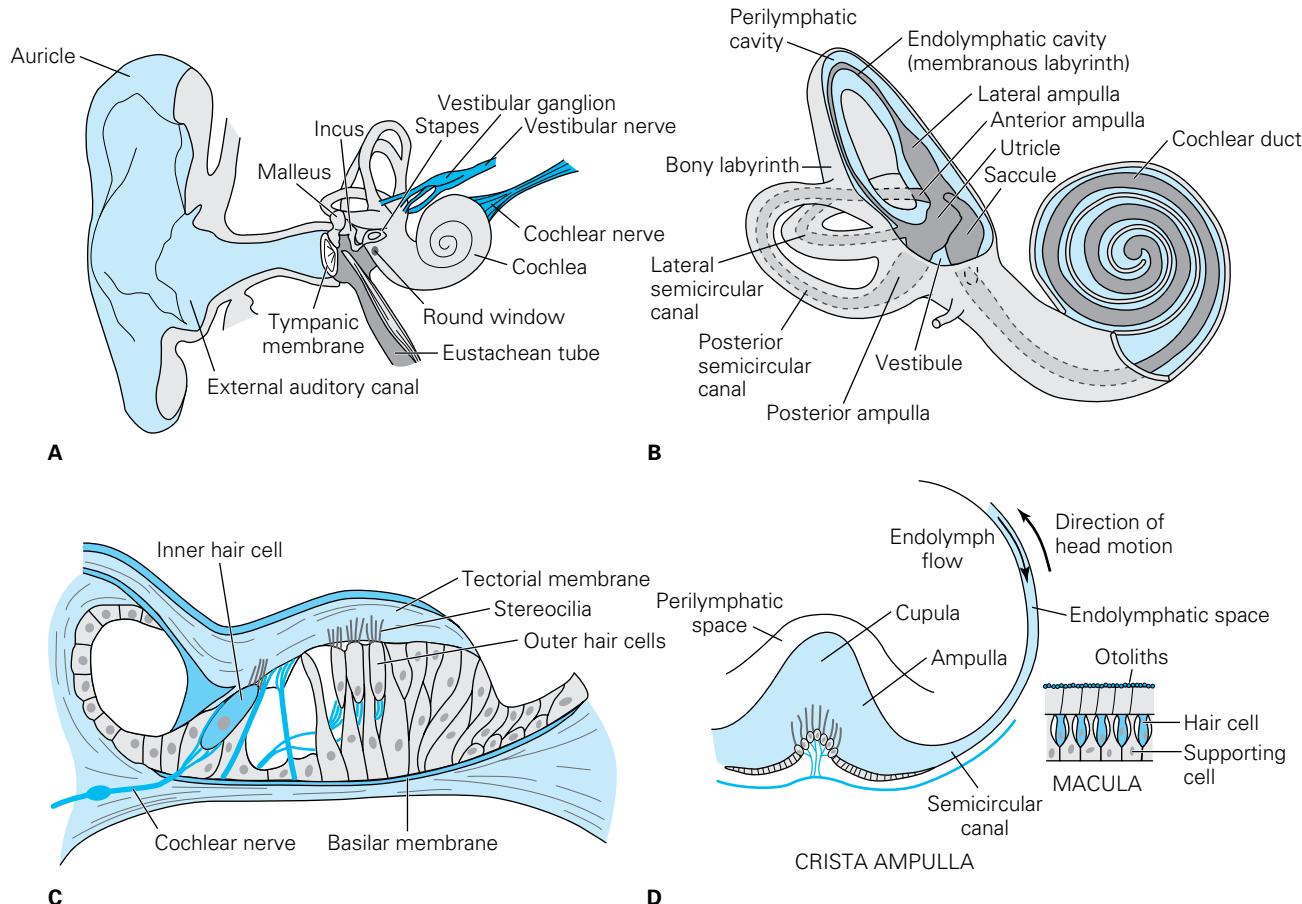

Figure 15-1. The auditory and vestibular systems. *A*, The right ear, viewed from the front, showing the external ear and auditory canal, the middle ear and its ossicles, and the inner ear. *B*, The main parts of the right inner ear, viewed from the front. The *perilymph* is located between the wall of the bony labyrinth and the membranous labyrinth. In the cochlea, the perilymphatic space takes the form of two coiled tubes—the *scala vestibuli* and *scala tympani*. The *endolymph* is located within the membranous labyrinth, which includes the three semicircular canals, utricle, and saccule. *C*, The *organ of Corti*. This is the end organ of hearing; it consists of a single row of inner hair cells and three rows of outer hair cells. The stereocilia of the hair cells are embedded in the tectorial membrane. *D*, Diagram of a crista ampulla, the specialized sensory epithelium of a semicircular canal. The crista senses the displacement of endolymph during head rotation. The direction of head rotation is indicated by the large arrow, and endolymph flow by the small arrow. The *macula* is the locus of the sensory epithelium in the utricle and saccule. Note that the tips of the hair cells are in contact with the otoliths (calcareous material), which are embedded in a gelatinous mass called the *cupula*.

latter are of particular importance in the interpretation of sound (Celesia). Bilateral temporal lobe lesions involving the geniculocortical fasciculi result in cortical deafness, although such lesions are rare; unilateral cortical lesions do not affect hearing, but defects in function such dichotic listening can be detected by specialized tests. At several levels of these ascending fiber systems, there is feedback to lower structures.

The vestibular fibers of the eighth nerve terminate in the four vestibular nuclei: superior (Bechterew), lateral (Deiters), medial (triangular, or Schwalbe), and inferior (spinal, or descending). In addition, some of the fibers from the semicircular canals project directly to the cerebellum via the juxtarestiform body and terminate in the flocculonodular lobe and adjacent vermian cortex (these structures are therefore called the “vestibulocerebellum,” as noted in Chap. 5, on the cerebellum). Efferent fibers from this portion of the cerebellar cortex, in turn, project ipsilaterally to the vestibular nuclei and to the fastigial nucleus; fibers from the fastigial nucleus project back to the

contralateral vestibular nuclei, again via the juxtarestiform body. Thus each side of the cerebellum exerts an influence on the vestibular nuclei of both sides (Fig. 15-3; see also Chap. 5).

The lateral and medial vestibular nuclei also have important connections with the spinal cord, mainly via the uncrossed lateral vestibulospinal tract and the crossed and uncrossed medial vestibulospinal tracts (Fig. 15-4). Presumably, vestibular effects on posture are mediated via these pathways—the axial muscles being acted upon predominantly by the medial vestibulospinal tract, and the limb muscles by the lateral tract. The nuclei of the third, fourth, and sixth cranial nerves come under the influence of the vestibular nuclei through the projection pathways, mainly the medial longitudinal fasciculus described in Chap. 14. In addition, all the vestibular nuclei have afferent and efferent connections with the pontine reticular formation (Fig. 15-4). The latter connections subserve vestibulo-ocular and vestibulospinal reflexes that are essential for clear vision and stable posture.

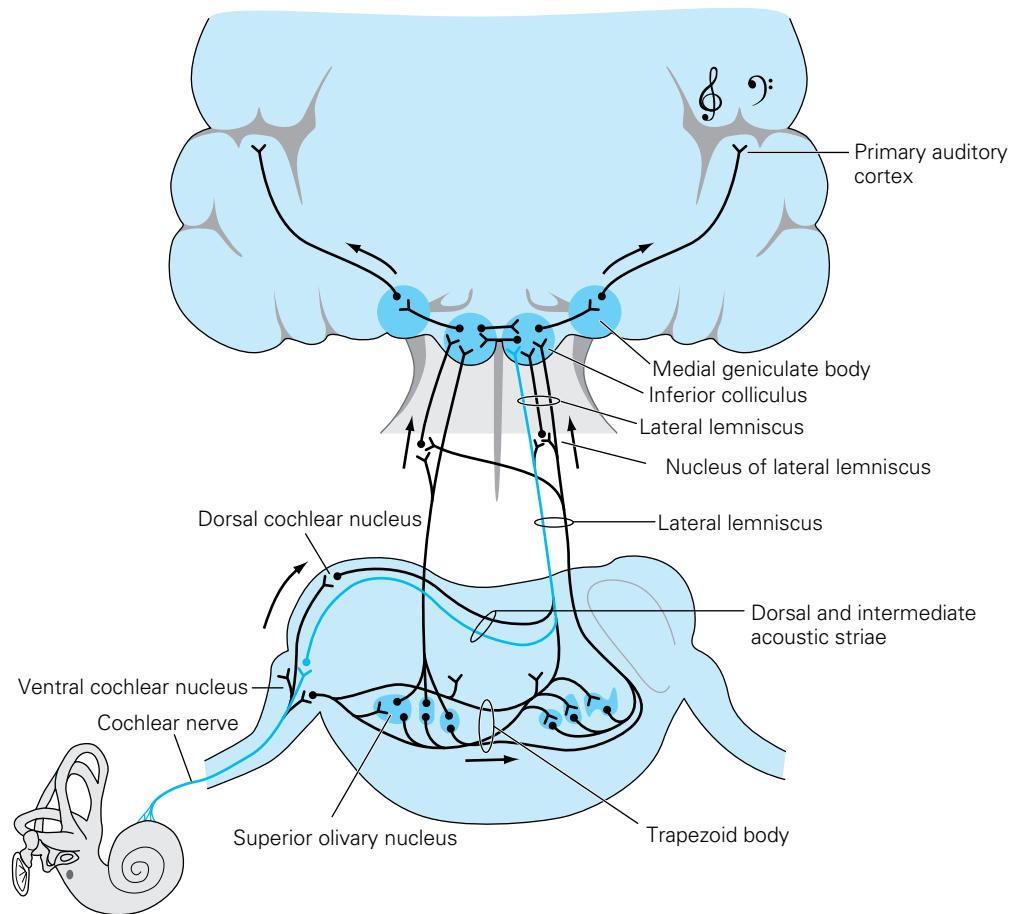

Figure 15-2. The ascending auditory pathways. The lower part of the diagram is a horizontal section through the upper medulla. (Reproduced with permission from Noback CR: The Human Nervous System, 3rd ed. New York, McGraw-Hill, 1981.)

Finally, there are projections from the vestibular nuclei to the cerebral cortex, specifically to the regions of the intraparietal sulcus and superior sylvian gyrus. In the monkey, these projections are almost exclusively contralateral, terminating near the “face area” of the first somatosensory cortex (area 2 of Brodmann). Lesions in the posterior insula impair the sense of verticality, body orientation, and movement. Whether the vestibular nuclei project to the thalamus in humans is not entirely settled; most anatomists indicate that there are no such direct connections.

These brief remarks convey some notion of the complexity of the anatomic and functional organization of the vestibular system (for a full discussion, see the monographs of Brodal and of Baloh and Honrubia). In view of the proximity of cochlear and vestibular elements, it is understandable that acoustic and vestibular functions are often affected together in the course of disease; each may also be affected separately, however.

DEAFNESS, TINNITUS, AND OTHER DISORDERS OF AUDITORY PERCEPTION

Deafness

This is a problem of immense proportions. In 1969, Konigsmark estimated that there were at least 6 million persons in the United

States with hearing loss of sufficient severity to impair the understanding of speech; there were probably three times this many with some impairment of hearing. He also noted that in about half of the affected children and about one-third of the affected adults, the deafness was on a hereditary basis. Figures from a more recent (1989) National Health Survey indicated that approximately 28 million Americans of all ages had a significant degree of deafness and that 2 million of this group were profoundly deaf. More than one-third of persons over the age of 75 were handicapped to some extent by hearing loss.

Deafness is of three general types: (1) *Conductive deafness*, due to a defect in the mechanism by which sound is transformed (amplified) and conducted to the cochlea. Disorders of the external or middle ear—obstruction of the external auditory canal by atresia or cerumen, thickening of the tympanic membrane from infection or trauma, chronic otitis media, otosclerosis (the main cause of deafness in early adult life), and obstruction of the eustachian tube—are the main causes. (2) *Sensorineural deafness* (also called *nerve deafness*), which is due to disease of the cochlea or of the cochlear division of the eighth cranial nerve. Although cochlear and eighth nerve causes of deafness have conventionally been combined in one (sensorineural) category, the neurologist recognizes that the symptoms and causes of the two are quite different and that it is more practical to think of them separately. (3) *Central deafness*, due to lesions of the cochlear nuclei and their connections

with the primary auditory receptive areas in the temporal lobes. Complete tone deafness, which is probably inherited as an autosomal dominant trait, is another central disorder.

The two peripheral forms of deafness, conductive and nerve deafness, must be distinguished from each other, since important remedial measures are available, particularly for the former. In differentiating them, the tuning-fork tests are often of value. When a vibrating fork, preferably of 512-Hz frequency, is held about 2.5 cm from the ear (test for air conduction), sound waves can be appreciated only as they are transmitted through the middle ear; they will be reduced with disease in this location. When the vibrating fork is applied to the skull (test for bone conduction), the sound waves are conveyed directly to the cochlea, without intervention of the sound-transmission apparatus of the middle ear, and will therefore not be reduced or lost in outer or middle ear disease. Normally air conduction is better than bone conduction, and the sound transmitted through the air is appreciated for about twice as long as that passing through the bone. These principles form the basis for several simple tests of auditory function.

In the *Weber test*, the vibrating fork is applied to the forehead in the midline (or to a central incisor). A normal person hears the bone-conducted sound equally in both ears. In nerve deafness, the sound is localized in the normal ear for obvious reasons; in conductive deafness, the sound is perceived as louder in the affected ear because interference from ambient sounds is muted on the affected side. In the *Rinne test*, the fork is applied to the mastoid process. At the moment the sound ceases, the fork is held at the auditory meatus. In middle ear deafness, the sound cannot be heard by air conduction after bone conduction has ceased (abnormal or negative Rinne test). In nerve deafness, the reverse is true (normal or positive Rinne test), although both air and bone conduction may be quantitatively decreased. The *Schwabach test* consists of comparing the patient's bone conduction with that of the normal examiner.

In general, early sensorineural deafness is characterized by a partial loss of perception of high-pitched sounds and conductive deafness by a partial loss of low-pitched sounds. This can be ascertained by the use of tuning forks of different frequencies but most accurately by the use of an audiometer and the construction of an audiogram, which reveals the entire range of hearing at a glance. The audiogram is the one essential test in the evaluation of hearing loss and the point of departure for subsequent diagnostic evaluation. A ticking watch or rubbing the patient's hair together near the ear can be used as a surrogate test of gross hearing for the bedside, but these maneuvers emit mostly high-frequency noise and will not detect low-frequency conductive loss.

A cochlear type of hearing loss can be recognized by the presence of the symptoms of recruitment and diplacusis. *Recruitment* refers to a heightened perception of loudness once the threshold for hearing has been exceeded; thus the common retort "You don't have to shout" when the examiner raises his voice (see below).

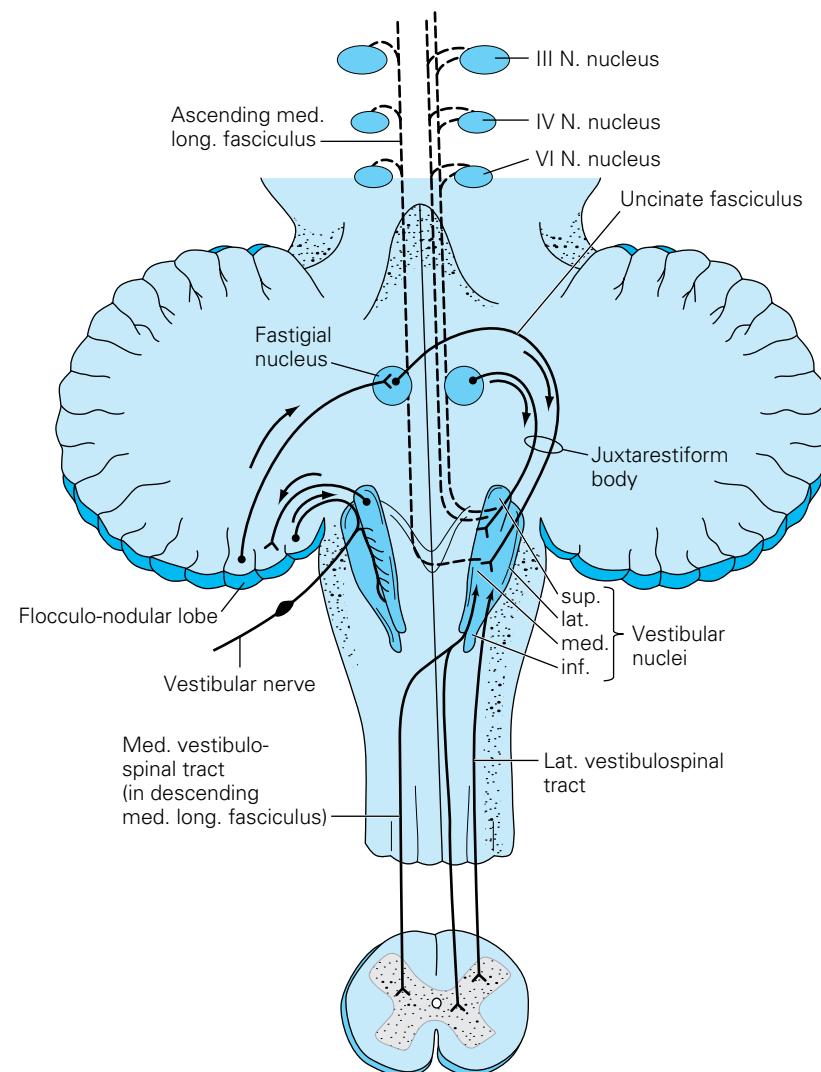

Figure 15-3. A simplified diagram of the vestibulocerebellar and vestibulospinal pathways and connections between vestibular and ocular motor nuclei. The medial longitudinal fasciculi (dotted vertical lines) are the main pathways for ascending vestibular impulses. (See text and also Fig. 14-1.)

Diplacusis refers to a defect in frequency discrimination that is manifest by a lack of clarity of spoken syllables or by the perception that music is out of tune and unpleasant (described by patients as a "mushiness" of sounds).

Since each cochlear nucleus is connected with the cortex of both temporal lobes, hearing is unaffected by unilateral cerebral lesions. Deafness due to brainstem lesions is observed only rarely, since a massive lesion is required to interrupt both the crossed and uncrossed projections from the cochlear nuclei—so massive, as a rule, that other neurologic abnormalities make the testing of hearing impossible.

The main causes of sensorineural and conductive hearing loss are discussed further on.

Special Audiologic Procedures

A number of special tests have proved to be helpful in distinguishing cochlear from retrocochlear (nerve) lesions. Although an absolute distinction cannot be made on the basis of any one test, the

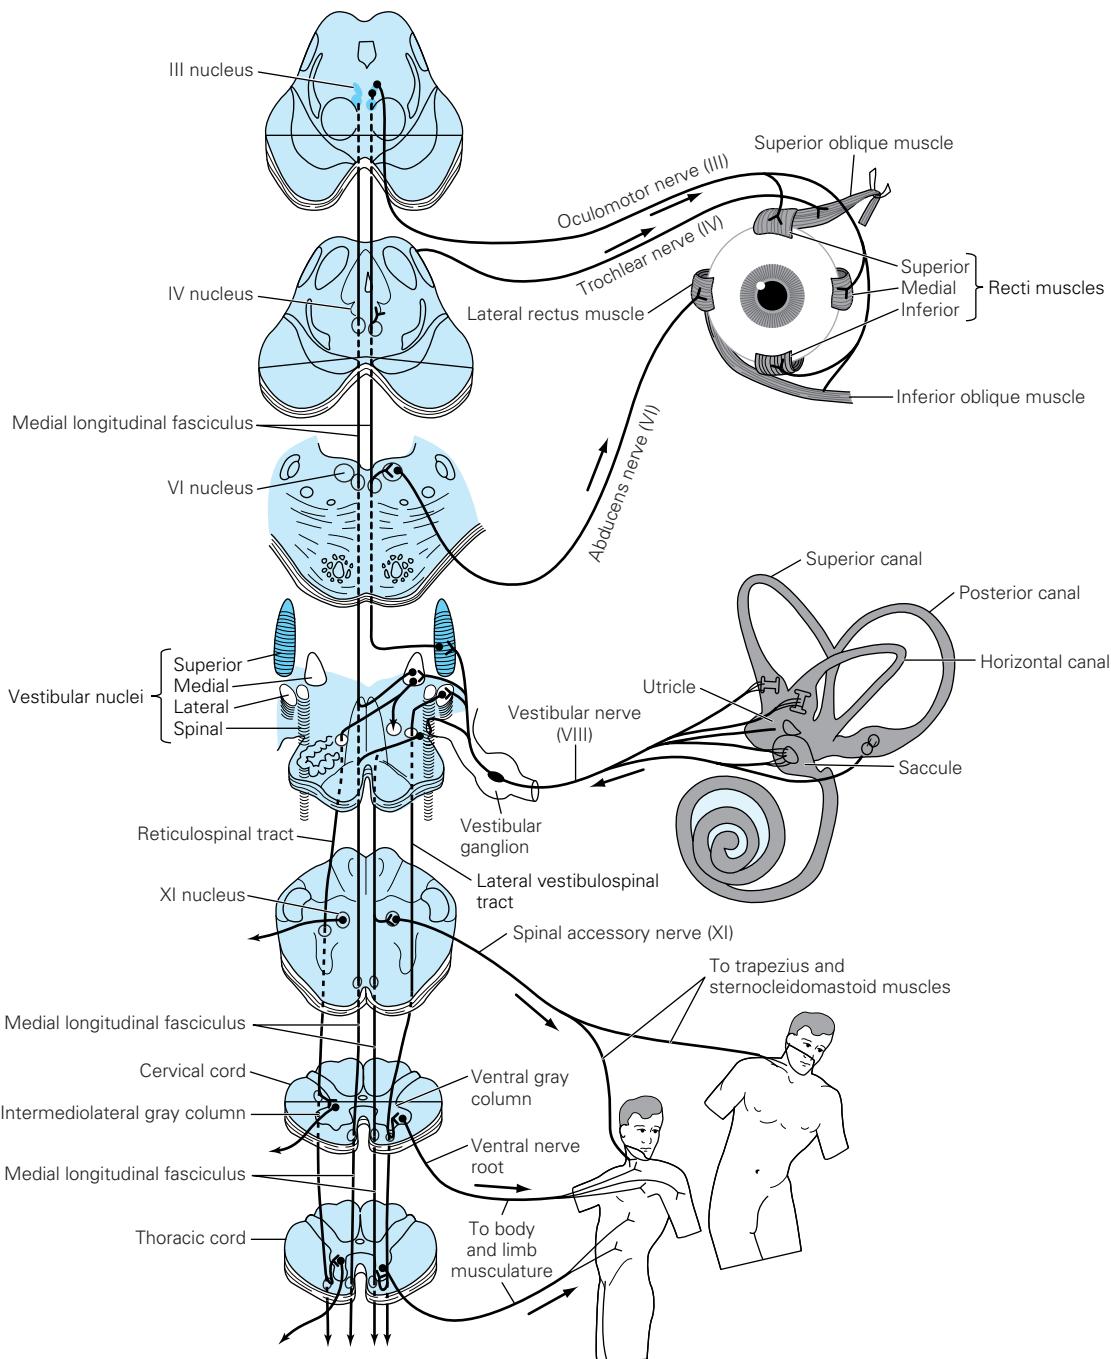

Figure 15-4. The vestibular reflex pathways. (Reproduced by permission from House EL, et al: A Systematic Approach to Neuroscience. New York, McGraw-Hill, 1979.)

results taken together (particularly loudness recruitment and threshold tone decay) make it possible to predict the site of the lesion with considerable accuracy. These tests, usually carried out by an otologist or audiologist, include the following:

1. *Loudness recruitment.* This phenomenon, mentioned above, is thought to depend on the selective destruction of low-intensity elements subserved by the external hair cells of the organ of Corti. The high-intensity elements are preserved, so that loudness is appreciated only at high intensities. In testing for loudness recruitment, the difference in hearing between the two ears is estimated and the loudness of the pure-tone stimulus of

a given frequency delivered to each ear is then increased by regular increments. In *nonrecruiting deafness* (characteristic of a nerve lesion), the original difference in hearing persists in all comparisons of loudness, since both high- and low-intensity fibers are affected. In *recruiting deafness* (which occurs with a lesion in the organ of Corti—e.g., Ménière disease), the more affected ear gains in loudness and may finally be equal to the better one. In bilateral disease, recruitment is assessed by the intensity of the stimulus that causes discomfort, about 100 dB (decibels) in normal persons.

2. *Speech discrimination.* This consists of presenting the patient with a list of 50 phonetically balanced monosyllabic words

(e.g., *thin, sin*) at suprathreshold levels. The speech-discrimination score is the percentage of the 50 words correctly repeated by the patient. Marked reduction (less than 30 percent) in the speech-discrimination scores is characteristic of eighth nerve lesions.

3. *Audiometry.* Continuous and interrupted tones are presented at various frequencies. Tracings are made, measuring the increments by which the patient must increase the volume in order to continue to hear the continuous and interrupted tones just above threshold. Analysis of many tracings has shown that there are four basic configurations, referred to as types I to IV Békésy audiograms. Types III or IV usually indicate the presence of a retrocochlear lesion, the type II response points to a lesion of the cochlea itself, and type I is considered normal.
- Related tests such as threshold tone decay and the short increment sensitivity index were formerly used to a greater extent than they are currently; therefore we have not described them in detail.
4. *Brainstem auditory evoked potentials, or response* (BAEP, or BAER; page 31). This method provides very refined information as to the integrity of primary and secondary auditory pathways from the cochlea to the superior colliculus. It has the advantage of being accurate in uncooperative and even comatose patients as well as infants who cannot cooperate with audiometry. It is of some value in detecting small acoustic neuromas; in localizing brainstem lesions such as those due to demyelination; in corroborating the state of brain death, where all waves except occasionally the eighth nerve (wave I) responses are abolished; and in assessing sensorineural damage in neonates who have had meningitis or been exposed to ototoxic medications.
5. The *acoustic-stapedial reflex* can be used as a measure of conduction in the auditory (and the facial) nerve. This reflex normally protects the cochleas from excessively loud sound. When sound of intensity greater than 70 to 90 dB above threshold hearing reaches the inner ear, the stapedius muscles on both sides contract reflexly, relaxing the tympanum and offering impedance to further sound. It may be tested by insufflating the external auditory canal with pressured air and measuring the change in pressure that follows immediately after a loud sound. The response is muted in patients with conductive hearing loss because of the mechanical restriction of ossicular movement, but otherwise the test is sensitive to cochlear and acoustic nerve lesions.

Tinnitus

This is the other major manifestation of cochlear and auditory disease. *Tinnitus aurium* literally means “ringing of the ears” (Latin *tinnire*, “to ring or jingle”) and refers to sounds originating in the ear, although they need not be ringing in character. Buzzing, humming, whistling, roaring, hissing, clicking, chirping, or pulse-like sounds are also reported. Some otologists use the term *tinnitus cerebri* to distinguish other head noises from those that arise in the ear, but the term *tinnitus* when used without qualification refers to tinnitus aurium.

Tinnitus is a remarkably common symptom, affecting more than 37 million Americans, according to Marion and Cevette. It may be defined as any sensation of sound for which there is no source outside the individual. Two basic types are recognized, *tonal* and *nontonal* (nonvibratory and vibratory, in the terminology of

Fowler). The tonal type is by far the more common and is what is meant when the unqualified term *tinnitus* is used. It is also called *subjective tinnitus*, because it can be heard only by the patient. The nontonal form is sometimes *objective*, in the sense that under certain conditions the tinnitus can be heard by the examiner as well as by the patient. In either case, whether tinnitus is produced in the inner ear or in some other part of the head and neck, sensory auditory neurons must be stimulated, for only the auditory neural pathways can transmit an impulse that will be perceived as sound.

According to a large survey conducted by Stouffer and Tyler, about one-third of patients report that persistent tinnitus is unilateral; the others experience it bilaterally or with a lateralized predominance. Many more patients have brief episodes of tinnitus and do bring the symptom to the attention of a physician; some are produced by loud noises or due to the ingestion of common drugs, such as aspirin.

Nontonal and Pulsatile Tinnitus These head noises are mechanical in origin and are conducted to the inner ear through the various hard or soft structures or the fluid or gaseous media of the body. They are not due to a primary dysfunction of the auditory neural mechanism but have their origin in the contraction of muscles of the eustachian tube, middle ear (stapedius, tensor tympani), palate (palatal myoclonus), or pharynx (muscles of deglutition) or in vascular structures near the ear. One of the most common forms of subjective tinnitus is a self-audible bruit, the source of which is the turbulent flow of blood in the large vessels of the neck or in an arteriovenous malformation or glomus jugulare tumor. The sound is pulsatile and appreciated by the patient as emanating from one side of the cranium, but it is rarely detectable by the examiner.

Other noteworthy causes of pulsatile tinnitus are pseudotumor cerebri or raised intracranial pressure of any type, in which the noise is attributed to a pressure gradient between the cranial and cervical venous structures and the resulting venous turbulence; thyroid enlargement with increased venous blood flow; intracranial aneurysm; aortic stenosis; and vascular tumors of the skull, such as histiocytosis X. In the case of a vascular tumor or a large arteriovenous malformation, the examiner may hear the bruit over the mastoid process. Obliteration of the sound by gentle compression of the jugular vein on the symptomatic side is a useful indicator of a venous origin. It has been suggested that diseases that raise the cardiac output markedly (such as severe anemia) may cause pulsatile tinnitus. A flow-related bruit—originating from fibromuscular dysplasia, atherosclerotic stenosis, carotid dissection, and enhanced blood flow in a vessel contralateral to a carotid occlusion—has also been incriminated. It should be pointed out, however, that carotid artery stenosis is in our experience a relatively uncommon cause of a self-audible bruit. In 100 consecutive cases of pulsatile tinnitus, the most common causes were found to be intracranial hypertension, glomus tumors, and carotid disease (Sismanis and Smoker). One must be cautious in overinterpreting this symptom, because normal persons can hear their pulse when lying with one ear on a pillow, and introspective individuals may become excessively worried about it. We have suggested that normal variations in the size and location of the jugular bulb may explain some cases (Adler and Ropper).

A related problem is the rhythmic clicking of palatal myoclonus caused by intermittent contraction of the tensor tympani or stapedius muscles, termed *middle ear myoclonus*. This has been treated with a variety of medications, including diazepam, or, in extremely annoying cases, by section of the offending muscles (Badia et al.). Clicking noises due to palatal myoclonus have been

successfully treated by the injection of botulinum toxin into the soft palatal tissues (Jamieson et al).

Tonal Tinnitus This form of tinnitus arises in the middle or inner ear and is associated in a proportion of patients with cochlear damage. For this reason, the first step in analysis after the clinical examination is an audiogram. Under ideal acoustic circumstances (in a soundproof room having an ambient noise level of 18 dB or less), slight tinnitus is present in 80 to 90 percent of adults ("physiologic tinnitus"). The ambient noise level in ordinary living conditions usually exceeds 35 dB and is of sufficient intensity to mask physiologic tinnitus. Tinnitus due to disease of the middle ear and auditory neural mechanisms may also be masked by environmental noise and hence becomes troublesome only in quiet surroundings—at night, in the country, etc.

Most often, subjective tinnitus signifies a disorder of the tympanic membrane, ossicles of the middle ear, inner ear, or eighth nerve. As already remarked, a majority of patients who complain of persistent tinnitus have some degree of deafness as well. Tinnitus that is localized to one ear and is described as having a tonal character (such as a ringing, bell-like, or like a high and steady musical tone) is particularly likely to be associated with an impairment of cochlear or neural function. Tinnitus associated with sensorineural hearing loss of high frequency is often described as "chirping," and that of low frequency as "whooshing" or blowing (Marion and Cevette). Tinnitus due to middle ear disease (e.g., otosclerosis) tends to be more constant than the tinnitus of sensorineural disorders; it is of variable intensity and lower pitch and is characterized by clicks, pops, and rushing sounds.

As remarked above, the pitch of tinnitus associated with a conductive hearing loss is generally of low frequency (median frequency of 490 Hz, with a range of 90 to 1450 Hz). That which accompanies sensorineural loss is higher (median frequency of 3900 Hz, with a range of 545 to 7500 Hz). This rule does not apply to Ménière disease, in which the tinnitus is usually described as a low-pitched whoosh, buzz, or roar (median frequency of 320 Hz, with a range of 90 to 900 Hz), thus resembling the tinnitus that accompanies a conductive rather than a sensorineural hearing loss (Nodar and Graham). The tinnitus of Ménière disease often fluctuates in intensity, like the hearing loss.

The mechanism of tonal tinnitus has not been established, although a number of theories have been postulated. One supposition attributes tinnitus to an overactivity or disinhibition of hair cells adjacent to a part of the cochlea that has been injured. Another postulates a decoupling of hair cells from the tectorial membrane. Yet another theory is based on the finding of an abnormal discharge pattern of afferent neurons, attributed to ephaptic transmission between nerve fibers that have been damaged by vascular compression (Møller).

Treatment Relief of unilateral tinnitus in special cases has reportedly been achieved by vascular decompression of the eighth nerve in a manner comparable to hemifacial spasm, superior oblique myokymia, and some cases of trigeminal neuralgia (Jannetta), but this approach is controversial. For most forms of tinnitus, there is little effective treatment (see the review by Lockwood and colleagues). Most patients become reconciled to its presence once the benign nature of the disorder is explained to them. It is possible to fit some patients with a special audiologic instrument, like a hearing aid, that masks the tinnitus by delivering a sound of like pitch and intensity. Also, a hearing aid that improves audition may suppress or diminish tinnitus. Drugs such as anticonvulsants and tocainide

hydrochloride have not been helpful in our experience. Auditory masking devices are helpful to some patients; these individuals can be identified during the audiogram as improved with the application of superimposed tones. If bilateral tinnitus is the basis of persistent complaints, one often discovers that the patient is anxious or depressed, in which case a careful history will reveal the other symptoms of the psychiatric illness. Treatment then must be directed to the psychiatric symptoms. In their review, Lockwood and colleagues suggest that all patients with undifferentiated tinnitus be protected from loud sounds and ototoxic drugs (the main ones being aminoglycoside antibiotics, certain loop diuretics, neurotoxic chemotherapies such as cisplatin, and perhaps high doses of aspirin). These potentially damaging drugs are listed at www.hearusa.com. Also, the American Tinnitus Association website may be helpful to some patients as a source of reassurance (www.ata.org).

Tinnitus that is unilateral, pulsatile, or fluctuating and associated with vertigo must be investigated by appropriate neurologic and audiologic studies.

Other Disorders of Auditory Perception

On occasion, pontine lesions may be accompanied by complex auditory illusions, sometimes with the qualities of true hallucinations (*pontine auditory hallucinosis*) as in the three patients described by Cascino and Adams. These consist of alternating musical tones, like those of an organ; a jumble of sound, like a symphony orchestra tuning up; or siren-like or buzzing sounds, like a swarm of bees. These auditory sense disturbances are more complex than neurosensory tinnitus but less formed than temporal lobe hallucinations. They are usually associated with impairment of hearing in one or both ears and other neurologic signs related to the pontine lesion. An unpleasant degree of hyperacusis in the contralateral ear has also been reported with upper pontine tegmental lesions. BAEPs reveal intact cochlear, auditory nerve, and cochlear nuclear responses. As in the case of peduncular visual hallucinosis, patients realize that the sounds are unreal, i.e., they have insight into their illusory nature.

Another well-recognized but inexplicable type of auditory hallucinosis occurs in aged patients with long-standing neurosensory deafness. All day long, or for several hours at a time, they hear songs, symphonies, choral music, or familiar or unfamiliar melodies interrupted only by other ambient noise, sleep, or conversations that engage their attention. Our cases, like those reported by Hammeke and colleagues, have been neither depressed nor demented, and anticonvulsant and antipsychotic drugs had no effect. Activation of the right auditory cortex on single-photon emission tomography (SPECT) and magnetoencephalography has been reported in such a case by Kasai et al. The problem is analogous to the one of Charles Bonnet syndrome, in which elderly individuals with failing vision experience rich visual hallucinations (page 405). We find it puzzling that pontine lesions are implicated in some cases, as mentioned above.

Complex auditory hallucinations may occur as part of temporal lobe seizures arising from a variety of temporal lobe lesions. Conversely, seizures may be induced by musical sounds as well as by other auditory stimuli. These topics are discussed in Chaps. 16 and 22. Paracusis, a condition in which a sound, tune, or voice is repeated for several seconds, is also a cerebral auditory phenomenon, similar in a sense to the visual phenomenon of palinopsia. The precise anatomy is unknown. The auditory hallucinations of schizophrenia have been extensively studied in relation to activity of the temporal lobes as discussed in Chap. 58.

Causes of Middle Ear Deafness

The common causes are otosclerosis, otitis media, and trauma. Of the various types of progressive conductive deafness, otosclerosis is the most frequent, being the cause of about half the cases of bilateral (but not necessarily symmetrical) deafness that have their onset in early adult life, usually in the second or third decade. A predilection to otosclerosis is transmitted as an autosomal dominant trait with variable penetrance. Pathologically, it is characterized by an overgrowth of labyrinthine capsular bone around the oval window, leading to progressive fixation of the stapes. The remarkable advances in micro-otologic surgery, designed to mobilize or replace the stapes and to reconstruct the ossicular chain, have greatly altered the prognosis in this disease; significant improvement in hearing can now be achieved in the majority of such patients.

The use of antibiotic drugs has markedly reduced the incidence of suppurative otitis media, both the acute and chronic forms, which in former years were common causes of conductive hearing loss. Repeated attacks of serous otitis media are, however, still an important cause of this type of deafness.

Fractures of the temporal bone, particularly those in the long axis of the petrous pyramid, may damage middle ear structures; frequently there is bleeding into the middle ear as well, and a ruptured tympanic membrane. Transverse fractures through the petrous pyramid are more likely to damage both the cochlear-labyrinthine structures and the facial nerve. Other diseases of the temporal bone—such as Paget disease, fibrous dysplasia, and osteopetrosis—may impair hearing by compression of the cochlear nerve.

Causes of Sensorineural Deafness

This has many causes. Explosions or intense, sustained noise in certain industrial settings or from gun blasts or even rock music may result in a high-tone sensorineural hearing loss. Certain antimicrobial drugs (namely, the aminoglycoside group and vancomycin) damage cochlear hair cells and, after prolonged use, can result in severe hearing loss. If these drugs have been used to treat bacterial meningitis, it may be difficult to determine whether the antibiotic or the infection is the cause. A variety of other commonly used drugs are ototoxic, usually in a dose-dependent fashion (see Nadol). Quinine and acetylsalicylic acid may impair sensorineural function transiently. The common high-frequency sensorineural type of hearing loss in the aged (presbycusis) is probably due to neuronal degeneration, i.e., progressive loss of spiral ganglion neurons (Suga and Lindsay).

The cochlea of a neonate may have been damaged in utero by rubella in the pregnant mother. Mumps, acute purulent meningitis (particularly from *Pneumococcus* and *Haemophilus*), or chronic infection spreading from the middle to the inner ear may cause nerve deafness in childhood. The meningeal infection spreads along the cochlear aqueduct, a structure that connects the cerebrospinal fluid (CSF) space with the perilymph of the cochlea. Measles vaccination, *Mycoplasma pneumoniae* infection, and scarlet fever are sometimes associated with acute deafness with or without vestibular symptoms. It is uncertain whether the deafness in these cases is due to direct infection or represents an autoimmune reaction directed to the inner ear. Also, the inner ear contains melanocytes, and their involvement in Vogt-Koyanagi-Harada disease adds dysacusis, tinnitus, and sensorineural deafness to the usual manifestations of vitiligo of the eyebrows, iridocyclitis, retinal depigmentation, and recurrent meningitis. Meningeal hemosiderosis, a rare process that results from repeated bouts of subarachnoid hemor-

rhage, also causes eighth nerve damage and deafness, presumably as a toxic effect of iron deposition in the meninges.

Episodic deafness in one ear, even without vertigo, proves in most instances to be *Ménière disease* (see further on). Of equal concern to neurologists is the onset in an adult of sudden and permanent unilateral hearing loss without vertigo. Little is known about the pathogenesis of this syndrome. A vascular causation (occlusion of the auditory artery or its cochlear branch or presumed arterial spasm in the course of migraine) has been postulated, on uncertain grounds. We do not know how to interpret the findings of DeFelice and colleagues as well as others, who report that the posterior communicating arteries are absent in a disproportionate number of patients with sudden hearing loss. A few cases have complicated herpes zoster and mumps parotitis, but aside from these there is no proven relationship to the usual viral respiratory infections. In a prospective study of 88 cases of acute sensorineural hearing loss, two-thirds recovered their hearing completely within a few days or a week or two (Mattox and Simmons). In the remaining patients, recovery was much slower and often incomplete; in this latter group, the hearing loss was predominantly for high tones and in some cases was associated with varying degrees of vertigo and hypoactive caloric responses.

The *sudden onset of bilateral sensorineural hearing loss* has been reported to follow cardiopulmonary bypass surgery and has been ascribed to microemboli. Less often, such an event follows general anesthesia for nonotologic surgery (Evan et al); the pathogenesis is quite obscure. None of the currently popular therapeutic agents—such as histamine, calcium channel blockers, anticoagulants, carbogen inhalation, and steroids—seem to affect the outcome of sudden unilateral or bilateral deafness without vertigo. Nonetheless, corticosteroids are often prescribed.

Otolologists have described a progressive sensorineural type of hearing loss as a late manifestation of congenital syphilis, allegedly occurring despite prior treatment with adequate doses of penicillin. It has been claimed that the long-term administration of steroids may be useful in such cases. The pathologic basis of the hearing loss has not been determined and the causal relationship to congenital syphilis remains to be established.

The *auditory nerve* may be involved by tumors of the cerebellopontine angle or by mycotic, lymphomatous, carcinomatous, tuberculous, or other types of chronic meningitis and rarely in sarcoidosis. Lymphomatous meningitis has a particular predilection to cause unilateral hearing loss; we have seen several such cases in which no other cranial nerves were infiltrated. Carcinomatous meningitis may do the same but almost always in the context of other cranial and spinal nerve palsies (see Chap. 31). Of the solid tumors, the ones that involve the auditory nerve most frequently are schwannomas, neurofibromas, meningiomas, dermoids, and metastatic carcinoma. In central neurofibromatosis (type II), the involvement by acoustic neuromas is often bilateral. Unilateral deafness may also result from demyelinative plaques, infarction, or tumor involving the cochlear nerve fibers or nuclei in the brainstem. Rarely, deafness is the result of bilateral lesions of the temporal lobes (Chap. 22). The condition called *pure word deafness* is also due to left temporal lobe disease; despite normal pure-tone perception and audiometry and normal brainstem auditory evoked potentials, spoken words cannot be understood. This condition is discussed in Chap. 23.

Hereditary Deafness (Table 15-1) A large number of *genetically determined syndromes* that feature a neural or conductive type of deafness—some congenital and others having their onset in childhood or early adult life—have come to light (see articles by Tekin

Table 15-1
Representative genetic forms of hearing loss

DESIGNATION	INHERITANCE	GENE DEFECT	TYPE OF HEARING LOSS	ASSOCIATED DEFECTS	FREQUENCY
I. Nonsyndromic					
DFN A	AD	GJB2 (connexin), MYO7, USH, SLC26A4, and allelic variants of these genes; GJB2 accounts for half of cases in most populations (AD)	Progressive sensorineural	Same loci as cause syndromic hearing loss such as Usher and Pendred syndromes, as noted below; 80% of hereditary deafness from recessive gene	Accounts for half of nonsyndromic recessive deafness (connexin)
DFN B	AR (most common)				
DFN X	X-linked				
<i>Familial otosclerosis</i>	AD with reduced penetrance	COL1A1	Conductive	Dystopic canthus, heterochromia, iritis, ptosis	
II. Syndromic					
Waardenburg	AD	PAX3 and some due to SOX, WSIV (transcription factors)	Variable sensorineural	Dystopia, heterochromia, iritis, ptosis	Most common dominant syndromic hearing loss; accounts for 3% of childhood hearing loss
Type I					
Type II				Same as type I but no dystopia Upper limb defects	
Type III				Pigmentary defects and Hirschsprung disease	
Type IV				Second most common form of hearing loss. Brachial cleft cysts, cleft palate, malformations of external ear and of kidney	2%
Brachio-oto-renal syndrome	AD	EDN (receptors in endothelin pathways) EYA1 in half (transcription factor involved in development of inner ear and kidney)	Conductive (75%), sensorineural and mixed	Cleft palate, epiphysseal dysplasia; severe myopia and retinal detachment in types 1 and 3	
Stickler	AD	STL 1–3	Progressive sensorineural hearing loss		
Neurofibromatosis type 2	AD	NF 2	Acoustic neuromas	Evident on MRI; proclivity to other tumors	

Usher Type I	AR	USH genes (unconventional myosin and adhesion molecules)	Severe congenital sensorineural hearing loss, vestibular dysfunction; retinitis pigmentosa after first decade; type 1 has abnormal vestibular function	Most common recessive types; 3–6%
Type 2				
Pendred	AR	SLC13A4 in half (same mutation causes nonsyndromic hearing loss)	Profound congenital sensorineural hearing loss; abnormal bony labyrinth (Mondini dysplasia)	4%
Jervell and Lange-Nielsen Refsum	AR	KVQT, KCNE (delayed potassium rectifier inner ear)	Congenital deafness	<1%
Alport	X-linked	X-linked in 85% but also autosomal dominant and recessive forms (basement membrane formation in cochlea, eye, and kidney)	Progressive sensorineural hearing loss	Glomerulonephritis and renal failure 1%
Mohr-Tranebjerg	X-linked	TIMMBA (a translocation protein from cytosol to mitochondria)	Progressive childhood deafness	Visual disability, dystonia, mild retardation
Kearns-Sayre	Mitochondrial	MTRNT 1 at 3243 site and MTTS 1 of mitochondrial genome	Late-onset progressive sensorineural hearing loss	Diabetes, other features typically associated with mitochondrial mutations—see Chap. 37
Bartter IV		BSND; Cl ⁻ channel	Congenital, severe	Salt wasting

Key: AD, autosomal dominant; AR, autosomal recessive.

and colleagues and Gorlin). The majority of cases of congenital deafness are inherited as an autosomal recessive trait with no other syndromic features. In most of the remainder, inheritance is autosomal dominant in type and in a small number it is sex-linked.

The singular advance in this field has been the identification in recessive nonsyndromic deafness of a mutation of the connexin-26 gene on chromosome 13 (designated GJB2). This mutation is found in half of recessive familial cases of pure deafness and, what is more striking, the same gene abnormality occurs in 37 percent of cases of ostensibly sporadic congenital deafness (Estivill et al, and Morell et al). The connexin protein is a component of gap junctions, and the mutation is theorized to interfere with the recycling of potassium from the cochlear hair cells to the endolymph. As a result of the human genome project, over 20 other gene loci have been detected that may be related to congenital deafness syndromes; these are summarized by Tekin and colleagues. But none except the one for connexin account for more than a very small proportion of cases. These unattached types of congenital deafness are denominated by genes called DFN; for example, the connexin mutation is in DFNB1. The genetic errors involve either cytoskeletal or structural proteins of the organ of Corti or the ion channel apparatus.

It should also be remarked that deafness is a component of over 400 different genetic syndromes (e.g., Waardenburg, brachio-oto-renal, Stickler, Pendred, Usher, Alport, Bartter, among many others listed in the table and those omitted because of their rarity). Here, the finding of a mutation in a gene called PAX3 in the Waardenburg syndrome in the early 1990s began a flood of other gene defects underlying the many disorders that had been described on clinical grounds over the previous century. The gene errors that give rise to some of these diseases, particularly the Usher syndrome, may also cause non-syndromic congenital deafness. The syndromic forms of genetic deafness have been classified largely on the basis of their associated defects: retinitis pigmentosa, malformations of the external ear; integumentary abnormalities such as hyperkeratosis, hyperplasia or scantiness of eyebrows, albinism, large hyperpigmented or hypopigmented areas, ocular abnormalities such as hypertelorism, severe myopia, optic atrophy, and congenital and juvenile cataracts, and mental deficiency; skeletal abnormalities; and renal, thyroid, or cardiac abnormalities. Deafness is also a feature of several mitochondrial disorders, particularly the Kearns-Sayre syndrome and occasionally the MELAS syndrome (page 844). (It is of interest that the ototoxic effect of aminoglycoside antibiotics is probably effected by mitochondrial dysfunction) The Wolfram syndrome can have either a nuclear or mitochondrial genetic origin. This and the other main hereditary syndromes are summarized in Table 15-1. The mitochondrial causes of deafness have been summarized by Chinnery et al. The association of neurosensory deafness with degenerative neurologic disease is discussed further in Chaps. 37 and 39.

Also to be mentioned as differing from the degenerations are a group of acoustic aplasias. Four types of inner ear aplasia have been described: (1) *Michel defect*, a complete absence of the otic capsule and eighth nerve; (2) *Mondini defect*, an incomplete development of the bony and membranous labyrinths and the spiral ganglion; (3) *Scheibe defect*, a membranous cochleosaccular dysplasia with atrophy of the vestibular and cochlear nerves; and (4) rare chromosomal aberrations (trisomies) characterized by abnormality of the end organ and absence of the spiral ganglion.

Hysterical Deafness

It is possible to distinguish hysterical and feigned deafness from that due to structural disease in several ways. In the case of bilateral deafness, the distinction can be made by observing a blink (cochleo-orbicular reflex) or an alteration in skin sweating (psychogalvanic skin reflex) in response to loud sound. Unilateral hysterical deafness may be detected by an audiometer, with both ears connected, or by whispering into the bell of a stethoscope attached to the patient's ears, closing first one and then the other tube without the patient's knowledge. The elicitation of the first several waves of the brainstem auditory evoked potentials provides indisputable evidence that sounds are reaching the receptive auditory structures and that the patient should be capable of hearing sounds. It should be kept in mind that a brief episode of deafness with fully preserved consciousness may rarely be caused by seizure activity in one temporal lobe (epileptic suppression of hearing).

DIZZINESS AND VERTIGO

Dizziness and other sensations of imbalance are, along with headache, back pain, and fatigue, the most frequent complaints among medical outpatients (Kroenke and Mangelsdorff). The significance of these complaints varies greatly. For the most part they are benign, but always there is the possibility that they signal the presence of an important neurologic disorder. Diagnosis of the underlying disease demands that the complaint of dizziness be analyzed correctly—the nature of the disturbance of function being determined first and then its anatomic localization. This classic approach to neurologic diagnosis is nowhere more valuable than in the patient whose main complaint is dizziness.

The term *dizziness* is applied by the patient to a number of different sensory experiences—a feeling of rotation or whirling as well as nonrotatory swaying, weakness, faintness, light-headedness, or unsteadiness. Blurring of vision, feelings of unreality, syncope, and even petit mal or other seizure phenomena may be called “dizzy spells.” Hence a close questioning of the patient as to how he is using the term becomes a necessary first step in clinical study. Essentially, the physician must determine whether the symptoms have the specific qualities of vertigo—which in this chapter refers to all subjective and objective illusions of motion or position—or whether they are more properly categorized as light-headedness or nonrotatory pseudovertigo. The distinction between these two groups of symptoms is elaborated after a brief discussion of the factors involved in the maintenance of equilibrium.

Physiologic Considerations

Several mechanisms are responsible for the maintenance of a balanced posture and for awareness of the position of the body in relation to its surroundings. Continuous afferent impulses from the eyes, labyrinths, muscles, and joints inform us of the position of different parts of the body. In response to these impulses, the adaptive movements necessary to maintain equilibrium are carried out. Normally we are unaware of these adjustments, since they operate largely at a reflex level. The most important of the afferent impulses are the following:

1. Visual impulses from the retinae and possibly proprioceptive ones from the ocular muscles, which enable us to judge the distance of objects from the body. This information is coor-

- dinated with sensory information from the labyrinths and neck (see below) to stabilize gaze during movements of the head and body.
2. Impulses from the labyrinths, which function as highly specialized spatial proprioceptors and register changes in the velocity of motion (either acceleration or deceleration) and position of the body. The cristae of the three semicircular canals sense angular acceleration of the head (side-to-side or rotary), and the maculae of the saccule and utricle sense linear acceleration and gravity. In each of these structures, displacement of sensory hair cells is the effective stimulus. In the semicircular canals, this is accomplished by movement of the endolymphatic fluid, which, in turn, is induced by rotation of the head and results in an illusion of rotation. In the utricle and saccule, the hairs are displaced in response to the force of gravity on the otoliths, giving rise to a sensation of linear displacement or tilt. In either case, the movement generates an electrical charge in the hair cells, causing depolarization of the nerve terminals and thereby initiating impulses in the vestibular nerve, with the production of two main reflex responses: the vestibulo-ocular, which stabilizes the eyes, and the vestibulospinal, which stabilizes the position of the head and body.
 3. Impulses from the proprioceptors of the joints and muscles are essential to all reflex, postural, and volitional movements. Those from the neck are of special importance in relating the position of the head to the rest of the body. The sense organs listed above are connected with the cerebellum and with certain ganglionic centers and pathways in the brainstem, particularly the vestibular nuclei, and, via the medial longitudinal fasciculi, with the ocular motor nuclei. These cerebellar and brainstem structures are the important coordinators of the sensory data and provide for postural adjustments and the maintenance of equilibrium. They are the basis of what is called the “space constancy mechanisms,” whereby the perceptions of one’s self (the body schema) and one’s surroundings (the environmental schema) are matched. Conversely, any disease that disrupts these neural mechanisms may give rise to vertigo and disequilibrium. The interdependence of the two schemata (self and environment) is ascribed to the fact that the various sense organs—retinal, labyrinthine, and proprioceptive—are usually activated simultaneously by any body movement. Through a process of learning, we come to see objects as stationary while we are moving and moving objects as having motion when we are either moving or stationary. At times, especially when our own sensory information is incomplete, we mistake movement of our surroundings for movements of our own body. A well-known example is the feeling of movement that one experiences in a stationary train when a neighboring train is moving. In this frame of reference, the orientation of the body to its surroundings depends on the maintenance of an orderly relationship between the bodily schema and the schema of the surround; as a result, disorientation in space, or disequilibrium, occurs when this relationship is upset.

Yet another factor that influences equilibrium is the effect of aging (pages 106 and 521). Old people may lose their balance on extending the neck, and their peripheral sensory afferents are often impaired, as are the protective postural mechanisms, making falls more frequent. A destructive lesion of one or both labyrinths may

leave an elderly person permanently unbalanced, while a younger person compensates for the loss.

Clinical Characteristics of Vertigo and Giddiness (Pseudovertigo)

Vertigo A careful history and physical examination usually affords the basis for separating true vertigo from the dizziness of the anxious patient and from the other types of pseudovertigo. The recognition of vertigo is not difficult when the patient states that objects in the environment have spun around or moved rhythmically in one direction or that a sensation of whirling of the head and body was experienced. (A distinction is sometimes drawn between subjective vertigo, meaning a sense of turning of one’s body, and objective vertigo, an illusion of movement of the environment, but its significance is doubtful.) Often, however, the patient is not so explicit. The feeling may be described as a to-and-fro or up-and-down movement of the body, usually of the head, or the patient may compare the feeling to that imparted by the pitch and roll of a ship. Or the floor or walls may seem to tilt or to sink or rise up. In walking, the patient may have felt unsteady and veered to one side, or may have had a sensation of leaning or being pulled to the ground or to one side or another (a static tilt), as though being drawn by a strong magnet. This feeling of impulsion, or “pulsion,” is particularly characteristic of vertigo. Oscillopsia, an illusory movement of the environment, is another effect of vestibular disorder, especially if induced by movement of the head. Observant patients may actually note this rhythmic movement of the environment due to nystagmus.

Some patients may be able to identify their symptoms only when asked to compare them with the feeling of movement they experience when they come to a halt after rapid rotation. If the patient is unobservant or imprecise in his descriptions, a helpful tactic is to provoke a number of dissimilar sensations by rotating him rapidly, irrigating his ears with warm and cold water, and then asking him to stoop for a minute and straighten up; having him stand relaxed for 3 min and checking his blood pressure for orthostatic effect; and particularly, having him hyperventilate for 3 min. Should the patient be unable to distinguish among these several types of induced dizziness or to ascertain the similarity of one of the types to his own condition, the history is probably too inaccurate for purposes of diagnosis.

When the patient’s symptoms are mild or poorly described, small items of the history—a desire to keep still and a disinclination to stoop or walk during an attack, a tendency to list to one side, an aggravation of symptoms by turning over in bed or closing his eyes, a sense of imbalance when making a quick turn on foot or in a car, and a preference for one position of the body or head—help to identify them as vertigo. At the other end of the scale are attacks of such abruptness and severity as to virtually throw the patient to the ground. Independently occurring vertiginous attacks of the usual variety mark these falling episodes as part of Ménière disease (see further on). On the other hand, a dizzy sensation that is not made worse markedly by vigorous shaking of the head is unlikely to relate to vertigo.

All but the mildest forms of vertigo are accompanied by some degree of nausea, vomiting, pallor, perspiration, and some difficulty with walking. The patient may simply be disinclined to walk or may walk unsteadily and veer to one side, or he may be unable to walk at all if the vertigo is intense. Forced to lie down, the patient realizes that one position, usually on one side with eyes closed,

reduces the vertigo and nausea, and that the slightest motion of the head aggravates them. One common form of vertigo, benign positional vertigo (see further on), occurs only with the repositioning that accompanies lying down, sitting up, or turning. The source of the gait ataxia associated with vertigo (vertiginous ataxia) is recognized by the patient as being "in the head," not in the control of the legs and trunk. It is noteworthy that the coordination of individual movements of the limbs is not impaired in these circumstances—a point of difference from most instances of cerebellar disease. Loss of consciousness as part of a vertiginous attack nearly always signifies another type of disorder (seizure or faint).

Pseudovertigo To be distinguished from true vertigo are symptoms of *giddiness and other types of pseudovertigo*. The patient, who may complain only of dizziness, will, on closer questioning, describe his symptoms as a feeling of swaying, light-headedness, a swimming sensation, or, less often, a feeling of uncertainty or imbalance, "walking on air," faintness, or some other unnatural sensation in the head. These sensory experiences are particularly common in states characterized by anxiety or panic attacks—namely, anxiety neurosis, hysteria, and depression. They are in part reproduced by hyperventilation, and then it may be appreciated that varying degrees of apprehension, palpitation, breathlessness, trembling, and sweating are concurrent.

This constellation of nonvertiginous symptoms has been loosely referred to as "phobic," "functional," and "psychogenic" vertigo. Every clinician encounters numerous such cases. In Brandt's extensive experience, phobic vertigo was second only to benign positional vertigo (described below) as a cause of consultation in his vertigo clinic. He relates the disorder to anxiety and panic spells but finds that it exists more often as an independent entity that is subject to improvement after careful explanation and reassurance. We agree with Furman and Jacobs that the term *psychiatric dizziness*, if used at all, should be restricted to dizziness that occurs as part of a recognized psychiatric syndrome, notably anxiety disorder. There seems to be little point in dignifying the nonvertiginous symptoms with separate designations based on the settings in which they commonly occur ("supermarket syndrome," "motorist disorientation syndrome," "phobic postural vertigo," "street neurosis," etc.), but they do emphasize the psychogenic nature. Furman and Jacobs have related psychiatric dizziness to minor degrees of vestibular dysfunction, but we have not found it possible to determine whether there is a genuine labyrinthine disorder in all of these patients.

Oculomotor disorders, such as ophthalmoplegia with diplopia of abrupt onset, may be a source of spatial disorientation and brief sensations of vertigo, mild nausea, and staggering. These symptoms are maximal when the patient looks in the direction of action of the paralyzed muscle; it is attributable to the receipt of two conflicting visual images. Some normal persons may experience such symptoms for brief periods when first adjusting to bifocal glasses. In a peculiar symptom called the *Tullio phenomenon*, a loud sound or, rarely, yawning produces a brief sensation of vertigo or tilting of the environment. Some patients with this symptom are found to have an absence or thinning of the bony roof of the superior semicircular canal (this is detected by fine-cut CT scans). Occasionally, patients with Ménière disease report this symptom.

Other pseudovertiginous symptoms are less definite. In severe anemic states, particularly pernicious anemia, and in aortic stenosis, easy fatigability and languor may be attended by light-headedness, related particularly to postural change and exertion. In the

emphysematous patient, physical effort may be associated with weakness and peculiar cephalic sensations, and violent paroxysms of coughing may lead to giddiness and even fainting (tussive syncope) because of impaired venous return to the heart. The dizziness that often accompanies hypertension is difficult to evaluate; sometimes it is an expression of anxiety, or it may conceivably be due to an unstable adjustment of cerebral blood flow. Postural dizziness is another state in which unstable vasomotor reflexes prevent a constant cerebral circulation; it is notably frequent in persons with primary orthostatic hypotension and in those taking antihypertensive drugs, as well as in patients with a polyneuropathy that has an autonomic component. Such persons, on rising abruptly from a recumbent or sitting position, experience a swaying type of dizziness, dimming of vision, and spots before the eyes that last for several seconds. The patient is forced to stand still and steady himself by holding onto a nearby object. Occasionally, a syncopal attack may occur at this time (see Chap. 18). Hypoglycemia gives rise to another form of pseudovertigo, marked by a sense of hunger and attended by trembling, sweating, and other autonomic symptoms. Drug intoxication—particularly with alcohol, sedatives, and anticonvulsants—may induce a nonspecific dizziness and, at advanced stages of intoxication, true vertigo.

In practice, it is usually not difficult to separate these types of pseudovertigo from true vertigo, for there is none of the feeling of rotation, impulsion, up-and-down movement, oscillopsia, or other disturbance of motion so characteristic of the latter. Lacking also are the ancillary symptoms of true vertigo—namely, nausea, vomiting, tinnitus and deafness, staggering, and the relief obtained by sitting or lying still.

The Neurologic and Otologic Causes of Vertigo

The fact that vertigo may constitute the aura of an epileptic seizure supports the view that this symptom may have a cerebrocortical origin. Indeed, electrical stimulation of the cerebral cortex in an unanesthetized patient, either of the posterolateral aspects of the temporal lobe or the inferior parietal lobule adjacent to the sylvian fissure, may evoke intense vertigo (page 277). The occurrence of vertigo as the initial symptom of a seizure is, however, infrequent. In such cases, a sensation of movement—either of the body away from the side of the lesion or of the environment in the opposite direction—lasts for a few seconds before being submerged in other seizure activity. *Vertiginous epilepsy* of this type should be differentiated from *vestibulogenic seizures*, in which an excessive vestibular discharge serves as the stimulus for a seizure. The latter is a rare form of reflex epilepsy, in which tests that induce vertigo may provoke the seizure (see Chap. 16).

The issue of *migraine* as a cause of vertigo has occasioned much discussion. Several authoritative clinicians attribute many instances of otherwise unexplained dizziness and vertigo to migraine with aura, but it is not entirely clear whether they are referring to an attack of basilar migraine, usually in children (migrainous vertigo), or to episodes of vague disequilibrium or vertigo at various times in migraineurs, which has been more typical in our experience. An extensive survey by Neuhauser and colleagues found that 7 to 9 percent of patients had conventional migrainous symptoms during or before a vertiginous attack, and in half of those the vertigo was regularly associated with migraine. This number is certainly higher than in most practices but it does seem to support the idea that migraine can cause vertigo.

Lesions of the cerebellum produce vertigo depending on which part of this structure is involved. Large, destructive processes in the cerebellar hemispheres and vermis such as cerebellar hemorrhage may, or at times may not, cause vertigo. However, strokes in the territory of the medial branch of the posterior inferior cerebellar artery (which arises distal to the branches to the medulla and therefore does not involve the lateral medulla) may cause intense vertigo and vomiting that is *indistinguishable from that due to labyrinthine disorder*. In two such pathologically studied cases, a large zone of infarction extended to the midline and involved the flocculonodular lobe (Duncan et al). Falling in these cases was toward the side of the lesion; nystagmus was present on gaze to each side but was more prominent on gaze to the side of the infarct. These findings have been confirmed by computed tomography (CT) and magnetic resonance imaging (MRI) (Amarenco et al). Labyrinthine disease, on the other hand, causes predominantly unidirectional nystagmus to the side opposite the impaired labyrinth and swaying or falling toward the involved side—i.e., the direction of the nystagmus is opposite to that of the falling and past pointing (the latter referring to overshooting a target by the patient's finger with eyes closed, as originally described by Bárány). Early in the course of an acute attack of vertigo, when it may be difficult to assess the gait and the quality of nystagmus, it is necessary to exclude a cerebellar infarct or hemorrhage by use of imaging procedures.

Bimond and DeJong described a kind of nystagmus and vertigo originating in the upper cervical roots and the muscles and ligaments that they innervate (so-called cervical vertigo). Spasm of the cervical muscles, trauma to the neck, and irritation of the upper cervical sensory roots were said to produce asymmetrical spinovestibular stimulation and thus to evoke nystagmus, prolonged vertigo, and disequilibrium. Cervical vertigo has also been attributed, on very uncertain grounds, to circulatory insufficiency in the vertebobasilar territory. Toole and Tucker demonstrated a reduced flow through these vessels (in cadavers) when the head was rotated or hyperextended. In our view, the existence of “cervical vertigo,” or at least these interpretations of it, is still open to question. However, we must acknowledge having encountered patients with cervical dystonia who describe something akin to vertigo, and this may speak to a relationship between cervical proprioceptors and vertigo.

Causes of vertigo other than Ménière disease that originate in the vestibular nerve are discussed further on.

In summary, although lesions of the cerebral cortex, eyes, and perhaps the cervical muscles may give rise to vertigo, they are not common sources of the symptom, and vertigo is rarely the dominant manifestation of disease in these parts. For all practical purposes, vertigo indicates a disorder of the vestibular end organs, the vestibular division of the eighth nerve, or the vestibular nuclei in the brainstem and their immediate connections, including the inferior cerebellum. The clinical problem resolves itself into deciding which portion of the labyrinthine-vestibular apparatus is primarily involved. Usually this decision can be made on the basis of the form of the vertiginous attack, the nature of the ancillary symptoms and signs, and tests of labyrinthine function. The latter are described below, followed by a description of the common labyrinthine-vestibular syndromes.

Tests of Labyrinthine Function

The most rudimentary test of labyrinthine function is simply to have the patient shake his head from side-to-side in an attempt to

elicit symptoms that simulate the dizziness that has been described and to observe the degree of postural instability during this maneuver. Falling and marked intensification of the dizziness is almost always an indication of labyrinthine disease. Also, nystagmus may be evoked, indicating a vestibular instability. More informative is the “rapid head impulse” test, which is conducted by asking the patient to fixate on a target and then for the examiner to quickly rotate the patient’s head by 10 degrees (an explanation must be given to encourage the patient to relax the neck muscles and remain focused on the fixation point). The eyes are observed for a slippage from the target; this is most evident by a quick saccadic return to the point of focus. Ocular instability is elicited when the patient turns his head toward the side of the affected labyrinth. This use of the vestibulo-ocular reflex is said by Halmagyi to be among the most dependable bedside tests of labyrinthine function.

Maneuvers designed to elicit positional vertigo by rapidly changing from a seated to a supine position with the head turned to one side bring about vertigo in a number of conditions but are specifically intended to detect so-called benign positional vertigo and are described further on.

A number of other interesting but unvalidated tests that bring out instabilities in station and gait may be used to supplement the conventional tests for vestibular dysfunction. The Unterberger maneuver requires the patient to march in place with eyes closed and arms outstretched. Normally, less than 15 degrees or so of rotation is displayed; asymmetry of labyrinthine function is manifest as excessive rotation away from the diseased side. A related test attributed to Fukada involves having the patient walk around a chair with eyes closed; an increasing or decreasing radius is indicative of an imbalance between the two sides of the labyrinthine apparatus. Both of these tests, however, often show abnormalities with cerebellar disease as well, and the sensitivity of maneuvers such as these has been questioned. We can only comment that they seem in our experience to demonstrate vestibulocerebellar lesions but are no more helpful than other less elaborate bedside investigations.

Irrigation of the ear canal alternately with cold and warm water (caloric or oculovestibular testing) may be used to disclose a reduction in labyrinthine function in the form of an impairment or loss of thermally induced nystagmus on the involved side. In caloric testing, the patient’s head is ideally tilted forward 30 degrees from the horizontal; this brings the horizontal semicircular canal into a vertical plane, the position of maximal sensitivity of this canal to thermal stimuli. Each external auditory canal is irrigated for 30 s, first with water at 30°C and then at 44°C (7°C below and above body temperature), with a pause of at least 5 min between each irrigation. In normal persons, cold water induces a slight tonic deviation of the eyes to the side being irrigated, followed, after a latent period of about 20 s, by nystagmus to the opposite side (direction of the fast phase). Warm water induces nystagmus to the irrigated side. (As noted in Chap. 14, this is the basis for the mnemonic “COWS”: cold opposite, warm same, referring to the direction of compensatory nystagmus.) In normal subjects, the nystagmus usually persists for 90 to 120 s, although the range is considerably larger. Nausea and symptoms of excessive reflex vagal activity may occur in sensitive individuals.

Simultaneous irrigation of both canals with cold water causes a tonic downward deviation of the eyes, with nystagmus (quick component) upward. Bilateral irrigation with warm water yields a tonic upward movement and nystagmus in the opposite direction. Caloric testing will reliably answer whether the vestibular end organs react, and comparison of the responses from the two ears will

indicate which one is paretic. Recording of eye movements during the test, as described below, allows quantification of these responses. Galvanic stimulation of the labyrinths offers no particular advantage over caloric stimulation.

Vestibular (labyrinthine) stimulation can also be produced by rotating the patient in a Bárány chair or any type of swivel chair. The patient's eyes are kept closed or blindfolded or defocused with Frenzel lenses during rotation to avoid the effects of optokinetic nystagmus. Electronystagmography (ENG) provides a more refined method of detecting disordered labyrinthine function because it permits the accurate recording of eye movements without visual fixation. ENG is usually coupled with caloric stimulation or with modern devices for rotational testing that allow precise control of the velocity, acceleration, and extent of rotation beyond what can be done with the traditional Bárány chair.

Ménière Disease and Other Forms of Labyrinthine Vertigo

Labyrinthine disease is the most common cause of true vertigo. The classic variety, *Ménière disease*, is characterized by recurrent attacks of vertigo associated with fluctuating tinnitus and deafness. One or the other of the latter symptoms—rarely both—may be absent during the initial attacks of vertigo, but invariably they assert themselves as the disease progresses and increase in severity during an acute attack. Ménière disease affects the sexes about equally and has its onset most frequently in the fifth decade of life, although it may begin earlier or later. Cases of Ménière disease are usually sporadic, but hereditary forms, both autosomal dominant and recessive, have been described (see reviews by Konigsmark). The main pathologic changes consist of an increase in the volume of endolymph and distention of the endolymphatic system (endolymphatic hydrops). It has been speculated that the paroxysmal attacks of vertigo are related to ruptures of the membranous labyrinth and a dumping of potassium-containing endolymph into the perilymph, changes that have a paralyzing effect on vestibular nerve fibers and lead to degeneration of the delicate cochlear hair cells (Friedmann).

In typical Ménière disease, the attacks of vertigo are characteristically abrupt and last for several minutes to an hour or longer. The vertigo is unmistakably whirling or rotational in type and usually so severe that the patient cannot stand or walk. Varying degrees of nausea and vomiting, low-pitched tinnitus, a feeling of fullness in the ear, and a diminution in hearing are practically always associated. Nystagmus is present during the acute attack; it is horizontal in type, usually with a rotary component and with the slow phase to the side of the affected ear. On attempting to touch a target with the eyes closed, there is past pointing as well as a tendency to fall toward the affected ear. The patient prefers to lie with the faulty ear uppermost and is disinclined to look toward the normal side, which exaggerates the nystagmus and dizziness. As the attack subsides, hearing improves, as does the sensation of fullness in the ear; with further attacks, however, there is a progressive increase of deafness.

The attacks vary considerably in frequency and severity. They may recur several times weekly for many weeks on end, or there may be remissions of several years' duration. Frequently recurring attacks may give rise to a mild chronic state of disequilibrium and a reluctance to move the head or to turn quickly. With milder forms of the disease, the patient may complain more of head discomfort and of difficulty in concentrating than of vertigo and may be considered neurotic.

Symptoms of anxiety are common in patients with Ménière disease, particularly in those who suffer frequent severe attacks.

As indicated earlier, a small proportion of patients with Ménière disease experience sudden, violent falling attacks. These episodes have been referred to by the quaint name "otolithic catastrophe of Tumarkin," who attributed them, with little evidence, to deformation of the otolithic membrane of the utricle and saccule. Patients characteristically describe a sensation of being pushed or knocked to the ground without warning, or there may be a sudden movement or tilt of the environment just before the fall. Consciousness is not lost, and vertigo of the usual type and its accompaniments are not part of the falling attack, although some patients become aware of these symptoms after falling. The attacks may occur early or late in the course of the disease. Typically, several attacks occur over a period of a year or less and remit spontaneously (Baloh et al). An initial attack must be distinguished from other types of drop attacks (see page 329), but the occurrence of the more typical vertiginous attacks of Ménière disease, with deafness and tinnitus, clarifies the diagnosis.

The hearing loss in Ménière disease usually precedes the first attack of vertigo, but it may appear later. Episodic deafness without vertigo has been called *cochlear Ménière syndrome*. As already mentioned, with recurrent attacks, there is a saltatory progressive unilateral hearing loss (in most series only 10 percent of cases involve both ears, but Baloh places the figure closer to 30 percent). Early in the disease, deafness affects mainly the low tones and fluctuates in severity; actually tones below 500 Hz are affected early on, and this loss is not evident to the patient. Without the fluctuations in pure-tone audiometric thresholds, the diagnosis is uncertain. Later the fluctuations cease and high tones are affected. Speech discrimination is relatively preserved. The attacks of vertigo usually cease when the hearing loss is complete, but there may be an interval of months or longer before this occurs. Audiometry reveals a sensorineural type of deafness, with air and bone conduction equally depressed. Provided that deafness is not complete, loudness recruitment can be demonstrated in the involved ear (see above).

Treatment During an acute attack of Ménière disease, rest in bed is the most effective treatment, since the patient can usually find a position in which vertigo is minimal. The antihistaminic agents cyclizine (Marezine), meclizine (Bonine, Antivert), or transdermal scopolamine are useful in the more protracted cases. Promethazine (Phenergan) is an effective vestibular suppressant, as is trimethobenzamide (Tigan), given in 200-mg suppositories, which also suppresses nausea and vomiting. For many years a low-salt diet in combination with ammonium chloride and diuretics have been used in the treatment of Ménière disease, but the value of this regimen has never been established. The same is true for dehydrating agents such as oral glycerol and the more recently popular calcium channel blockers. Mild sedative drugs may help the anxious patient between attacks.

If the attacks are very frequent and disabling, permanent relief can be obtained by surgical means. Destruction of the labyrinth should be considered only in patients with strictly unilateral disease and complete or nearly complete loss of hearing. In patients with bilateral disease or significant retention of hearing, the vestibular portion of the eighth nerve can be sectioned. An endolymphatic-subarachnoid shunt is the operation favored by some surgeons, and selective destruction of the vestibule by a cryogenic probe or trans-tympanic injection of gentamicin is favored by others. Decompression of the eighth cranial nerve, by separating it from an ad-

jacent vessel, as suggested by Janetta, is still a controversial measure and probably better suited to the treatment of sustained and disabling but unexplained vertigo, as discussed further on, than to the treatment of classic Ménière disease. The decision to undertake any surgical procedure must be tempered by the fact that a majority of the patients, who are middle-aged, stabilize spontaneously in a few years.

Benign Positional Vertigo

This disorder of labyrinthine function is more frequent than Ménière disease and—while it does not have the same implications in the long term—an acute attack can be quite disabling. It is characterized by *paroxysmal vertigo* and nystagmus that occur *only with the assumption of certain positions of the head*, particularly lying down or rolling over in bed, bending over and straightening up, and tilting the head backward. It has been common in our experience for the patient to report that the paroxysm of vertigo began in the middle of the night or early morning, presumably while shifting position during sleep and rapidly making one ear dependent or rolling over to get out of bed. Brandt prefers the descriptive adjective *positioning vertigo* to *positional vertigo*, insofar as the symptoms are induced not by a particular head position but only by rapid changes in head position. This disorder was first described by Bárány, but Dix and Hallpike emphasized its benign nature and were responsible for its further characterization, particularly the discrete positional movements that provoke it. Individual episodes last for less than a minute, but these may recur periodically for several days or for many months—rarely for years. As a rule, examination discloses no abnormalities of hearing or other identifiable lesions in the ear or elsewhere. A thorough summary of the condition has been given by Furman and Cass.

The diagnosis of this disorder is settled at the bedside by quickly moving the patient from the sitting position to recumbency, with the head tilted 30 to 40 degrees over the end of the table and 30 to 45 degrees to one side, as originally described by Dix and Hallpike. After a latency of a few seconds, this maneuver provokes a paroxysm of vertigo; the patient may become frightened and grasp the examiner or the table or struggle to sit up. The dysfunctional ear is the one that is downward when vertigo is elicited. We cannot refute the contention made by von Brevern and colleagues that the right labyrinth is more often responsible. The vertigo is accompanied by oscillopsia and nystagmus, predominantly torsional in type with the rapid components away from the affected (dependent) ear (Baloh et al). The vertigo and nystagmus last no more than 30 to 40 s and usually less than 15 s. *Changing from a recumbent to a sitting position reverses the direction of vertigo and nystagmus* (position-changing nystagmus), and this is perhaps the most certain sign that the disorder originates in the labyrinth. With repetition of the maneuver, vertigo and nystagmus become less apparent, and after three or four trials, they can no longer be elicited (referred to as “fatigue”); they can be reproduced in their original severity only after a protracted period of rest. The head-hanging maneuver does not always evoke vertigo and nystagmus in patients whose histories are otherwise consistent with the diagnosis of benign paroxysmal vertigo; therefore Froehling and coworkers do not insist on it for diagnosis.

Such attacks of vertigo may come and go for years, particularly in the elderly, and require no treatment. At the other end of the scale is the rare patient with positional vertigo of such persistence and severity as to require surgical intervention.

Baloh and colleagues, in their study of 240 cases of benign positional vertigo, found that 17 percent had their onset within several days or weeks after cerebral trauma and 15 percent after presumed viral neurorhabditis. The significance of these preceding events is unclear, insofar as they did not appear to influence the clinical symptoms or course of the otologic disorder. It should be pointed out that sudden changes in position, particularly of the head, may induce vertigo and nystagmus or cause a worsening of these symptoms in patients with all types of vestibular-labyrinthine disease, including Ménière disease and the types associated with vertebrobasilar stroke, trauma, and posterior fossa tumors. However, only if the paroxysm has the special characteristics noted above—namely, elicitation by change in head position, latency of onset, brevity, reversal of direction of nystagmus on sitting up, fatigability with repetition of the test, and the presence of distressing subjective symptoms of vertigo or its recurrence for months or years without other symptoms—can it be regarded as “benign paroxysmal” in type.

Schuknecht originally proposed that benign positional vertigo was due to cupulolithiasis, in which otolithic crystals become detached and attach themselves to the cupula of the posterior semicircular canal. It is now generally believed that the debris, probably detached from the otolith, forms a free-floating clot in the endolymph of the canal (canalolithiasis) and gravitates to the most dependent part of the canal during changes in the position of the head (see Brandt et al). The clot is thought to act as a plunger, inducing push-and-pull forces on the cupula and triggering an attack of vertigo. Based on this presumed mechanism, a canalith repositioning maneuver has been devised (Semont et al; Epley), allowing the debris to gravitate out of the semicircular canal and into the vestibule, where it will not induce a current during angular acceleration.

Treatment The first part of the Epley canalith repositioning maneuver (Fig. 15-5) is identical to the diagnostic Hallpike maneuver: the patient is positioned with the head in the hanging position, first with one ear down and the head turned, then the other ear, in order to establish the side responsible for symptoms. Next, with the patient in the head-hanging position that causes symptoms, the head is turned in a series of three steps, each separated by about 20 s: first the head is turned 45 to 60 degrees toward the opposite ear; the patient is then turned onto his side and the head turned an additional 45 degrees, until the head is parallel to the ground; then the head is turned once more until it more nearly faces the floor. We have become aware that this last step, which is a necessary part of the maneuver, is sometimes omitted by neurologists. After 20 s, the patient is returned to the upright position and must remain at least 45 degrees upright for the next 24 h (we encourage sleeping on several pillows). Often a single sequence suffices to terminate a period of positional vertigo. In recalcitrant cases, our otolaryngology colleagues have applied a large vibrator to the temporal bone while the Epley maneuver was being performed, after which the episodes ceased; presumably this mobilizes the crystals and aids in moving them out of the utricle.

It is important to reiterate that in some patients with positional vertigo, the disorder is neither benign nor paroxysmal. Jannetta and colleagues have described a group of patients in whom symptoms of vertigo and disequilibrium were almost constant (even in the upright position) and disabling and unresponsive to habituation and other medical therapy (*disabling positional vertigo*). They attributed this disorder to cross-compression of the root entry zone of

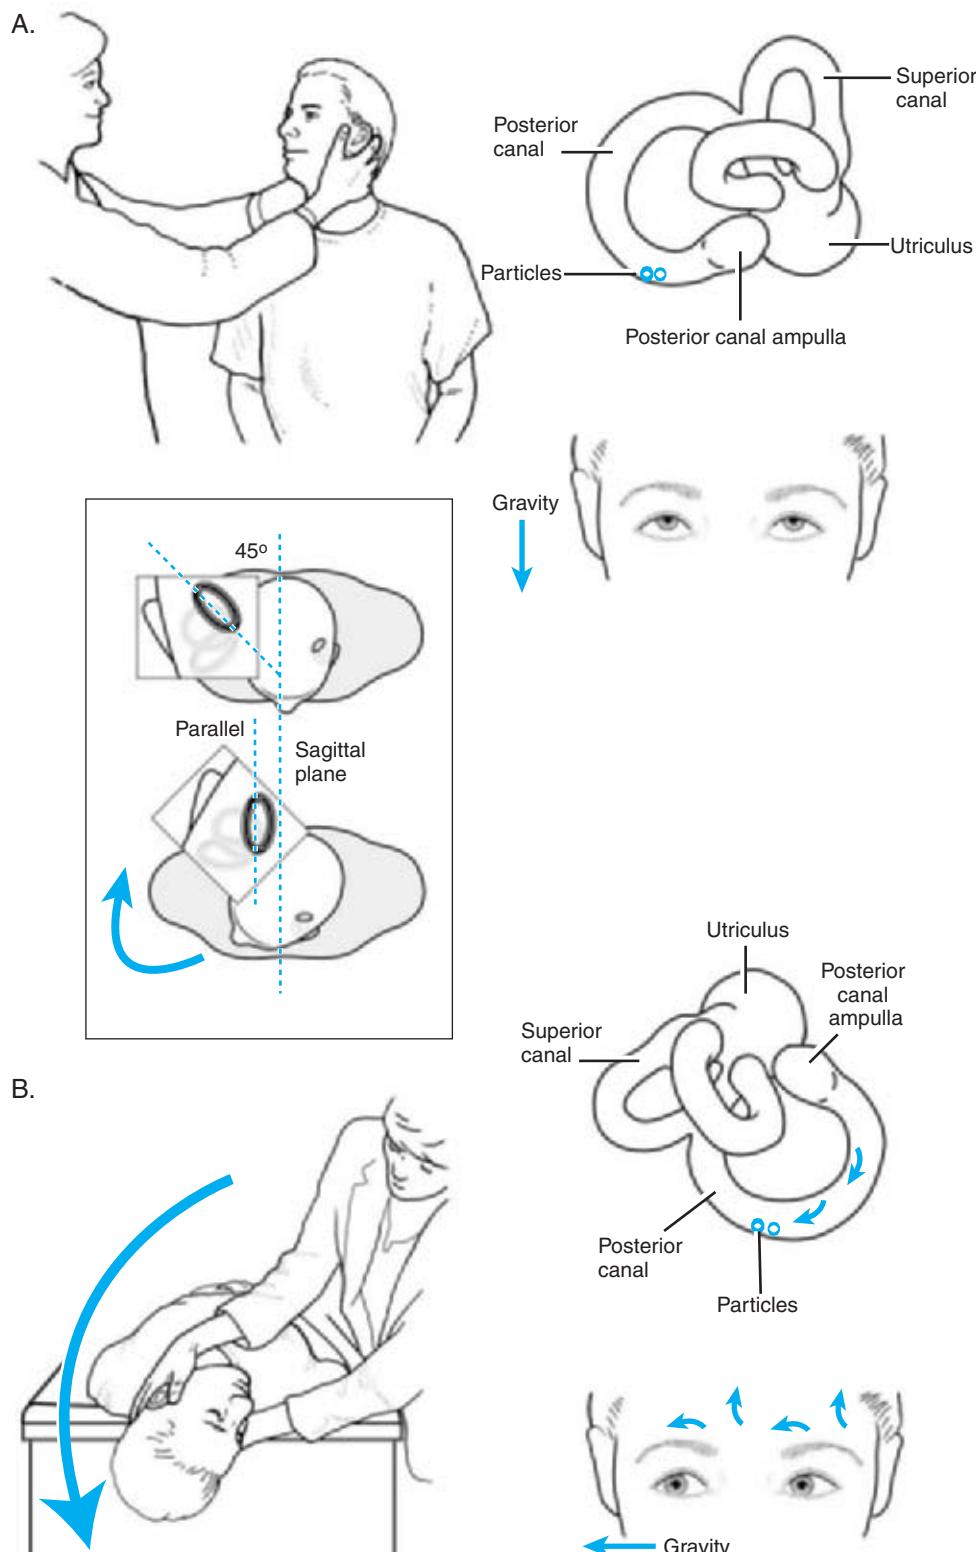

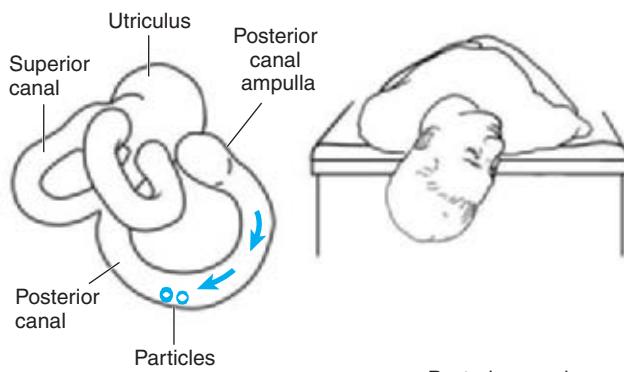

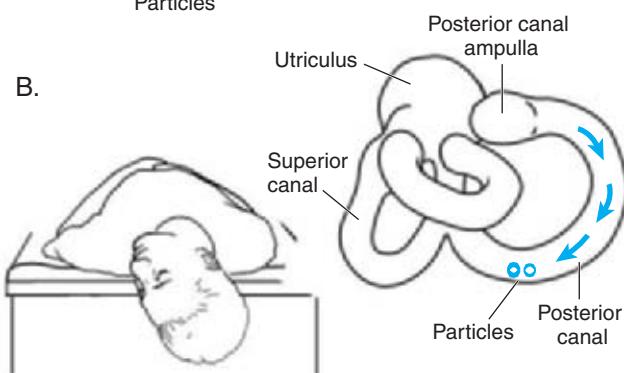

Figure 15-5. Dix-Hallpike maneuver to elicit benign positional vertigo (originating in the right ear). The maneuver begins with the patient seated and the head turned to one side at 45 degrees (*A*), which aligns the right posterior semicircular canal with the sagittal plane of the head. The patient is then helped to recline rapidly so that the head hangs over the edge of the table (*B*), still turned 45 degrees from the midline. Within several seconds, this elicits vertigo and nystagmus that is right beating with a rotary (counterclockwise) component. An important feature of this type of “peripheral” vertigo is a change in the direction of nystagmus when the patient sits up again with his head still rotated. If no nystagmus is elicited, the maneuver is repeated after a pause of 30 s, with the head turned to the left. Treatment with the canalith repositioning maneuver is shown in Fig. 15-6.

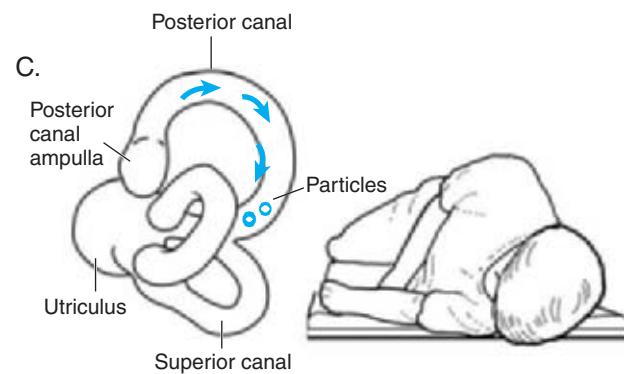

A.

B.

C.

D.

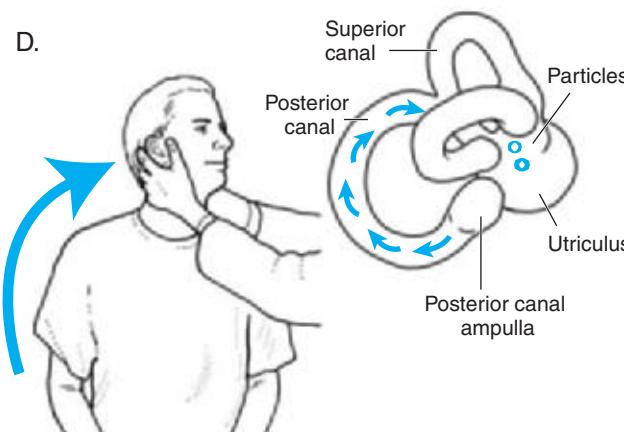

Figure 15-6. Bedside maneuver for the treatment of a patient with benign paroxysmal positional vertigo affecting the right ear. The presumed position of the debris within the labyrinth during the maneuver is shown on each panel. The maneuver is a four-step procedure. First, a Dix–Hallpike test is performed with the patient’s head rotated 45 degrees toward the (affected) right ear and the neck slightly extended with the chin pointed slightly upward. This position results in the patient’s head hanging to the right (Panel A). Once the vertigo and nystagmus provoked by this maneuver cease, the patient’s head is rotated about the rostral–caudal body axis until the left ear is down (Panel B). Then the head and body are further rotated until the head is almost face down (Panel C). The vertex of the head is kept tilted downward throughout the rotation. The patient should be kept in the final, facedown position for about 10 to 15 seconds. With the head kept turned toward the left shoulder, the patient is brought into the seated position (Panel D). Once the patient is upright, the head is tilted so that the chin is pointed slightly downward.

the eighth cranial nerve by an adjacent blood vessel and have reported that decompression of the nerve provides lasting relief of symptoms.

Toxic and Idiopathic Bilateral Vestibulopathy

The common and serious ototoxic effects of the aminoglycoside antibiotics have already been mentioned—both on the cochlear hair cells, with loss of hearing, and, often independently, on the vestibular labyrinth. Prolonged exposure to these agents can produce a bilateral vestibulopathy without vertigo. Instead, there tends to be a disequilibrium associated with oscillopsia. The symptoms are especially troublesome when the patient moves. Often the disequilibrium is not discovered until a bedfast patient tries to walk.

Less well appreciated is the occurrence of a slowly progressive vestibulopathy for which no cause can be discerned. The latter disorder affects men and women alike, with onset in middle or late adult life. The main abnormalities are unsteadiness of gait, which is worse in the dark or with eyes closed, and oscillopsia, which occurs with head movements and is particularly noticeable when walking. Vertigo and hearing loss are notably absent, as are other neurologic abnormalities. The bilateral vestibular loss can be documented with caloric and rotational testing. Baloh and colleagues, in a report of 22 patients with bilateral idiopathic vestibulopathy of this type, found that a significant proportion (9 of 22 cases) had a prior history of prolonged episodes of vertigo consistent with the diagnosis of bilateral sequential vestibular neuronitis.

Vestibular Neuronitis (Labyrinthitis)

This was the term applied originally by Dix and Hallpike to a distinctive disturbance of vestibular function, characterized clinically by a paroxysmal and usually a prolonged single attack of vertigo and by a conspicuous absence of tinnitus and deafness. The entity is, however, more nebulous than most discussions indicate.

This disorder occurs mainly in young to middle-aged adults (children and older individuals may be affected), without preference for either sex. The patient frequently gives a history of an antecedent upper respiratory infection of nonspecific type, but it is not clear whether this is requisite for the diagnosis. Usually the onset of vertigo is fairly abrupt, although some patients describe a prodromal period of several hours or days in which they felt “top-heavy” or “off balance.” Persistence of the symptoms for a day or more differentiates the process from Ménière disease. The vertigo is severe as a rule and is associated with nausea, vomiting, and the need to remain immobile.

Nystagmus (quick component) and a sense of body motion are to the opposite side, whereas falling and past pointing are to the side of the lesion. In some patients the caloric responses are abnormal bilaterally, and in some the vertigo may recur, affecting the same or the other ear. Auditory function is normal. Examination discloses vestibular paresis on one side, i.e., an absent or diminished response to caloric stimulation of the horizontal semicircular canal. If the patient will tolerate the small head movements, the previously described rapid-head-impulse test of Halmagyi and Cremer is one of the best means of demonstrating absent function of one lateral semicircular canal.

Although the symptoms can be quite disabling for a short period, vestibular neuronitis is a benign disorder. The severe vertigo and associated symptoms subside in a matter of several days,

but lesser degrees of these symptoms, made worse by rapid movements of the head, may persist for several weeks or months. The caloric responses are gradually restored to normal as well. In some patients there has been a recurrence months or years later.

The portion of the vestibular pathway that is primarily affected in this disease is thought to be the superior part of the vestibular nerve trunk, which was observed to show degenerative changes by Schuknecht and Kitamura. Earlier, Dix and Hallpike had reasoned that the lesion was located central to the labyrinth, since hearing is spared and vestibular function usually returns to normal. They used the term *vestibular neuronitis* because of the uncertainty of more precise localization within the peripheral vestibular pathway. The cause is uncertain, but most authorities have attributed it to a viral infection of the vestibular nerve, analogous to Bell’s palsy, and from time to time, enhancement of the eighth nerve or the membranous labyrinth is seen after gadolinium administration on MRI. For want of more specific etiologic or pathologic data, many neurologists prefer the term *vestibular neuropathy* or *neuritis* or *acute unilateral peripheral vestibulopathy*. It is likely that many of the conditions described under the terms *epidemic vertigo*, *epidemic labyrinthitis*, and *acute labyrinthitis* or *neurolabyrinthitis* refer to the same process. These many names attest to the fact that the distinction between vestibular neuronitis and labyrinthitis has never been clarified; some otolaryngologists use the term *labyrinthitis* for a vestibular neuronitis with mild or moderate hearing loss. Certainly herpes zoster oticus causes this syndrome (as well as affecting the seventh nerve); this characterizes the Ramsay Hunt syndrome (pages 642 and 1183).

During the acute stage, antihistamine drugs, phenergan, clonazepam, and scopolamine may be helpful in reducing the symptoms. Vestibular exercises are recommended by Baloh in his review of the subject (2003). One study has demonstrated a more rapid recovery with the use of methylprednisolone, 100 mg orally, tapered over 3 weeks; valacyclovir did not have this effect (Strupp et al).

Other Causes of Vertigo of Vestibular Nerve Origin

Vertigo may occur with diseases that involve the eighth nerve in the petrous bone or at the cerebellopontine angle. Aside from vestibular neuronitis, discussed above, the two most common causes of vertigo of eighth nerve origin are probably an acoustic neuroma and vascular irritation or compression by a small branch of the basilar artery. The frequency of the vascular compression syndrome (see earlier) as a cause of otherwise undifferentiated vertigo is not known. Regarding acoustic neuroma, vertigo is rarely the initial symptom; the usual sequence is deafness affecting the high-frequency tones initially, followed some months or years later by mild chronic imbalance rather than vertigo and by impaired caloric responses, and then, if untreated, by additional cranial nerve palsies (the seventh, fifth, and tenth nerves), ipsilateral ataxia of limbs, and headache (see page 572). Variations in the sequence of development of symptoms are frequent, and probably many acoustic neuromas discovered in the process of an evaluation for vertigo are incidental; i.e., almost 1 percent of the general population harbor small tumors. In the diagnosis of acoustic neuroma, MRI and BAEP are the most important ancillary examinations.

Labyrinthine infarction can be a component of the stroke syndrome from occlusion of the anterior inferior cerebellar artery (AICA). In the complete syndrome there is hearing loss, cerebel-

lar ataxia, and sometimes “screaming tinnitus” (see page 680). Also reported is a clinical syndrome of unknown nature consisting of a single abrupt attack of severe vertigo, nausea, and vomiting without tinnitus or hearing loss but with permanent ablation of labyrinthine function on one side. It has been suggested that this syndrome is due to occlusion of the labyrinthine division of the internal auditory artery, but so far anatomic confirmation has not been obtained. Labyrinthine hemorrhage has been demonstrated by MRI in some of these patients; others are attributed, speculatively, to viral infection.

A particular form of paroxysmal vertigo occurs in childhood. The attacks occur in a setting of good health and are of sudden onset and brief duration. Pallor, sweating, and immobility are prominent manifestations; occasionally vomiting and nystagmus occur. No relation to posture or movement has been observed. The attacks are recurrent but tend to cease spontaneously after a period of several months or years. The outstanding abnormality is demonstrated by caloric testing, which shows impairment or loss of vestibular function, bilaterally or unilaterally, frequently persisting after the attacks have ceased. Cochlear function is unimpaired. The pathologic basis of this disorder has not been determined and a suggested connection with migraine is tenuous. The special case of basilar artery migraine is discussed below.

Cogan has described an infrequent syndrome in young adults in which a *nonsyphilitic interstitial keratitis* is associated with vertigo, tinnitus, nystagmus, and rapidly progressive deafness. The prognosis for vision is good, but the deafness and loss of vestibular function are usually permanent. The cause and pathogenesis of this syndrome are unknown, although approximately half of the patients later develop aortic insufficiency or a systemic vasculitis that resembles polyarteritis nodosa. These vascular complications proved fatal in 7 of 78 cases reviewed by Vollertsen and colleagues.

There are many other causes of aural vertigo, such as purulent labyrinthitis complicating mastoiditis or meningitis; serous labyrinthitis due to infection of the middle ear; “toxic labyrinthitis” due to intoxication with alcohol, quinine, or salicylates; motion sickness; and hemorrhage into the inner ear. Bárány was the first to draw attention to the nystagmus and positional vertigo, worse on closing the eyes, that occurs at a certain level of intoxication with alcohol and lasts a few hours. Such an episode of alcohol-induced vertigo tends to last longer than a vertiginous attack of Ménière disease, but in other respects the symptoms (excepting tinnitus) are similar.

Vertigo with varying degrees of spontaneous or positional nystagmus and reduced vestibular responses is a frequent complication of *head trauma*. Vertigo, often of the nonrotatory, to-and-fro type, may follow cerebral concussion or whiplash injury, in which the head has not been impacted. Brandt has attributed this syndrome to a loosening or dislodgement of the otoconia in the otoliths. The vertigo in these circumstances usually improves in a few days or weeks and is rarely accompanied by impairment of hearing—in distinction to the vertigo that follows fractures of the temporal bones (as described earlier in this chapter in the discussion of deafness). Dizziness is also a common complaint as part of the syndrome of posttraumatic nervous instability (page 764), but usually this proves to be giddiness rather than true vertigo. Otolaryngologists are familiar with a syndrome resulting from a perilymph fistula after traumatic injury. The trauma may be minor, even forceful coughing, sneezing, or lifting; some cases are due to chronic ear infection or cholesteatoma. If the tympanic membrane is ruptured, vertigo and nystagmus can be induced by pressure in the external ear canal.

Vertigo of Brainstem Origin

Reference was made above to the occurrence of vertigo and nystagmus with lower and upper brainstem lesions. In these cases, vestibular nuclei and their connections are implicated. Auditory function is nearly always spared, since the vestibular and cochlear fibers diverge upon entering the brainstem at the junction of the medulla and pons. The vertigo of brainstem origin as well as the accompanying nausea, vomiting, nystagmus, and disequilibrium are generally more protracted but less severe than with labyrinthine lesions, but one can think of exceptions to this statement. Nevertheless, with brainstem lesions, one often observes marked nystagmus without the slightest degree of vertigo—which does not happen with labyrinthine disease. The nystagmus of brainstem origin may be uni- or bidirectional, purely horizontal, vertical or rotary, and is characteristically worsened by attempted visual fixation. In contrast, nystagmus of labyrinthine origin is unidirectional, usually with a rotary component, and past pointing and falling are in the direction of the slow phase; a purely vertical nystagmus does not occur, and a purely horizontal nystagmus without a rotary component is unusual. Furthermore, labyrinthine nystagmus is inhibited by visual fixation and reverses direction with changes in the position of the head; nystagmus of brainstem origin generally displays none of these features. Either may have a positional- or movement-induced worsening, but this finding is more prominent in labyrinthine disease.

The central localization of vertigo is confirmed by finding signs of involvement of other structures within the brainstem (cranial nerves, sensory and motor tracts, etc.). The mode of onset, duration, and other features of the clinical picture depend on the nature of the causative disease, which may be vascular, demyelinating, or neoplastic.

Vertigo is a prominent symptom of ischemic attacks and of brainstem infarction occurring in the territory of the vertebrobasilar arteries, particularly the Wallenberg syndrome of lateral medullary infarction (page 678). On the other hand, vertigo as the sole manifestation of brainstem disease is rare. Unless other symptoms and signs of brainstem disorder appear within several days, one can postulate that the vertigo has an aural origin and one can nearly always exclude vascular disease of the brainstem. The same is true of multiple sclerosis, which may be the explanation of a persistent vertigo in an adolescent or young adult. Vertigo of cerebellar origin is exceptional in this respect in that it may rarely be the sole manifestation of cerebellar infarction or hemorrhage, as described on pages 680 and 714. One hypothesis for cerebellar vertigo attributes it to small infarctions or compression of the lateral medulla, but this does not appear to be necessary. The nystagmus and ataxia of gait (more of a propelling or pulsion to one side) that accompany acute cerebellar lesions are toward the same side (the side of the lesion), while in acute vestibulopathies, nystagmus beats away from the side of the lesion and pulsion is still toward the affected side.

The putative relationship of migraine to vertigo was mentioned earlier. This refers to otherwise mundane migraine in which the vertigo is perhaps an aura. In addition, attacks of vertigo followed by an intense unilateral and often suboccipital headache and vomiting are the characteristic features of *basilar artery migraine* (see page 151). The prodromal visual symptoms take the form of blindness or of photopsia that occupies all of the visual fields. Between headaches, tests of cochlear and vestibular function in these patients are normal. The relationship of this form of migraine to disease of the vertebral and basilar arteries is obscure.

Table 15-2
Vertiginous syndromes with lesions of different parts of the vestibular system

SYNDROME	NEUROLOGIC FINDINGS	DISORDERS OF EQUILIBRIUM	TYPE OF NYSTAGMUS ^a	HEARING	LABORATORY EXAM
Labyrinthitis (postural vertigo, trauma, Ménière disease, aminoglycoside toxicity, labyrinthitis)	None	Ipsilateral past pointing and lateral propulsion to side of lesion	Horizontal or rotary to side opposite lesion, positional and position changing, fatigable	Normal or conduction or neurosensory deafness with recruitment	Vestibular paresis by caloric testing, directional preponderance
Vestibular nerve and ganglia (vestibular neuronitis, herpes zoster)	Auditory eighth and seventh cranial nerve abnormalities; abnormal head impulse test to affected side	Ipsilateral past pointing and lateral propulsion to side of lesion	Unidirectional positional	Sometimes sensorineural deafness, without recruitment (vestibulolabyrinthitis)	Radiography and CT may be normal or abnormal Vestibular paresis on caloric testing
Cerebellopontine angle (acoustic neuroma, glomus and other tumors)	Ipsilateral fifth, seventh, ninth, tenth cranial nerves, cerebellar ataxia	Ataxia and falling ipsilaterally	Gaze-paretic, positional, coarser to side of lesion	Sensorineural deafness without recruitment	Directional preponderance CT and MRI abnormal Vestibular paresis on caloric testing
Brainstem and cerebellum (infarcts, tumors, viral infections)	Increased intracranial pressure (late) Multiple cranial nerves, brainstem tract signs, cerebellar ataxia	Ataxia present with eyes open	Coarse horizontal and vertical, gaze-paretic	Usually normal	BAEPs abnormal Increased CSF protein Hyperactive labyrinths or directional preponderance on caloric testing CT, MRI, and BAEPs abnormal in most cases
Higher (cerebral) connections	Aphasia, visual field, hemimotor, hemisensory, and other cerebral abnormalities, seizures	No change	Usually absent	Normal	No change in caloric responses CT and EEG may be abnormal

^a See text and Chap. 14 for description of types of nystagmus.

Finally, mention should be made of a *familial vestibulo-cerebellar syndrome*, beginning in childhood or early adult life and characterized by recurrent episodes of vertigo and imbalance. Diplopia and dysarthria complicate some attacks, which seem to be precipitated by extreme exertion and emotion. Repeated attacks are followed by a mild, persistent ataxia, mainly of the trunk. This disorder was first described by Farmer and Mustian and more recently by Baloh and Winder, who have pointed out that both the episodic vertigo and ataxia are markedly reduced or abolished by the administration of acetazolamide. This

process is most likely related to the inherited acetazolamide-responsive ataxic syndrome described in Chap. 5. A form that is kinesogenic, i.e., brought on by activity, has a similar appearance.

In summary, the nature of the nystagmus, instability of the eyes during the head impulse test, and the other features of the neurologic examination allow a distinction to be made between central and peripheral cases of vertigo. Associated hearing loss favors a vestibular cause of vertigo. The features of the various vertiginous syndromes are summarized in Table 15-2.

SECTION 4

EPILEPSY AND DISORDERS OF CONSCIOUSNESS

This page intentionally left blank.

CHAPTER 16

EPILEPSY AND OTHER SEIZURE DISORDERS

In contemporary society, the frequency and importance of epilepsy can hardly be overstated. From the epidemiologic studies of Hauser and colleagues, one may extrapolate an incidence of approximately 2 million individuals in the United States who are subject to epilepsy (i.e., chronically recurrent cerebral cortical seizures) and predict about 44 new cases per 100,000 population occur each year. These figures are exclusive of patients in whom convulsions complicate febrile and other intercurrent illnesses or injuries. It has also been estimated that slightly less than 1 percent of persons in the United States will have epilepsy by the age of 20 years (Hauser and Annegers). Over two-thirds of all epileptic seizures begin in childhood (most in the first year of life), and this is the age period when seizures assume the widest array of forms. The incidence increases again slightly after age 60. In the practice of pediatric neurology, epilepsy is one of the most common disorders. The chronicity of childhood forms and their persistence in patients of all ages adds to their importance. For all these reasons, every physician should know something of the nature of seizure disorders and their treatment. It is, however, notable that in striking contrast to the many treatments available for epilepsy, as pointed out by J. Engle, 80 to 90 percent of epileptics in the developing world never receive treatment.

Epilepsy was in the past defined as an intermittent derangement of the nervous system due to "an excessive and disorderly discharge of cerebral nervous tissue on muscles." This was the postulate, in 1870, of Hughlings Jackson, the eminent British neurologist, and modern electrophysiology offers no evidence to the contrary. The discharge may result in an almost instantaneous loss of consciousness, alteration of perception or impairment of psychic function, convulsive movements, disturbance of sensation, or some combination thereof. A terminologic difficulty arises from the diversity of the clinical manifestations. The term *convulsion*, referring as it does to an intense paroxysm of involuntary repetitive muscular contractions, is inappropriate for a disorder that may consist only of an alteration of sensation or consciousness. *Seizure* is preferable as a generic term, since it embraces a diversity of paroxysmal events and also because it lends itself to qualification. The term *motor* or *convulsive seizure* is therefore not tautologic, and one may likewise speak of a *sensory seizure* or *psychic seizure*. The word *epilepsy* is derived from Greek words meaning "to seize upon" or a "taking hold of." Our predecessors referred to it as the "falling sickness" or the "falling evil." Although a useful medical term to denote recurrent seizures, the words *epilepsy* and *epileptic* still have unpleasant connotations to the laity and should be used advisedly in dealing with patients.

Viewed in its many clinical contexts, the first solitary seizure or brief outburst of seizures may occur during the course of many medical illnesses. It indicates that the cerebral cortex has been affected by disease, either primarily or secondarily. Convulsive seizures by their nature, if repeated every few minutes, as in status epilepticus, may threaten life. Equally important, a seizure or a series of seizures may be the manifestation of an ongoing neuro-

logic disease that demands the employment of special diagnostic and therapeutic measures, as in the case of a brain tumor.

A more common and less grave circumstance is for a seizure to be but one in an extensive series recurring over a long period of time, with most of the attacks being more or less similar in type. In this instance they may be the result of a burned-out lesion that originated in the past and remains as a scar. The original disease may have passed unnoticed, or perhaps had occurred in utero, at birth, or in infancy, in parts of the brain inaccessible for examination or too immature to manifest signs. It may have affected a very small or "silent" area in a mature brain. The increasingly refined techniques of magnetic resonance imaging (MRI) are now beginning to reveal small zones of cortical dysplasia and hippocampal sclerosis, both of which tend to be epileptogenic. Patients with such long-standing lesions probably make up the majority of those with recurrent seizures but are necessarily classified as having "idiopathic" or "cryptogenic epilepsy," because it is often impossible to ascertain the nature of the original disease and the seizures may be the only sign of brain abnormality.

There are other types of epilepsy for which no pathologic basis has been established and for which there is no apparent underlying cause except perhaps a genetic one. These epilepsies have been referred to as *primary*. Included in this category are hereditary forms, such as certain generalized tonic-clonic (grand mal) and "absence" seizure states. Some authors (Lennox and Lennox; Forster) have reserved the term *idiopathic* for recurrent seizures of these types.

CLASSIFICATION OF SEIZURES

Seizures have been classified in several ways: according to their supposed etiology, i.e., idiopathic (primary) or symptomatic (secondary); their site of origin; their clinical form (generalized or focal); their frequency (isolated, cyclic, or repetitive, or the closely spaced sequence of status epilepticus); or their electrophysiologic correlates. A distinction must be made between the classification of *seizures* (the clinical manifestations of epilepsy: grand mal, petit mal, myoclonic, partial, and others), considered below, and the classification of the *epilepsies*, or *epileptic syndromes*, which are disease constellations, most of which may manifest several seizure types. These are discussed later in the chapter.

The classification to be followed here was first proposed by Gastaut in 1970 and was then refined repeatedly by the Commission on Classification and Terminology of the International League Against Epilepsy (1981). This classification, based mainly on the clinical form of the seizure and its electroencephalographic (EEG) features, has been adopted worldwide and is generally referred to as the International Classification. A modified version of it is reproduced in Table 16-1.

The strength of the International Classification lies in its easy applicability to patients with epilepsy and its universal adoption. The main value of classifying a seizure by its clinical and EEG features is the reasonable predictability of response to specific med-

Table 16-1**International classification of epileptic seizures**

- I. Generalized seizures (bilaterally symmetrical and without local onset)
 - A. Tonic, clonic, or tonic-clonic (grand mal)
 - B. Absence (petit mal)
 - 1. With loss of consciousness only
 - 2. Complex—with brief tonic, clonic, or automatic movements
 - C. Lennox-Gastaut syndrome
 - D. Juvenile myoclonic epilepsy
 - E. Infantile spasms (West syndrome)
 - F. Atonic (atonic, akinetic) seizures (sometimes with myoclonic jerks)
- II. Partial, or focal, seizures (seizures beginning locally)
 - A. Simple (*without* loss of consciousness or alteration in psychic function)
 - 1. Motor—frontal lobe origin (tonic, clonic, tonic-clonic; jacksonian; benign childhood epilepsy; epilepsia partialis continua)
 - 2. Somatosensory or special sensory (visual, auditory, olfactory, gustatory, vertiginous)
 - 3. Autonomic
 - 4. Pure psychic
 - B. Complex (*with* impaired consciousness)
 - 1. Beginning as simple partial seizures and progressing to impairment of consciousness
 - 2. With impairment of consciousness at onset
- III. Special epileptic syndromes
 - A. Myoclonus and myoclonic seizures
 - B. Reflex epilepsy
 - C. Acquired aphasia with convulsive disorder
 - D. Febrile and other seizures of infancy and childhood
 - E. Hysterical seizures

ications and to some extent in prognosis. Basically, this classification divides seizures into two types—*partial*, in which a focal or localized onset can be discerned, and *generalized*, in which the seizures appear to begin bilaterally.

It is also useful clinically and etiologically to separate epilepsies that originate as truly generalized electrical discharges in the brain from those which spread secondarily from a focus to become generalized. The *primary generalized epilepsies* are a group of somewhat diverse, age-dependent phenotypes that are characterized by generalized 2.5- to 4-Hz bifrontally predominant spikes or polyspike-and-slow-wave discharges that arise without underlying structural abnormalities. In most instances, these individuals have normal intelligence. What is most significant is that a genetic component underlies many of these disorders (see below). By contrast, seizures that begin locally and evolve into generalized tonic-clonic seizures, termed *secondary generalized seizures*, generally have no such genetic component and are usually the result of underlying brain disease, either acquired or due to congenital malformations or metabolic defects. Quite often, the initial focal phase is missed, leading to misdiagnosis. Individuals with secondary generalized epilepsies tend to have more diffuse brain dysfunction and may have a progressive course. These seizures may be of different types, including atonic, myoclonic, and tonic-clonic seizures. An increas-

ing frequency and severity of this group of disorders with age reflects the accumulation of focal insults from trauma, strokes, and other damage.

Partial or focal seizures are further classified as *simple* when consciousness is undisturbed and *complex* when consciousness is altered or impaired. Simple partial seizures are further classified according to their main clinical manifestations—motor, sensory, autonomic, or psychic. When one of these subjective manifestations precedes the progression of the attack to a loss of consciousness, it is referred to as an *aura* and has commonly been regarded as a premonitory sign or warning of the impending seizure. In reality, the aura represents the initial phase of a focal seizure; in some instances it may constitute the entire epileptic attack.

Generalized seizures are of two types—*convulsive* and *non-convulsive*. The common convulsive type is the *tonic-clonic (grand mal) seizure*. Less common is a purely tonic, purely clonic, or clonic-tonic-clonic generalized seizure. The classic nonconvulsive generalized seizure is the brief lapse of consciousness or absence (*petit mal*); included also under this heading are minor motor phenomena such as brief myoclonic, atonic, or tonic seizures.

The classification of seizures and of the epilepsies is constantly being modified. In one of the latest versions, the so-called syndromic classification (*Epilepsia* 30:389, 1989), an attempt has been made to incorporate all of the seizure types and epileptic syndromes and to categorize them not only as partial and generalized but also according to their age of onset, their primary or secondary nature, the evidence of cortical loci of the epileptogenic lesions, and the many clinical settings in which they occur. This classification is semantically difficult and, in our view, too complicated as yet for general clinical application. Since many epileptic syndromes share overlapping features, it is often not possible to fit a newly diagnosed case of epilepsy into a specific category in this new classification (Manford et al). The commission is engaged in an extensive revision of terminology and classification in the field of epilepsy. Until this revision is widely adopted, we propose to begin our discussion with the 1981 classification of seizures, with certain modifications and additions, to be followed by a consideration of a number of well-defined epilepsies and epileptic syndromes.

In the discussions that follow, the various types of seizures are viewed largely in the context of the age at which they occur. An approximation of the distribution of the seizure types for each age epoch, obtained and aggregated from several sources, is shown in Fig. 16-1.

There has also been substantial progress in defining the molecular basis of familial and hereditary epilepsies over the last decade; it is highly likely that these new insights will lead to further modification of both the clinical classifications and the therapeutic management of the epilepsies (see further on).

GENERALIZED SEIZURES

The Generalized Tonic-Clonic Seizure (Grand Mal)

As has already been pointed out, it is important, whenever possible, to distinguish between a primary (generalized) type of seizure, with widespread EEG abnormalities at the onset, and a secondarily generalized type, which begins as a focal or partial seizure and then becomes generalized.

The patient sometimes senses the approach of a seizure by one of several subjective phenomena (a *prodrome*). For some hours, the patient may feel apathetic, depressed, irritable, or, very rarely, the opposite—ecstatic. One or more myoclonic jerks of the trunk or limbs on awakening may herald a seizure later in the day. In more than half the cases, there is some type of movement for a few seconds before consciousness is lost (turning of the head and eyes or whole body or intermittent jerking of a limb), although the patient fails to form a memory of this and such information is obtained only from an observer. Abdominal pains or cramps, a sinking, rising, or gripping feeling in the epigastrium, pallor or redness of the face, throbbing headache, constipation, or diarrhea have also been given prodromal status, but we have not found them consistently enough to be helpful.

Most often, the seizure strikes “out of the blue,” i.e., without warning, beginning with a sudden loss of consciousness and fall to the ground. The initial motor signs are a brief flexion of the trunk, an opening of the mouth and eyelids, and upward deviation of the eyes. The arms are elevated and abducted, the elbows semiflexed, and the hands pronated. These are followed by a more protracted extension (*tonic*) phase, involving first the back and neck, then the arms and legs. There may be a piercing cry as the whole musculature is seized in a spasm and air is forcibly emitted through the closed vocal cords. Since the respiratory muscles are caught up in the tonic spasm, breathing is suspended, and after some seconds the skin and mucous membranes may become cyanotic. The pupils are dilated and unreactive to light. The bladder may empty at this stage or later, during the postictal coma. This is the tonic phase of the seizure and lasts for 10 to 20 s.

There then occurs a transition from the tonic to the *clonic* phase of the convulsion. At first there is a mild generalized tremor, which is, in effect, a repetitive relaxation of the tonic contraction. It begins at a rate of eight per second and coarsens to four per second; then it rapidly gives way to brief, violent flexor spasms that come in rhythmic salvos and agitate the entire body. The face becomes violaceous and contorted by a series of grimaces, and often the tongue is bitten. Autonomic signs are prominent: the pulse is rapid, blood pressure is elevated, pupils are dilated, and salivation and sweating are abundant; bladder pressure may increase six-fold during this phase. The clonic jerks decrease in amplitude and frequency over a period of about 30 s. The patient remains apneic until the end of the clonic phase, which is marked by a deep inspiration. Instead of the whole dramatic sequence described above, the seizures may be abbreviated or limited in scope by anticonvulsive medications.

In the terminal phase of the seizure, all movements have ended and the patient lies still and limp, in a deep coma. The pupils, equal or unequal, now begin to contract to light. Breathing may be quiet or stertorous. This state persists for several minutes, after which the patient opens his eyes, begins to look about, and is obviously bewildered and confused and may be quite agitated. The patient may speak and later not remember anything that he said. Undis-

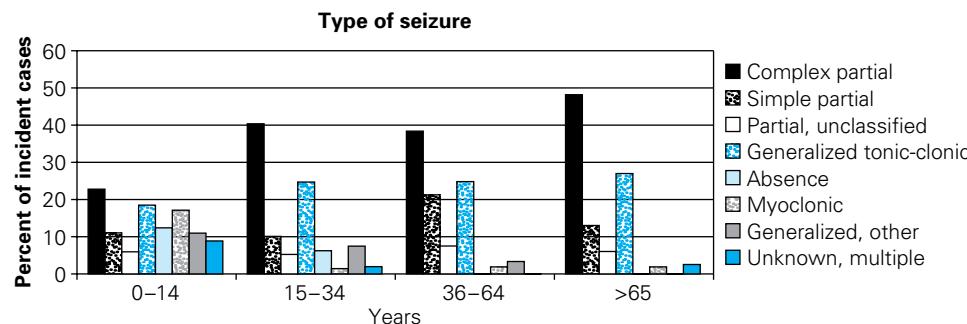

Figure 16-1. The distribution of the main types of epilepsy by age. Apparent is the overrepresentation of absence and myoclonic seizures in childhood and of complex partial seizures in older individuals. (Adapted from Hauser and Annegers and the texts of Engel and of Pedley.)

turbed, he becomes drowsy and falls asleep, sometimes for several hours, then sometimes awakens with a pulsatile headache. When fully recovered, such a patient has no memory of any part of the spell but knows that something has happened because of the strange surroundings (in ambulance or hospital); the obvious concern of those around him; and a sore, bitten tongue and aching muscles from the violent contractions. The latter, if violent enough, may crush a vertebral body or result in a serious injury; a fracture, periorbital hemorrhages, subdural hematoma, or burn may have been sustained in the fall.

Each of these phases of the generalized tonic-clonic seizure has its characteristic EEG accompaniment. Initially, movement artifacts obscure the EEG changes; sometimes there are repetitive spikes or spike-wave discharges lasting a few seconds, followed by an approximately 10-s period of 10-Hz spikes. As the clonic phase asserts itself, the spikes become mixed with slow waves and then the EEG slowly assumes a polyspike-and-wave pattern. When all movements have ceased, the EEG tracing is nearly flat for a variable time, and then the brain waves resume their preseizure pattern.

Convulsions of this type ordinarily come singly or in groups of two or three and may occur when the patient is awake and active or during sleep, or frequently when falling asleep or awakening. Some 5 to 8 percent of such patients will at some time have a prolonged series of such seizures without resumption of consciousness between them; this is called *convulsive status epilepticus* and demands urgent treatment. Sometimes the first outburst of seizures takes the form of convulsive status.

Few clinical states closely simulate a grand mal convolution, but several are worthy of mention. One is a clonic jerking of the extended limbs (usually less severe than those of a grand mal seizure) that occurs with vasodepressor syncope or a Stokes-Adams attack. In contrast to an epileptic type of EEG, the brain waves are slow and flat during the jerking movements. A rarer phenomenon that may be indistinguishable from a generalized convolution occurs as part of basilar artery occlusion (Ropper). This presumably has its basis in ischemia of the corticospinal tracts in the pons; a similar ischemic mechanism in the cortex has been invoked for “limb-shaking TIAs” (transient ischemic attacks), in which there are clonic movements of one limb or one side of the body during an episode of cerebral ischemia. Hysterical (nonepileptogenic, “psychogenic”) seizures, as discussed further on, are often difficult to distinguish from a true seizure. Rarely, in adults, an attack of panic (page 438) or the rare entity of rapid-eye-movement (REM) sleep

behavior disorder (page 343) may resemble a seizure. In infants, a breath-holding spell may resemble the tonic phase of a generalized seizure.

Idiopathic Nonconvulsive Seizures (Absence, Petit Mal)

In contrast to major generalized seizures, absence seizures (formerly referred to as *petit mal* or *pykno-epilepsy*) are notable for their brevity and the paucity of motor activity. Indeed, they may be so brief that the patients themselves are sometimes not aware of them; to an onlooker, they resemble a moment of absentmindedness or daydreaming. The attack, coming without warning, consists of a sudden interruption of consciousness, for which the French word *absence* ("not present," "not in attendance") has been retained. The patient stares and briefly stops talking or ceases to respond. Only about 10 percent of such patients are completely motionless during the attack; in the remainder, one observes a brief burst of fine clonic movements of the eyelids, facial muscles, or fingers or synchronous movements of both arms at a rate of three per second. This rate corresponds to that of the EEG abnormality, which takes the form of a generalized three-per-second spike-and-wave pattern (Fig. 2-3E, page 26). Minor automatisms—in the form of lip-smacking, chewing, and fumbling movements of the fingers—are common during an attack but do not assume prominence. Postural tone may be slightly decreased or increased, and occasionally there is a mild vasomotor disorder. As a rule, such patients do not fall; they may even continue such complex acts as walking or riding a bicycle. After 2 to 10 s, occasionally longer, the patient re-establishes full contact with the environment and resumes preseizure activity. Only a loss of the thread of conversation or the place in reading betrays the occurrence of the momentary "blank" period (the absence). In many such patients, voluntary hyperventilation for 2 to 3 min is an effective way of inducing absence attacks.

Typical absence seizures constitute the most characteristic epilepsy of childhood; rarely do the seizures begin before 4 years of age or after puberty. Another attribute is their great frequency (hence the old term *pykno*, meaning "compact" or "dense"). As many as several hundred may occur in a single day, sometimes in bursts at certain times of the day. Most often they relate to periods of inattention and may appear in the classroom when the child is sitting quietly rather than participating actively in his lessons. If frequent, they may disturb attention and thinking to the point that the child's performance in school is impaired. Such attacks may last for hours with no interval of normal mental activity between them—so-called *absence* or *petit mal status*. Small, subtle three-per-second myoclonic movements are the only motor display (myoclonic petit mal), and are accompanied by a continuous three-per-second spike-wave abnormality in the EEG. Most cases of absence status have been described in adults with frontal lobe epilepsy (see below). Such attacks may begin or end with a generalized tonic-clonic seizure or a burst of seizures.

Absence may be the only type of seizure during childhood. The attacks tend to diminish in frequency in adolescence and then often disappear, only to be replaced in many instances by major generalized seizures.

Absence or Petit Mal Variants To be distinguished from typical absence seizures are varieties in which the loss of consciousness is less complete or in which myoclonus is prominent, and others in

which the EEG abnormalities are less regularly of a 3-per-second spike-and-wave type (they may occur at the rate of 2 to 2.5 per second or take the form of 4- to 6-Hz polyspike-and-wave complexes). *Atypical petit mal* is a term that was coined to describe long runs of slow spike-and-wave activity, usually with no apparent loss of consciousness. External stimuli such as asking the patient to answer a question or to count will interrupt the run of abnormal EEG activity.

About one-third of children with absence attacks will, in addition, display symmetrical or asymmetrical myoclonic jerks without loss of consciousness, and about half will also at some time have major generalized (tonic-clonic) convulsions. As described further on, a common and relatively benign variety of myoclonic seizure occurs in late childhood and adolescence (*juvenile myoclonic epilepsy*).

In sharp contrast to the aforementioned epilepsies is a form that has its onset between 2 and 6 years of age and is characterized by atonic, or astatic, seizures (i.e., falling attacks), often succeeded by various combinations of minor motor, tonic-clonic, and partial seizures and by progressive intellectual impairment in association with a distinctive, slow (1- to 2-Hz) spike-and-wave EEG pattern. This is the *Lennox-Gastaut syndrome*. Often it is preceded in earlier life by infantile spasms, a characteristic EEG picture (3-Hz "hyparrhythmia"), and an arrest in mental development, a triad sometimes referred to as the *West syndrome* (see further on). The early onset of atonic seizures with abrupt falls, injuries, and associated abnormalities nearly always has a grave implication—namely, the presence of serious neurologic disease. Prematurity, perinatal injury, and metabolic diseases of infancy are the most common underlying conditions. This is essentially a symptomatic generalized epilepsy, in contrast to the foregoing idiopathic types. The Lennox-Gastaut syndrome may persist into adult life and is one of the most difficult forms of epilepsy to treat.

The notion that absence, myoclonic, and akinetic seizures constitute a petit mal triad, as originally proposed by Lennox, has been generally abandoned. Akinesia (motionlessness) is not unique to any seizure type. The typical absence, with or without myoclonic jerks, rarely causes the patient to fall and should be considered a separate entity because of its relative benignity.

Myoclonic Seizures

The phenomenon of myoclonus has already been discussed in Chap. 6, where the relationship to seizures was indicated. Characterized by a brusque, brief, muscular contraction, some myoclonic jerks are so small as to involve only one muscle or part of a muscle; others are so large as to implicate a limb on one or both sides of the body or the entire trunk musculature. Many are brief, lasting 50 to 100 ms. They may occur intermittently and unpredictably or present as a single jerk or a brief salvo.

As mentioned earlier, an outbreak of several small, rhythmic myoclonic jerks may appear with varying frequency as part of absence seizures and as isolated events in patients with generalized clonic-tonic-clonic or tonic-clonic seizures. As a rule, these types of myoclonus are quite benign and respond well to medication. In contrast, *disseminated myoclonus (polymyoclonus)*, having its onset in childhood, raises the suspicion of acute viral encephalitis, the myoclonus-opsoclonus-ataxia syndrome of Kinsbourne, lithium or other drug toxicity, or, if lasting a few weeks, subacute sclerosing panencephalitis. Chronic progressive polymyoclonus with dementia characterizes the group of juvenile lipidosis, Lafora-

type familial myoclonic epilepsy, certain mitochondrial disorders, or other chronic familial degenerative diseases of undefined type (paramyoclonus multiplex of Friedreich, dyssynergia cerebellaris myoclonica of Ramsay Hunt). In middle and late adult years, disseminated myoclonus joined with dementia usually indicates the presence of so-called Creutzfeldt-Jakob disease (page 653) and rarely of Alzheimer disease. A few late-onset cases of *Lafora disease* have been reported (Messouak et al), but this remains mainly a childhood process, autosomal recessive in transmission, characterized by a triad of progressive dementia, myoclonus, and episodes of generalized seizures, some of which are visual in nature. Intraneuronal cortical inclusions of amyloid are found, and similar inclusions are found in muscle, liver, and skin (polyglucosan body disease is another process associated with these changes). Myoclonus is usually the main manifestation of juvenile myoclonic epilepsy, as discussed below. Uremia at any age gives rise to myoclonus, twitching, and sometimes seizures. The large number of diseases causative of myoclonus and seizure disorders are discussed in Chaps. 33, 37, and 39.

Juvenile Myoclonic Epilepsy This is the most common form of idiopathic generalized epilepsy in older children and young adults. It begins in adolescence, typically about age 15, with a range that essentially spans all of the teenage years. The patient comes to attention because of a generalized seizure, often upon awakening or because of myoclonic jerks in the morning that involve the entire body; sometimes absence seizures are prominent. The family reports that the patient has occasional myoclonic jerks of the arm and upper trunk that become prominent with fatigue, during early stages of sleep, or after alcohol ingestion. A few patients in our experience have had only the myoclonic phenomena and rare absence seizures that persisted unnoticed for years. The EEG characteristically shows bursts of 4- to 6-Hz irregular polyspike activity. A linkage has been established to chromosome 6 in some cases of this illness and in some other forms of juvenile-onset epilepsy, but no mendelian pattern of inheritance has been established. The disorder does not impair intelligence and tends not to be progressive, but a proclivity to infrequent seizures usually continues throughout life. Valproic acid in particular and some other anticonvulsants have been highly effective in eliminating the seizures and myoclonus; they should be continued indefinitely.

PARTIAL OR FOCAL SEIZURES

As indicated earlier, the International Classification divides all seizures into two types—generalized (described above), in which the clinical and EEG manifestations indicate bilateral and diffuse cerebral cortical involvement from the onset, and focal or partial (more recently termed *localization-related*), in which the seizure is often the product of a demonstrable focal lesion or EEG abnormality in some part of the cerebral cortex (or perhaps in the diencephalon). As noted, partial seizures vary with the locale of the lesion and are conventionally divided into two groups, *simple* and *complex*, depending on whether consciousness is retained or impaired. Simple partial seizures most often arise from foci in the sensorimotor cortex. Complex partial seizures most often have their focus in the temporal lobe on one side or the other, but a frontal localization is also well known. The sites of the offending lesions and the types of seizures to which they give rise are listed in Table 16-2. These relationships are so helpful in diagnosis that they should be familiar to all neurologists.

Table 16-2
Common seizure patterns

CLINICAL TYPE	LOCALIZATION
<i>Somatic motor</i>	
Jacksonian (focal motor)	Prerolandic gyrus
Masticatory, salivation, speech arrest	Amygdaloid nuclei, opercular
Simple contraversive	Frontal
Head and eye turning associated with arm movement or athetoid- dystonic postures	Supplementary motor cortex
<i>Somatic and special sensory (auras)</i>	
Somatosensory	Contralateral postrolandic
Unformed images, lights, patterns	Occipital
Auditory	Heschl's gyri
Vertiginous	Superior temporal
Olfactory	Mesial temporal
Gustatory	Insula
Visceral: autonomic	Insular-orbital-frontal cortex
<i>Complex partial seizures</i>	
Formed hallucinations	Temporal neocortex or amygdaloid-hippocampal complex
Illusions	
Dyscognitive experiences (déjà vu, dreamy states, depersonalization)	
Affective states (fear, depression, or elation)	Temporal
Automatism (ictal and postictal)	Temporal and frontal
<i>Absence</i>	Frontal cortex, amygdaloid- hippocampal complex, reticular-cortical system
<i>Bilateral epileptic myoclonus</i>	Reticulocortical, frontocentral

Frontal Lobe Partial Seizures (Focal Motor and Jacksonian Seizures)

Focal or partial motor seizures are attributable to a discharging lesion of the opposite frontal lobe. The most common type, originating in the supplementary motor area, takes the form of a turning movement of the head and eyes to the side opposite the irritative focus, often associated with a tonic contraction of the trunk and limbs on that side. This may constitute the entire seizure, or it may be followed by generalized clonic movements; the extension of the seizure may occur just before or simultaneously with loss of consciousness. On the other hand, a lesion in one frontal lobe may give rise to a major generalized convulsion without an initial turning of the head and eyes. It has been postulated that in both types of seizure, the one with and the one without turning movements, there is an immediate spread of the discharge from the frontal lobe to integrating centers in the thalamic or high midbrain reticular formation, accounting for the loss of consciousness.

Seizures that begin with forceful, sustained deviation of the head and eyes, and sometimes of the entire body, are referred to as

versive or *adversive*. Since the turning movements are usually to the side opposite the irritative focus (sometimes to the same side), *contraversive* and *ipsiversive*, respectively, would be preferable terms. Nonforceful, unsustained, or seemingly random lateral head movements during the ictus do not have localizing value. The same is true for the head and eye turning that occurs at the end of the generalized tonic-clonic phase of *versive* seizures (Wylie et al). Contraversive deviation of only the head and eyes can be induced most consistently by electrical stimulation of the superolateral frontal region (area 8), just anterior to area 6 (see Fig. 22-1). Less dependably, the same movements can be obtained by stimulating the more anterior portions of the frontal cortex, or the supplementary motor area, and the temporal or occipital cortex—presumably through propagation of the ictal discharge to the frontal contraversive area. In seizures of temporal lobe origin, early in the seizure, there may be head turning ipsilaterally followed by forceful, contraversive head (and body) turning. These head and body movements, if they occur, are preceded by quiet staring and other automatisms.

The *jacksonian motor seizure* begins with a tonic contraction of the fingers of one hand, the face on one side, or the muscles of one foot. This transforms into clonic movements in these parts in a fashion analogous to that in a generalized clonic-tonic-clonic convulsion. Sometimes a series of clonic movements of increasing frequency build up to a tonic contraction. The movements may remain localized or spread (“march”) from the part first affected to other muscles on the same side of the body. In the latter, or “classic,” *jacksonian* form, which is relatively uncommon, the seizure spreads from the hand, up the arm, to the face, and down the leg; or, if the first movement is in the foot, the seizure marches up the leg, down the arm, and to the face, usually in a matter of 20 to 30 s. Interestingly, spontaneously occurring focal motor seizures, e.g., those beginning in the toes or fingers, may sometimes be arrested (inhibited) by applying a ligature above the affected part or, in the case of focal sensory seizures, by applying a vigorous sensory stimulus ahead of the advancing sensory aura. Rarely, the first muscular contraction is in the abdomen, thorax, or neck. In some cases, the one-sided seizure activity is followed by turning of the head and eyes to the convulsing side, occasionally to the opposite side, and then by a generalized seizure with loss of consciousness. Consciousness is not lost if the sensorimotor symptoms remain confined to one side.

Following convulsions that have a prominent focal motor signature, there may be a transient paralysis of the affected limbs. This “Todd’s paralysis” persists for minutes or at times for hours after the seizure, usually in proportion to the duration of the convulsion. Continued focal paralysis beyond this time usually indicates the presence of a focal brain lesion as the underlying cause of the seizure. A similar phenomenon is found in cases of focal epilepsy that involve the language, somesthetic, or visual areas; here the persistent deficit corresponds to the region of brain affected.

The high incidence of onset of focal motor epilepsy in the face, hands, and toes is probably related to the disproportionately large cortical representation of these parts. The disease process or focus of excitation is usually in or near the rolandic (motor) cortex, i.e., area 4 of Brodmann (Figs. 3-3 and 22-1); in some cases, and especially if there is a sensory accompaniment, it has been found in the postrolandic convolution. Lesions confined to the motor cortex are reported to assume the form of clonic contractions, and

those confined to the premotor cortex (area 6), tonic contractions of the contralateral arm, face, neck, or all of one side of the body. Tonic elevation and extension of the contralateral arm (“fencer’s posture”) and choreoathetotic and dystonic postures have been associated with high medial frontal lesions (area 8 and supplementary motor cortex), as have complex, bizarre, and flailing movements of a contralateral limb, but this always raises the suspicion of hysterical seizure. Perspiration and piloerection occur occasionally in parts of the body involved in a focal motor seizure, suggesting that these autonomic functions have a cortical representation in or adjacent to the rolandic area. Focal motor and *jacksonian* seizures have essentially the same localizing significance.

Seizure discharges arising from the cortical language areas may give rise to a brief aphasic disturbance (*ictal aphasia*) and ejaculation of a word, or, more frequently, a vocal arrest. Ictal aphasia is usually succeeded by other focal or generalized seizure activity but may occur in isolation, without loss of consciousness, in which case it can later be described by the patient. Postictal aphasia is more common and has much the same localizing value. Vocalization at the onset of a seizure has no such significance. These disturbances should be distinguished from the stereotyped repetition of words or phrases or the garbled speech that characterizes some cases of complex partial seizures or the postictal confusional state.

As pointed out by Manford and colleagues, relatively few focal seizures can be localized precisely from clinical data alone. However, when combined with scalp and intracranial EEG recording and MRI, the data are reasonably accurate.

Somatosensory, Visual, and Other Types of Sensory Seizures

Somatosensory seizures, either focal or “marching” to other parts of the body on one side, are nearly always indicative of a focus in or near the postrolandic convolution of the opposite cerebral hemisphere. Penfield and Kristiansen found the seizure focus in the postcentral or precentral convolution in 49 of 55 such cases. The sensory disorder is usually described as numbness, tingling, or a “pins-and-needles” feeling and occasionally as a sensation of crawling (formication), electricity, or movement of the part. Pain and thermal sensations may occur but are exceedingly rare. In the majority of cases, the onset of the sensory seizure is in the lips, fingers, or toes, and the spread to adjacent parts of the body follows a pattern determined by sensory arrangements in the postcentral (postrolandic) convolution of the parietal lobe. If the sensory symptoms are localized to the head, the focus is in or adjacent to the lowest part of the convolution, near the sylvian fissure; if the symptoms are in the leg or foot, the upper part of the convolution, near the superior sagittal sinus or on the medial surface of the hemisphere, is involved.

Visual seizures are relatively rare but also have localizing significance. Lesions in or near the striate cortex of the occipital lobe usually produce elemental visual sensations of darkness or sparks and flashes of light, which may be stationary or moving and colorless or colored. According to Gowers, red is the most frequently reported color, followed by blue, green, and yellow. These images may be referred to the visual field on the side opposite of the lesion or may appear straight ahead. If they occur on one side of the visual field, patients perceive that only one eye is affected (the one opposite the lesion), probably because most persons are aware of only

the temporal half of a homonymous field defect. Curiously, a seizure arising in one occipital lobe may cause momentary blindness in both fields. It has been noted that lesions on the lateral surface of the occipital lobe (Brodmann's areas 18 and 19) are likely to cause a sensation of twinkling or pulsating lights. More complex or formed visual hallucinations are usually due to a focus in the posterior part of the temporal lobe, near its junction with the occipital lobe, and may be associated with auditory hallucinations. The localizing value of visual auras has been confirmed recently by Bien and colleagues in a group of 20 surgically treated patients with intractable seizures. They found that elementary visual hallucinations and visual loss were typical of occipital lobe epilepsy but could also occur with seizure foci in the anteromedial temporal and occipitotemporal regions.

Auditory hallucinations are infrequent as an initial manifestation of a seizure. Occasionally a patient with a focus in one superior temporal convolution will report a buzzing or roaring in the ears. A human voice, sometimes repeating unrecognizable words, or the sound of music, has been noted a few times with lesions in the more posterior part of one temporal lobe.

Vertiginous sensations of a type suggesting a vestibular origin may on rare occasions be the first symptom of a seizure. The lesion is usually located in the superoposterior temporal region or the junction between parietal and temporal lobes. In one of the cases reported by Penfield and Jasper, a sensation of vertigo was evoked by stimulating the cortex at the junction of the parietal and occipital lobes. Occasionally with a temporal focus, the vertigo is followed by an auditory sensation. Giddiness, or light-headedness, is a frequent prelude to a seizure, but this symptom, as discussed in Chap. 15, has so many different connotations that it is of little diagnostic value.

Olfactory hallucinations are often associated with disease of the inferior and medial parts of the temporal lobe, usually in the region of the parahippocampal convolution or the uncus (hence Jackson's term *uncinate seizures*, pages 199 and 398). Usually the perceived odor is exteriorized, i.e., projected to someplace in the environment, and is described as disagreeable or foul, though otherwise unidentifiable. *Gustatory hallucinations* have also been recorded in proven cases of temporal lobe disease (see page 201) and with lesions of the insula and parietal operculum; salivation and a sensation of thirst may be associated. Electrical stimulation in the depths of the sylvian fissure, extending into the insular region, has produced peculiar sensations of taste.

Vague and often indefinable *visceral sensations* arising in the thorax, epigastrium, and abdomen are among the most frequent of auras, as already indicated. Most often they have a temporal lobe origin, although in several such cases the seizure discharge has been localized to the upper bank of the sylvian fissure; in a few others, the focus was located in the upper or middle frontal gyrus or in the medial frontal area near the cingulate gyrus. Palpitation and acceleration of the pulse at the beginning of the attack have also been related to a temporal lobe focus.

Complex Partial Seizures (Psychomotor Seizures, Temporal Lobe Seizures)

These differ from the major generalized and absence seizures discussed above in that (1) the aura (i.e., the initial event in the seizure) may be either a focal seizure of simple type or a hallucination or perceptual illusion, indicating (usually) a temporal lobe origin, and

(2) instead of a complete loss of control of thought and action, there is a period of altered behavior and consciousness, for which the patient is later found to be amnesic.

Although it is difficult to enumerate all the psychic experiences that may occur during complex partial seizures, they may be categorized into a somewhat arbitrary hierarchy of illusions, hallucinations, dyscognitive states, and affective experiences. Sensory illusions, or distortions of ongoing perceptions, are the most common. Objects or persons in the environment may shrink or recede into the distance, or they may enlarge (micropsia and macropsia), or persevere as the head is moved (palinopsia). Tilting of the visual environment has been reported. Hallucinations are most often visual or auditory, consisting of formed or unformed visual images, sounds, and voices; less frequently, they may be olfactory (usually unpleasant, unidentifiable sensations of smell), gustatory, or vertiginous. The term *dyscognitive* state refers to feelings of increased reality or familiarity (*déjà vu*) or of strangeness or unfamiliarity (*jamais vu*) or a sense of depersonalization. Fragments of certain old memories or scenes may insert themselves into the patient's mind and recur with striking clarity, or there may be an abrupt interruption of memory. (See Gloor for a more detailed description of the experiential phenomena of temporal lobe epilepsy.) Associated epigastric and abdominal sensations have been alluded to above.

Emotional experiences, while less common, may be dramatic—sadness, loneliness, anger, happiness, and sexual excitement have all been recorded. Fear and anxiety are the most common affective experiences, while occasionally the patient describes a feeling of rage or intense anger as part of a complex partial seizure. Ictal fear may have no apparent connection to objective experience and is generally not related to the situation in which the patient finds himself during the seizure.

Each of these subjective psychic states may constitute the entire seizure (simple partial seizure), or some combination may occur and proceed to a period of unresponsiveness. Patients call these "auras," but they represent electrical seizures and have the same significance as a motor convulsion. The motor components of the seizure, if they occur, do so during the latter phase and take the form of automatisms such as lip-smacking, chewing or swallowing movements, salivation, fumbling of the hands, or shuffling of the feet. Patients may walk around in a daze or act inappropriately (undressing in public, speaking incoherently, etc.). Certain complex acts that were initiated before the loss of consciousness—such as walking, chewing food, turning the pages of a book, or even driving—may continue. However, when asked a specific question or given a command, the patients are obviously out of contact with their surroundings. There may be no response at all, or the patient may look toward the examiner in a perplexed way or utter a few stereotyped phrases. In a very small number of patients with temporal lobe seizures (7 of 123 patients studied by Ebner et al), some degree of responsiveness (to simple questions and motor commands) is preserved in the presence of prominent automatisms such as lip-smacking and swallowing. Interestingly, in this small group of partially responsive patients, the seizures originate in the right temporal lobe.

The patient, in a confused and irritable state, may resist or strike out at the examiner. The *violence and aggression* that are said to characterize patients with temporal lobe seizures usually take this form of nondirected oppositional resistance in response to restraint during the period of automatic behavior (so called be-

cause the patient presumably acts like an automaton) or, more often, in the postictal period. Unprovoked assault or outbursts of intense rage or blind fury are very unusual; Currie and associates found such outbursts in only 16 of 666 patients (2.4 percent) with temporal lobe epilepsy. Penfield once commented that he had never observed a rage state as a result of temporal lobe stimulation. It is exceedingly unlikely that an organized violent act requiring several sequential steps in its performance, such as obtaining a gun and using it, could represent a temporal lobe seizure.

Rarely, laughter may be the most striking feature of an automatism (*gelastic epilepsy*). A particular combination of gelastic seizures and precocious puberty has been traced to a hamartoma of the hypothalamus. Or the patient may walk repetitively in small circles (*volvular epilepsy*), run (*epilepsia procursiva*), or simply wander aimlessly, either as an ictal or postictal phenomenon (*pioromania*). These forms of seizure are actually more common with frontal lobe than with temporal lobe foci. Dystonic posturing of the arm and leg contralateral to the seizure focus is found to be a frequent accompaniment if sought—again, the origin is more often in the frontal than the temporal lobes, localizing particularly to the supplementary motor area. After the attack, the patient usually has no memory or only fragments of recall for what was said or done. Any type of complex partial seizures may proceed to other forms of secondary generalized seizures. The tendency to generalization holds true for all types of partial or focal epilepsy.

The patient with temporal lobe seizures may exhibit only one of the foregoing manifestations of seizure activity or various combinations of them. In a series of 414 patients studied by Lennox, 43 percent displayed some of the motor changes; 32 percent, automatic behavior; and 25 percent, alterations in psychic function. Because of the frequent concurrence of these symptom complexes, he referred to them as the *psychomotor triad*. Probably the clinical pattern varies with the precise locality of the lesion and the direction and extent of spread of the electrical discharge. Because of their focal origin and complex symptomatology, all these types of seizures are best subsumed under the heading of *complex partial seizures*. This term is preferable to *temporal lobe seizures*, since typical complex partial seizures sometimes arise from a focus in the medial-orbital part of the frontal lobe. Also, seizures originating in the parietal or occipital lobes may be manifested as complex partial seizures because of seizure spread into the temporal lobes. Often the brief ictal aura is not reflected in cortical epileptic activity and therefore may be missed by routine surface EEG recordings.

Complex partial seizures are not peculiar to any period of life, but they do show an increased incidence in adolescence and the adult years. In the series of Ounsted and coworkers, about one-third of such cases could be traced to the occurrence of severe febrile convulsions in early life (see further on). As a corollary, about 5 percent of all their patients with febrile seizures continued to have seizures during adolescence and adult life; in the latter group there were many in whom the seizures were of the temporal lobe type. Also, in Falconer's series in which a temporal lobectomy was performed for intractable epilepsy, there were many patients who had previously had this complicated type of febrile seizure. Neonatal convulsions, head trauma, and various other nonprogressive perinatal neurologic disorders are antecedents that place a child at risk of developing complex partial seizures (Rocca et al). Two-thirds of patients with complex partial seizures also have generalized tonic-clonic seizures or have had them at some earlier time, and it has been theorized that the generalized seizures may have

led to secondary ischemic damage to the hippocampal portions of the temporal lobes. In the latter cases, carefully performed and quantitated MRI in the coronal plane may disclose a loss of volume in the hippocampi and adjacent gyri on one or both sides—i.e., *medial temporal sclerosis* (Fig. 16-2).

Complex partial seizures are notably variable in duration. Behavioral automatisms rarely last longer than a minute or two, although postictal confusion and amnesia may persist for a considerably longer time. Some complex partial seizures consist only of a momentary change in facial expression and a blank spell, resembling an absence. Almost always, however, the former are characterized by distinct ictal and postictal phases, whereas patients with absence attacks usually have an instantaneous return of full consciousness following the ictus.

Postictal behavior after partial complex seizures is often accompanied by widespread slowing in the EEG. With seizures of left-sided origin there is likely to be global and nonfluent aphasia. Prolonged disorientation for time and place suggests a right-sided source. Automatisms in the postictal period have no lateralizing connotation (Devinsky et al). However, postictal posturing and paresis of an arm (*Todd's paralysis*) or an aphasic difficulty are helpful in determining the side of the lesion (Cascino). Also, postictal nose wiping is carried out by the hand ipsilateral to the seizure focus in 97 percent of patients, according to Leutzezer and colleagues, but we are in no position to confirm this.

Amnesic Seizures Rarely, brief, recurrent attacks of transient amnesia are the only manifestations of temporal lobe epilepsy, although it is unclear whether the amnesia in such patients represents an ictal or postictal phenomenon. These attacks of pure amnesia have been referred to as *transient epileptic amnesia*, or TEA (Palmini et al; Zeman et al). If the patient functions at a fairly high level during the attack, as may happen, there is some resemblance to transient global amnesia (page 379). However, the brevity and frequency of the TEA spells, their tendency to occur on awakening, the impaired performance on complex cognitive tasks, and, of course, a history of epilepsy and associated seizure discharges in the EEG help to make the distinction.

Behavioral and Psychiatric Disorders Some comments are in order concerning the issues of *personality*, *behavioral*, and *psychiatric disorders* in patients with complex partial seizures. Data as to prevalence of these disorders are limited and have been derived mainly from studies of selected groups of patients attending university hospitals and other specialty clinics that tend to treat the most difficult and complicated cases. In one such study (Victoroff), about one-third of the patients had a history of major depressive illness, and an equal number had symptoms of anxiety disorder; psychotic symptoms were found in 10 percent. Similar figures, also from a university-based epilepsy center, have been reported by Blumer et al. It must be emphasized that these remarkable rates of psychiatric morbidity do not reflect the prevalence in the entire population of epileptics.

The postictal state in patients with temporal lobe epilepsy sometimes takes the form of a protracted *paranoid-delusional* or *amnesic psychosis* lasting for days or weeks. The EEG during this period may show no seizure discharge, though this does not exclude repeated or sustained seizure activity in the amygdala and other deep temporal lobe structures. This disorder, virtually indistinguishable from schizophrenia in form (but not in temporal evolution), may also present in the interictal period. An excess of psy-

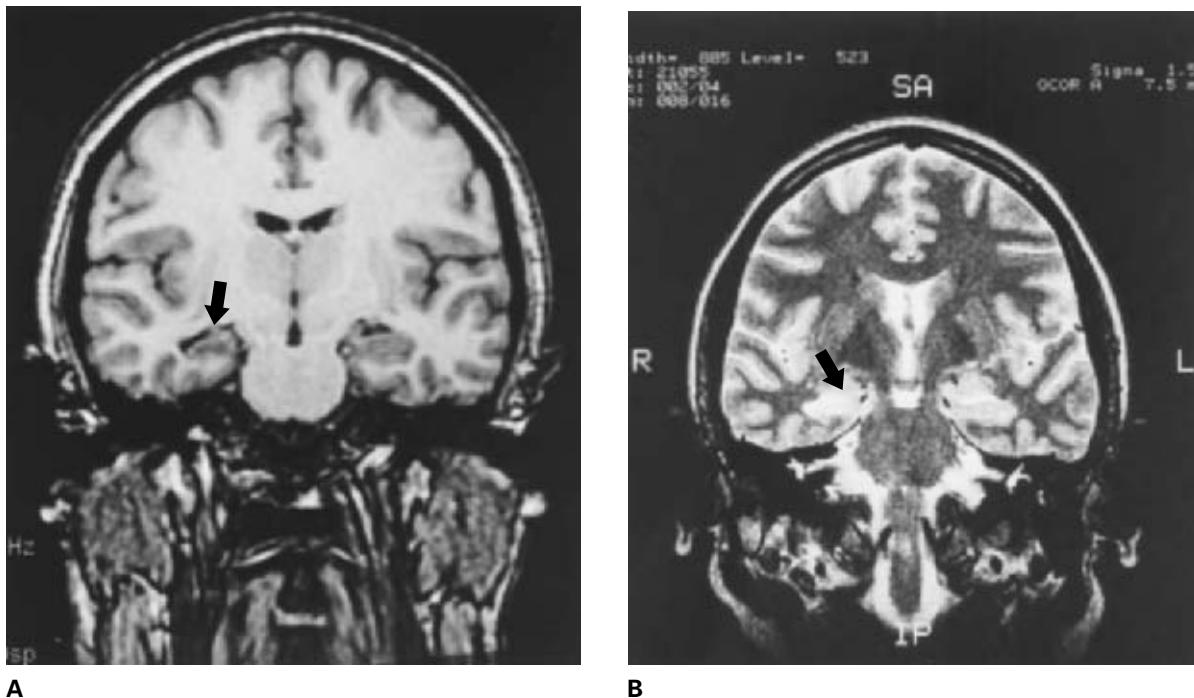

Figure 16-2. Medial temporal sclerosis. *A*, Thin-slice volumetric MRI in the coronal plane, showing shrinkage of the right hippocampus (shown by arrow) and secondary enlargement of the temporal horn of the lateral ventricle. *B*, T2-weighted image showing signal change in the hippocampi (shown by arrow). (Courtesy of Dr. Peter Williamson.)

chosis has been reported only in studies emanating from specialized centers; epidemiologic studies provide only limited evidence of an association with psychosis in the overall population of epileptics (see Trimble and Schmitz and the review by Trimble for a critical discussion of this subject). Again, the frequency of this association with temporal lobe epilepsy is uncertain.

Epileptic Personality Disorder It has long been observed that some patients with temporal lobe seizures may exhibit a number of abnormalities of behavior and personality during the interictal period. Often they are slow and rigid in their thinking, verbose, circumstantial and tedious in conversation, inclined to mysticism, and preoccupied with rather naive religious and philosophical ideas. Also, they are often subject to outbursts of bad temper and aggressiveness. Obsessionalism, humorless sobriety, emotionality (mood swings, sadness and anger), and a tendency to paranoia are other frequently described traits. Diminished sexual interest and potency in men and menstrual problems in women, not readily attributable to anticonvulsant drugs, are common among patients with complex partial seizures of temporal lobe origin. Geschwind proposed that a triad of behavioral abnormalities—hyposexuality, hypergraphia, and hyperreligiosity—constitute a characteristic syndrome in such patients.

Bear and Fedio have suggested that certain of these traits (obsessionalism, elation, sadness, and emotionality) are more common with *right* temporal lesions and that anger, paranoia, and cosmologic or religious conceptualizing are more characteristic of *left* temporal lesions. However, Rodin and Schmaltz, who administered the Bear-Fedio inventory to patients with both primary generalized and temporal lobe epilepsy, found no features that would distinguish patients with right-sided temporal foci from those with left-sided ones. Moreover, they found no behavioral changes that

would distinguish patients with temporal lobe epilepsy from other groups of epileptics. The problem of personality disturbances in epilepsy remains to be clarified (see review by Trimble).

SPECIAL EPILEPTIC SYNDROMES

There remain to be considered several epileptic syndromes and other seizure states that cannot be readily classified with the usual types of generalized or partial seizures. These special types are described below.

Benign Childhood Epilepsy with Centrotemporal Spikes (Rolandic Epilepsy, Sylvian Epilepsy) and Epilepsy with Occipital Spikes

This type of focal motor epilepsy is unique among the partial epilepsies of childhood in that it tends to be a self-limited disorder, transmitted in families as an autosomal dominant trait. The convulsive disorder begins between 5 and 9 years of age and usually announces itself by a nocturnal tonic-clonic seizure with focal onset. Thereafter, the seizures take the form of clonic contractions of one side of the face, less often of one arm or leg, and the interictal EEG shows high-voltage spikes in the contralateral lower rolandic or centrotemporal area. The seizures are readily controlled by a single anticonvulsant drug and gradually disappear during adolescence. The relation of this syndrome to acquired aphasia with convulsive disorder in children, described by Landau and Kleffner, is unsettled.

A similar type of epilepsy, usually benign in the sense that there is no intellectual deterioration and a cessation of seizures in adolescence, has been associated with spike activity over the oc-

capital lobes, as identified by Panayiotopoulos. As described in the review by Taylor and colleagues, visual hallucinations, while not invariable, are the most common clinical feature; sensations of movements of the eyes, tinnitus, or vertigo are also reported in cases of occipital epilepsy. These authors point out symptomatic causes of the syndrome, such as cortical heterotopias. In both of these types of childhood epilepsy, the observation that spikes are greatly accentuated by sleep is a useful diagnostic aid.

Infantile Spasms (West Syndrome)

This is the term applied to a particular form of epilepsy of infancy and early childhood. West, in the mid-nineteenth century, described the condition in his son in exquisite detail. This seizure disorder, which in most cases appears during the first year of life, is characterized by recurrent, single or brief episodes of gross flexion movements of the trunk and limbs and, less frequently, by extension movements (hence the alternative terms *infantile spasms* or *salaam* or *jackknife seizures*). Most but not all patients with this disorder show severe EEG abnormalities, consisting of continuous multifocal spikes and slow waves of large amplitude. However, this pattern, referred to originally by Gibbs and Gibbs as *hypsrhythmia* ("mountainous" dysrhythmia), is not specific for infantile spasms, being frequently associated with other developmental or acquired abnormalities of the brain. As the child matures, the seizures diminish; they usually disappear by the fourth to fifth year. If MRI and computed tomography (CT) scans are more or less normal, the usual pathologic findings according to Jellinger are cortical dysgeneses. Both the seizures and the EEG abnormalities may respond dramatically to treatment with adrenocorticotropic hormone (ACTH), corticosteroids, or the benzodiazepine drugs, of which clonazepam is probably the most widely used. However, most patients, even those who were apparently normal when the seizures appeared, are left mentally impaired. Infantile spasms may also be part of the *Lennox-Gastaut syndrome*, a seizure disorder of early childhood of grave prognosis (see page 274).

Febrile Seizures

The well-known *febrile seizure*, peculiar to infants and children between 6 months and 5 years of age (peak incidence 9 to 20 months) and with a strong tendency to be inherited, is generally regarded as a benign condition. Usually it takes the form of a single, generalized motor seizure occurring as the temperature rises or reaches its peak. Seldom does the seizure last longer than a few minutes; by the time an EEG can be obtained, there is usually no abnormality. Recovery is complete. Except for a presumed genetic relationship with benign epilepsy of childhood (Luders et al), which in itself is transient in nature, these patients' risk of developing epilepsy in later life is only slightly greater than that of the general population. In some families, such as those studied by Nabuout and colleagues, febrile seizures alone, without generalized epilepsy, have been associated with a particular gene defect by linkage analysis. Presumably, when the gene product is identified, some insight into the nature of defects that lower the seizure threshold will be forthcoming.

This benign type of febrile seizure should not be confused with a second and more serious type of illness in which an acute encephalitic or encephalopathic state presents during a febrile illness with focal or prolonged seizures, generalized or focal EEG abnormalities, and repeated episodes of febrile convulsions with

the same or different illnesses (*complicated febrile seizures*). These seizures may recur not only with infections but also at other times. When patients with both types are lumped together under the rubric of *febrile convulsions*, it is not surprising that a high percentage are complicated by atypical petit mal, atonic, and astatic spells followed by tonic seizures, mental retardation, and partial complex epilepsy. Falconer, who studied psychomotor seizures in adults, noted retrospectively a high incidence of "febrile seizures" during the infancy and childhood in his cohort of surgical subjects. The present authors believe that he was referring to complicated febrile seizures, i.e., fever and convulsions with structural brain disease, which should be kept separate from the common benign febrile seizures. In a later study of 67 patients with proven medial temporal lobe epilepsy (French et al), 70 percent had a history of complicated febrile seizures during the first 5 years of life, although many did not develop temporal lobe epilepsy until their teens. Bacterial meningitis was another important risk factor; head and birth trauma were less common factors. All of the patients had complex partial seizures and half of them, in addition, had secondarily generalized tonic-clonic seizures.

Epidemiologic studies have substantiated this clinical point of view. Annegers and colleagues observed a cohort of 687 children for an average of 18 years after their initial febrile convolution. Overall, these children had a fivefold excess of unprovoked seizures in later life. Among the children with simple febrile convulsions, the risk was only 2.4 percent. By contrast, children with what Annegers et al called complex febrile convulsions (focal, prolonged, or repeated episodes of febrile seizures) had a greatly increased risk—8, 17, or 49 percent, depending on the association of one, two, or three of the complicating features.

Reflex Epilepsy

For a long time it has been known that seizures could be evoked in certain epileptic individuals by a discrete physiologic or psychologic stimulus. The term *reflex epilepsy* is reserved for this small subgroup. Forster has classified these seizures in accordance with their evocative stimuli into five types: (1) *visual*—flickering light, visual patterns, and specific colors (especially red), leading to rapid blinking or eye closure; (2) *auditory*—sudden unexpected noise (startle), specific sounds, musical themes, and voices; (3) *somatosensory*—either a brisk unexpected tap or sudden movement after sitting or lying still, or a prolonged tactile or thermal stimulus to a certain part of the body; (4) *writing or reading* of words or numbers; and (5) *eating*.

Visually induced seizures are by far the most common type of reflex epilepsy. The seizures are generalized and are most often triggered by the photic stimulation of television or an EEG examination or by the photic or pattern stimulation of video games. In other types of reflex epilepsy, the evoked seizure may be focal (beginning often in the part of the body that was stimulated) or generalized and may take the form of one or a series of myoclonic jerks or of an absence or tonic-clonic seizure. Seizures induced by reading, voices, or eating are most often of the complex partial type; seizures induced by music are usually myoclonic. A few such instances of reflex epilepsy have been due to focal cerebral disease, particularly occipital lesions.

Clonazepam, valproate, carbamazepine, and phenytoin are all effective in controlling individual instances of reflex epilepsy. Some patients learn to avert the seizure by undertaking a mental task, e.g., thinking about some distracting subject, counting, etc.,

or by initiating some type of physical activity. Forster has demonstrated that in certain types of reflex epilepsy, the repeated presentation of the noxious stimulus may eventually render the stimulus innocuous. This technique requires a great deal of time and assiduous reinforcement, which limits its therapeutic value.

Epilepsia Partialis Continua

This is another special type of focal motor epilepsy characterized by persistent rhythmic clonic movements of one muscle group—usually of the face, arm, or leg—which are repeated at fairly regular intervals every few seconds and continue for hours, days, weeks, or months without spreading to other parts of the body. Thus epilepsia partialis continua is, in effect, a highly restricted and very persistent focal motor status epilepticus. The distal muscles of the leg and arm, especially the flexors of the hand and fingers, are affected more frequently than the proximal ones. In the face, the recurrent contractions involve either the corner of the mouth or one or both eyelids. Occasionally, isolated muscles of the neck or trunk are affected on one side. The clonic spasms may be accentuated by active or passive movement of the involved muscles and may be reduced in severity but not abolished during sleep.

First described by Kozhevnikov in patients with Russian spring-summer encephalitis, these partial seizures may be induced by a variety of acute or chronic cerebral lesions. In some cases the underlying disease is not apparent (this applies to about half of our cases), and the clonic movements may be mistaken for some type of slow tremor or extrapyramidal movement disorder. Most patients with epilepsia partialis continua show focal EEG abnormalities, either repetitive slow-wave abnormalities or sharp waves or spikes over the central areas of the contralateral hemisphere. In some cases, the spike activity can be related precisely in location and time to the clonic movements (Thomas et al). In the series of cases collected by Obeso and colleagues, there were various combinations of epilepsia partialis continua and cutaneous reflex myoclonus (cortical myoclonus occurring only in response to a variety of afferent stimuli); these investigators view epilepsia partialis continua as part of a spectrum of motor disorders that also includes stimulus-sensitive myoclonus, focal motor seizures, and grand mal seizures.

As would be expected, a wide range of causative lesions has been implicated—developmental anomalies, encephalitis, demyelinative diseases, brain tumors, and degenerative diseases; but in many instances, as mentioned, the underlying cause is not found even after extensive investigation. Epilepsia partialis continua has been particularly common in patients with Rasmussen encephalitis (page 289). As a rule, this type of seizure activity responds poorly or not at all to anticonvulsant medications, but there is little alternative other than to try several drugs in combination. Surgical extirpation or circumscription of the discharging cortex is a last resort.

Whether cortical mechanisms or subcortical ones are responsible for epilepsia partialis continua is an unresolved question. The electrophysiologic evidence adduced by Thomas and colleagues favors a cortical origin. The pathologic evidence is less definite. In each of eight cases in which the brain was examined postmortem, they found some degree of involvement of the motor cortex or adjacent cortical area contralateral to the affected limbs. However, all but one of these patients also had some involvement of deeper structures on the same side as the cortical lesion, on the opposite side, or on both sides.

Hysterical Seizures

These episodes, referred to as “psychogenic” seizures, are non-epileptic in nature—i.e., they are not caused by an abnormal neuronal discharge. They are mentioned here because they are quite common and frequently mistaken for epileptic seizures and treated with anticonvulsant drugs, to which they are characteristically unresponsive. Such seizures are most often a symptom of hysteria in the female (*Briquet disease*) or of compensation neurosis and malingering in males and females, in which case the terms *sham seizures* and *pseudoseizures* are appropriate. Of course, patients with true epileptic seizures sometimes exhibit hysterical seizures as well, and distinguishing the two may be difficult. Usually, however, the motor display in the course of a nonepileptic seizure is sufficient to identify it as such: completely asynchronous thrashing of the limbs and repeated side-to-side movements of the head; striking out at a person who is trying to restrain the patient; hand-biting, kicking, trembling, and quivering; pelvic thrusting and opisthotonic arching postures; and screaming or talking during the ictus. In general, pseudoseizures tend to occur in the presence of other people, to be precipitated by emotional factors, and to be prolonged for many minutes or hours; with few exceptions, tongue-biting, incontinence, hurtful falls, or postictal confusion are lacking. No single one of these features is determinative, however.

Prolonged *fugue states* in our practice usually have proved to be manifestations of hysteria or a psychopathy even in a known epileptic. The serum creatine kinase and prolactin levels are normal after hysterical seizures; this may be helpful in distinguishing them from genuine convulsions. Where doubt remains, a recording of the ictal or postictal EEG or the combined video and EEG recording of an attack will settle the issue. This subject is discussed further in Chap. 56.

THE NATURE OF THE DISCHARGING LESION

Physiologically, the epileptic seizure has been defined as a sudden alteration of central nervous system (CNS) function resulting from a paroxysmal high-frequency or synchronous low-frequency, high-voltage electrical discharge. This discharge arises from an assemblage of excitable neurons in any part of the cerebral cortex and possibly in secondarily involved subcortical structures as well. Of course, there need not be a visible lesion. In the proper circumstances, a seizure discharge can be initiated in an entirely normal cerebral cortex, as when the cortex is activated by ingestion or injection of drugs, by withdrawal from alcohol or other sedative drugs, or by repeated stimulation with subconvulsive electrical pulses (“kindling phenomenon”).

Viewed from a larger physiologic perspective, seizures require three conditions: (1) a population of pathologically excitable neurons; (2) an increase in excitatory glutaminergic activity through recurrent connections in order to spread the discharge; and (3) a reduction in the activity of the normally inhibitory GABA-nergic projections. The last of these has been challenged, but it is supported by considerable data and serves as a reasonable model, as noted below. Understanding of the initial discharges and their spread has been greatly advanced by the identification of several rare forms of familial epilepsy that are the direct result of mutations in sodium, potassium, acetylcholine receptor, or GABA channels on neurons. These are discussed further under “Genetics of Epilepsy.”

Just why the neurons in or near a focal cortical lesion discharge abnormally is not fully understood. Some of the electrical properties of a cortical epileptogenic focus suggest that its neurons have been deafferented. Such neurons are known to be hyperexcitable, and they may remain so chronically, in a state of partial depolarization, able to fire irregularly at rates as high as 700 to 1000 per second. The cytoplasmic membranes of such cells appear to have an increased ionic permeability, which renders them susceptible to activation by hyperthermia, hypoxia, hypoglycemia, hypocalcemia, and hyponatremia as well as by repeated sensory (e.g., photic) stimulation and during certain phases of sleep (where *hypersynchrony* of neurons is known to occur).

As an example, epileptic foci induced in the animal cortex by the application of penicillin are characterized by spontaneous interictal discharges, during which the neurons of the discharging focus exhibit large, presumably Ca-mediated paroxysmal depolarizing shifts (PDSs), followed by prolonged after-hyperpolarizations (AHPs). The latter also are due in part to Ca-dependent K currents but are better explained by enhanced synaptic inhibition. The PDSs occur synchronously in the penicillin focus and summate to produce surface-recorded interictal EEG spikes; the AHPs correspond to the slow wave of the EEG spike-and-wave complex (Engel). The neurons surrounding the epileptogenic focus are hyperpolarized from the beginning and are inhibitory and release gamma aminobutyric acid. Seizure spread probably depends on any factor or agent that activates neurons in the focus or inhibits those surrounding it. The precise mechanisms that govern the transition from a circumscribed interictal discharge to a widespread seizure state are not understood.

Biochemical studies of neurons from a seizure focus have not greatly clarified the problem. Levels of extracellular K are found to be elevated in glial scars near epileptic foci, and a defect in voltage-sensitive Ca channels has also been postulated. Epileptic foci are known to be sensitive to acetylcholine and to be slower in binding and removing it than is normal cerebral cortex. A deficiency of the inhibitory neurotransmitter GABA, increased glycine, decreased taurine, and either decreased or increased glutamic acid have been variously reported in excised human epileptogenic tissue, but whether these changes are the cause or result of seizure activity has not been determined. The interpretation of reported abnormalities of GABA, biogenic amines, and acetylcholine in the cerebrospinal fluid (CSF) of epileptic patients poses similar difficulties.

Concurrent EEG recordings from an epileptogenic cortical focus and subcortical, thalamic, and brainstem centers in the animal model have enabled investigators to construct a sequence of electrical and clinical events that characterize an evolving focal seizure. Firing of the involved neurons in the cortical focus is reflected in the EEG as a series of periodic spike discharges, which increase progressively in amplitude and frequency. Once the intensity of the seizure discharge exceeds a certain point, it overcomes the inhibitory influence of surrounding neurons and spreads to neighboring cortical regions via short corticocortical synaptic connections. If the abnormal discharge remains confined to the cortical focus and the immediate surrounding cortex, there are probably no clinical symptoms or signs of seizure, and the EEG abnormality that persists during the interseizure period reflects this restricted type of abnormal cortical activity. A provocative new finding, based on sophisticated mathematical analysis of EEG tracings, demonstrates subtle electrographic changes up to several minutes before the ictal discharge (see LeVan Quyen

et al). This suggests that seizures are triggered either by a change in central thalamic rhythm generators or a subtle change in the electrical activity in the region of a focal lesion. The clinical utility of this finding has not been determined. Even more provocative are the findings of Litt and colleagues; using complex techniques in a small number of patients, they have detected prolonged bursts of seizure-like activity days before the onset of temporal lobe seizures. Their unconventional proposal is that these events cause a cascade of electrophysiologic changes that very gradually culminate in a seizure.

If unchecked, cortical excitation spreads to the adjacent cortex and to the contralateral cortex via interhemispheric pathways and also to anatomically and functionally related pathways in subcortical nuclei (particularly the basal ganglionic, thalamic, and brainstem reticular nuclei). It is at this time that the clinical manifestations of the seizure begin, the initial signs and symptoms depending on the portion of the brain from which the seizure originates. The excitatory activity from the subcortical nuclei is fed back to the original focus and to the other parts of the forebrain, a mechanism that serves to amplify their excitatory activity and to give rise to the characteristic high-voltage polyspike discharge in the EEG. There is propagation downward to spinal neurons as well, via corticospinal and reticulospinal pathways, yielding a generalized tonic-clonic convulsion.

The spread of excitation to the subcortical, thalamic, and brainstem centers is thought to correspond to the tonic phase of the seizure and loss of consciousness as well as to the signs of autonomic nervous system overactivity (salivation, mydriasis, tachycardia, increase in blood pressure). Vital functions may be arrested, but usually for only a few seconds. In rare instances, however, death may occur owing to a sustained cessation of respiration, a derangement of cardiac action, or some unknown cause. The development of unconsciousness and the generalized tonic contraction of muscles is reflected in the EEG by a diffuse high-voltage discharge pattern appearing simultaneously over the entire cortex.

Soon after the spread of excitation, a diencephalocortical inhibition begins and intermittently interrupts the seizure discharge, changing it from the persistent discharge of the tonic phase to the intermittent bursts of the clonic phase. Electrically, a transition occurs from a continuous polyspike to a spike-and-wave pattern. The intermittent clonic bursts become less and less frequent and finally cease altogether, leaving in their wake an "exhaustion" (paralysis) of the neurons of the epileptogenic focus and a regional increase in permeability of the blood-brain barrier. An overshoot of these inhibitory mechanisms is thought to be the basis of *Todd's post-epileptic paralysis* (and of postictal stupor, sensory loss, aphasia, hemianopia, headache, and diffuse slow waves in the EEG, as described earlier) and regional edema in T2-weighted MR images. Plum and associates have observed a two- to threefold increase in glucose utilization during seizure discharges and suggested that the paralysis that follows might be due to neuronal depletion of glucose and increase in lactic acid. However, inhibition of epileptogenic neurons may occur in the absence of neuronal exhaustion. The exact roles played by each of these factors in postictal paralysis of function are not settled.

Bilaterally synchronous three-per-second high-voltage spike-and-wave discharges and seizures resembling absence attacks have been produced in animals by a number of experimental procedures. The spike-and-wave complex, which represents brief excitation followed by slow-wave inhibition, is the type of EEG pattern that

characterizes the clonic (inhibitory) phase of the focal motor or grand mal seizure. By contrast, this strong element of inhibition is present diffusely throughout an “absence” attack, a feature that perhaps accounts for the failure of excitation to spread to lower brainstem and spinal structures (tonic-clonic movements do not occur). However, the absence seizure can also at times activate the mechanism for rhythmic myoclonus, probably at an upper brainstem level.

Current physiologic data indicate that the characteristic EEG patterns of both generalized forms of epilepsy (i.e., tonic or tonic-clonic and absence) are generated in the neocortex and are enhanced by the synchronizing influences of subcortical structures. In both instances, the generalization of the clinical and electrical manifestations depends upon activation of a deep, centrally located physiologic mechanism, which, for reasons outlined in Chap. 17, includes the midbrain reticular formation and its diencephalic extension, the intralaminar and nonspecific thalamic projection systems (originally referred to by Penfield as the “centrencephalon”). There is no evidence, however, that seizure activity originates in these deep activating structures; therefore the term *centrencephalic epilepsy* has been replaced by *corticoreticular epilepsy*.

Complex partial seizures are almost always of temporal lobe origin, arising in foci in the medial temporal lobe, amygdaloid nuclei, and hippocampus. Only rarely do they originate in the convexity of the temporal lobe and propagate to the amygdaloid nuclei, hippocampus, and posteroinferior parts of the frontal lobe. Electrical stimulation in these areas reproduces feelings of depersonalization, emotionality, and automatic behavior, the characteristic features of psychomotor epilepsy. The automatic behavior appears to be a direct effect of the temporal lobe discharge in some instances and a postexcitatory or inhibitory effect in others. Loss of memory for the events of the episode may be due to the paralytic effect of the discharge on neurons of the hippocampus.

Of theoretical importance is the observation that a seizure focus, if active for a time, may sometimes establish, via commissural connections, a persistent secondary focus in the corresponding cortical area of the opposite hemisphere (*mirror focus*). The nature of this phenomenon is obscure; it may be similar to the “kindling” phenomenon mentioned earlier in animals, where a repeated non-convulsive electrical stimulation of normal cortex induces a permanent epileptic focus. No morphologic change is visible in the mirror focus, at least by light microscopy. The mirror focus may be a source of confusion in trying to identify the side of the primary lesion by EEG, but there is little evidence that it can produce chronic seizures in humans. Similarly, there are no firm data supporting a role for kindling in the diagnosis and management of patients with epilepsy (Goldensohn).

Severe seizures may be accompanied by a systemic lactic acidosis with a fall in arterial pH, reduction in arterial oxygen saturation, and rise in PCO_2 . These effects are secondary to the respiratory arrest and excessive muscular activity. If prolonged, they may cause hypoxic-ischemic damage to remote areas in the cerebrum, basal ganglia, and cerebellum. In paralyzed and artificially ventilated subjects receiving electroconvulsive therapy, these changes are less marked and the oxygen tension in cerebral venous blood may actually rise. Heart rate, blood pressure, and particularly CSF pressure rise briskly during the seizure. According to Plum and colleagues, the rise in blood pressure evoked by the seizure usually causes a sufficient increase in cerebral blood flow to meet the increased metabolic needs of the brain.

The Electroencephalogram in Epilepsy

(See also Chap. 2.)

The EEG provides confirmation of Hughlings Jackson’s concept of epilepsy—that it represents a recurrent, sudden, excessive discharge of cortical neurons. The EEG is undoubtedly the most sensitive, indeed indispensable, tool for the diagnosis of epilepsy; but like other ancillary tests, it must be used in conjunction with clinical data. In patients with idiopathic generalized seizures and in a high proportion of their relatives, interictal spike-and-wave abnormalities without any clinical seizure activity are common, especially if the EEG is repeated several times. Contrariwise, a proportion of epileptic patients have a perfectly normal interictal EEG; occasionally, using standard methods of scalp recording, the EEG may even be normal during a simple or complex partial seizure. Furthermore, a small number of healthy persons (approximately 2 to 3 percent) show paroxysmal EEG abnormalities; some of them have a family history of epilepsy (particularly of absence seizures) and may themselves later develop seizures.

EEG abnormalities that characterize a spreading epileptogenic focus and generalization of seizure activity, both the grand mal and absence types, have been described in the preceding section and are illustrated in Chap. 2. At first there was thought to be a characteristic EEG picture for seizures, but further studies have not confirmed this, many patterns being possible. One consistent observation, however, has been that the region of earliest spike activity corresponds best to the epileptogenic focus. This rule guides epilepsy surgery. The postseizure or postictal state following generalized seizures also has its EEG correlate, taking the form of random generalized slow waves. Following partial or focal seizures, the EEG shows focal slowing. With clinical recovery, the EEG returns to normal or to the preseizure state. A single EEG tracing obtained during the interictal state is abnormal to some degree in 30 to 50 percent of epileptic patients; this figure rises to 60 to 70 percent if patients are subjected to three or more studies utilizing standard activating measures (hyperventilation, photic stimulation, and sleep; see Chap. 2). With structural lesions, focal slow and sharp activity, which is not clearly epileptiform, may be the only clue to a seizure focus.

A higher yield of abnormalities and a more precise definition of seizure types can be obtained by the use of several special EEG procedures. Overnight EEG recording is particularly helpful because focal abnormalities, particularly in the temporal lobes, may become prominent in stage II sleep. Sphenoidal leads have been used to detect inferomedial temporal seizure activity, but they are uncomfortable and probably add little more information than can be obtained by the placement of additional subtemporal scalp electrodes. In our experience, nasopharyngeal electrode recordings are too contaminated by artifact to be clinically useful. Activating procedures such as hyperventilation, photic stroboscopic stimulation, and sleep increase the yield of EEG recordings, as detailed in Chap. 2.

Beyond dependably identifying artifacts in the EEG recording, one of the main challenges for the electroencephalographer is to differentiate between normal patterns that simulate seizures and true epileptic discharges. These paroxysmal but ostensibly normal patterns appear mostly during sleep, each with a highly characteristic morphology. These include small sharp spikes, “14 and 6” polyspike activity, lambda and posterior occipital mu rhythm, and occipital sharp transients. These are pictured in most standard textbooks on the subject of EEG.

Several methods of *long-term EEG monitoring* are now in common use and are of particular value in the investigation of patients with surgically removable epileptogenic foci. The most common of these makes use of telemetry systems, in which the patient is attached to the EEG machine by cable or radio transmitter without unduly limiting his freedom of movement. The telemetry system is joined to an audiovisual recording system, making it possible to record seizure phenomena (even at night, under dim infrared light) and to synchronize them with the EEG abnormalities. An alternative is the use of a small cassette recorder that is attached to a miniature EEG machine worn by the patient at home and at work. The patient is instructed to push a button if he experiences an “event,” which can later be correlated with EEG activity. The role of intensive neurodiagnostic monitoring in the investigation and treatment of seizures, which is also a necessary part of the evaluation for epilepsy surgery, is described in detail in the monographs of Engel and of Niedermeyer.

The EEG changes in epilepsy are discussed further in Chap. 2.

Other Laboratory Abnormalities Associated with Seizures

MRI is the most important diagnostic tool for the detection of structural abnormalities underlying epilepsy. Medial temporal sclerosis, glial scars, porencephaly, heterotopias, and other disorders of neuronal migration can be clearly visualized. After a seizure, particularly one with a focal component, MRI sometimes discloses subtle focal cortical swelling and signal change in the FLAIR sequence, or, if a contrast agent is administered, an ill-defined cortical blush may be visible on CT or MRI. There is a rough relationship between the duration of seizure activity and the intensity and size of these cortical changes. Likewise, angiography performed soon after a seizure may show a focal area of enhanced flow. This phenomenon was often a source of confusion when radionuclide scans were routinely performed for the evaluation of new seizures—focal increased uptake being mistaken for a tumor or stroke. All of these imaging abnormalities are thought to reflect transient disruption of the blood-brain barrier, and they rarely persist for more than a day or two. Less well understood is the finding on MRI of increased T2 signal (probably due to hypoxia) in the hippocampi after a prolonged seizure or status epilepticus.

The CSF occasionally contains a small number of white blood cells (rarely up to $50/\text{mm}^3$, but more often in the range of $10/\text{mm}^3$) in about 15 percent of patients after a seizure. A slight increase in protein is also possible. Like the imaging abnormalities these findings may lead to spurious conclusions about the presence of an intracranial infection, particularly if polymorphonuclear leukocytes predominate. Nonetheless, a significant pleocytosis after a seizure should always be construed as a sign of inflammatory or infectious disease.

Systemic acidosis is a common result of convulsive seizures, and it is not unusual for the serum pH to reach levels near or below 7 if taken immediately after a convulsion. Of more practical value is the fact that almost all generalized convulsions produce a rise in serum creatine kinase activity that persists for hours, a finding that could be used to greater advantage in emergency departments to assist in distinguishing seizures from fainting. Of course, extensive muscle injury from a fall or prolonged compression during a period of unconsciousness can produce the same abnormality.

Concentrations of serum prolactin, like those of other hypo-

thalamic hormones, rise for 10 to 20 min after all types of generalized seizures, including complex partial seizures, but not in absence or myoclonic types. An elevation may help differentiate a hysterical seizure from a genuine one; however, serum prolactin may also be slightly elevated after a syncopal episode. Detection is facilitated by collecting capillary blood from the finger on filter paper for analysis (Fisher et al). There is also a postictal rise in ACTH and serum cortisol, but these changes have a longer latency and briefer duration. If changes in these hormonal levels are used as diagnostic tests, one must have information about normal baseline levels, diurnal variations, and the effects of concurrent medications. Changes in body temperature, which are said to sometimes precede a seizure, may reflect hypothalamic changes but are far less consistent and difficult to use in clinical work.

Pathology of Epilepsy

In most autopsied cases of primary generalized epilepsy of the grand mal and absence types, the CNS has been said to be grossly and microscopically normal. However, it is unlikely that the brains in these cases were examined completely—at least there is not a single case that has been subjected to whole-brain serial sectioning in a search for disorders of neural migration and old scars. Not surprisingly, there are also no visible lesions in the seizure states complicating drug intoxication and withdrawal, transient hyper- and hyponatremia, and hyper- and hypoglycemia, which presumably represent derangements at the cellular level.

In contrast, most of the so-called secondary epilepsies have definable lesions. These include zones of neuronal loss and gliosis (scars) or other signs of tissue loss such as a porencephaly, heterotopia, dysgenetic cortex, hamartoma, vascular malformation, and tumor. The frequency of these lesions is not fully known. Certainly the focal epilepsies are associated with the highest incidence of structural abnormalities, although in certain cases no morphologic change is visible. In several series of cases of temporal lobe excisions, such as that of Falconer, a specific pattern of neuronal loss with gliosis (sclerosis) in the hippocampal and amygdaloid region was found in the majority, and this abnormality is being increasingly recognized with MRI, as noted below. Vascular malformations, hamartomas, and low-grade astrocytomas were less frequent; in a small number, no abnormalities could be found.

The widespread use of CT and MRI represents an important surrogate approach to the pathologic study of epilepsy. More than 25 years ago, Gastaut and Gastaut reported that in primary grand mal and absence epilepsies, CT abnormalities were found in approximately 10 percent of cases, whereas in the Lennox-Gastaut syndrome, the West syndrome, and partial complex epilepsies it was found in 52, 77, and 63 percent, respectively. Atrophy, calcification, and malformations were the most frequent changes. MRI and particularly the FLAIR images have proved to be a particularly sensitive means of detecting epileptogenic lesions of the medial-basal portion of the temporal lobes (mesial temporal sclerosis; Fig. 16-2). Repeatedly, patients are observed in whom MRI disclosed a cortical or subcortical developmental malformation such as a cortical heterotopia or another surgically treatable lesion of the temporal lobe, even after CT scanning had failed to do so. More subtle epileptogenic foci may be demonstrated by positron emission tomography (PET) or by interictal single-photon emission computed tomography (SPECT). Ictal SPECT, which shows hyperperfusion of the seizure focus, is a more demanding but also more sensitive and specific procedure.

With reference to the focal epilepsies, it has not been possible to determine which component of the lesion is responsible for the seizures. Gliosis, fibrosis, vascularization, and meningocephalic cicatrix have all been incriminated, but they are found in nonepileptic foci as well. The Scheibels' Golgi studies of neurons from epileptic foci in the temporal lobe showed distortions of dendrites, loss of dendritic spines, and disorientation of neurons near the scars, but these findings have dubious status since they were not usually compared with similar nonepileptic lesions. Moreover, changes such as these have proved to be nonspecific and artifactual. Once a gliotic focus of whatever cause, bordered by groups of discharging neurons, becomes epileptogenic, it may remain so throughout the patient's lifetime. Nevertheless, with the passage of years, seizures tend to diminish or cease in as many as half of childhood and adult traumatic epilepsies.

The most common histologic finding in the brains of epileptics is a bilateral loss of neurons in the CA1 segment (Sommer sector) of the pyramidal cell layer of the hippocampus, extending into contiguous regions of both the pyramidal layer and the underlying dentate gyrus. It is still undecided whether this neuronal loss is primary or secondary and, if the latter, whether it was incurred at birth or happened later as the consequence of recurrent seizures. The cessation of seizures in many patients following surgical resection of the medial temporal lobe favors the first interpretation (page 298). Attesting to the uncertainty of cause or effect regarding hippocampal damage are case reports and surgical series too numerous to list that favor one view or the other. It can be stated, however, that seizures, even in adulthood, are capable of inducing hippocampal shrinkage. This does not preclude a causative role for medial temporal sclerosis (see editorial by Sutula and Pitkänen).

Role of Heredity

Most primary epilepsies are thought to have a genetic basis and, as in many other idiopathic diseases such as diabetes and atherosclerosis, the mode of inheritance is complex, i.e., polygenic. That a genetic factor is operative in primary generalized tonic-clonic seizures is suggested by the finding of a familial incidence in 5 to 10 percent of such patients and, in particular families, the inheritance of a generalized seizure disorder through specific chromosomal regions (Berkovic). The importance of genetic factors in the primary (idiopathic) epilepsies is also underscored by evidence from twin studies; in six major series, the overall concordance rate was 60 percent for monozygotic twins and 13 percent for dizygotic pairs.

In only a few of the idiopathic seizure disorders is a simple (mendelian) pattern of inheritance recognized. These include a subgroup of benign neonatal familial convulsions inherited as an autosomal dominant trait (Leppert) and a similar disorder of infantile onset and a benign myoclonic epilepsy of childhood (autosomal recessive).

Particularly informative are a special group of epileptic disorders in which monogenic genetic defects have been found to be related to ion channels or neurotransmitter receptors (Table 16-3). These were mentioned earlier in the discussion of the physiology of seizures and, despite their rarity, they suggest that idiopathic epilepsy may be due to a disruption in the function of these channels. Functional studies suggest that the consequences of almost all of these mutations are to enhance overall neuronal excitability. Examples include nocturnal frontal lobe epilepsy, which may present as a partial seizure (in which the offending mutations are in sub-

units of the nicotinic acetylcholine receptor subunit); generalized epilepsy with febrile seizures (subunits of a neuronal sodium channel); benign familial neonatal convulsions (two different potassium channels); and forms of juvenile myoclonic epilepsy and childhood absence epilepsy (subunits of the brain GABA_A receptor). These are summarized in Table 16-3 and their number will almost certainly expand in the next few years. As with numerous other genetic neurologic disorders, a single mutation may produce different seizure types, and a single type may be the result of one of several different mutations. This is particularly true in a group that has been termed *generalized epilepsy with febrile seizures plus*. This denotes various combinations of uncomplicated febrile seizures, febrile seizures persisting beyond childhood, generalized, absence, myoclonic, atonic, and temporal lobe seizures. Several of the mutations mentioned above, two in sodium channels and one in a GABA receptor subunit, produce this constellation, the manifestations of any one of these mutations varying between members of a single family. Also notable is the low penetrance of some monogenic epileptic disorders, particularly the autosomal dominant one associated with nocturnal frontal seizures.

Another group of epilepsies with mendelian inheritance has been ascribed to genetic defects that do not implicate ion channels. Most of these are primarily myoclonic disorders in which the epilepsy is symptomatic. Thus, two forms of progressive myoclonic epilepsy, Unverricht-Lundborg disease and Lafora body disease, are the result respectively of mutations in genes encoding cystatin B and a protein, tyrosine phosphatase. Other forms of myoclonic epilepsy are presumably related to primary defects that cause different forms of ceroid lipofuscinosis (see Chap. 37). To these inherited forms of epilepsy may be added diseases such as tuberous sclerosis, which have a strong proclivity to cause seizures.

A more complex genetic element is also identified in several other classic childhood seizure disorders—absence epilepsy with three-per-second spike-and-wave discharges and benign epilepsy of childhood with centrotemporal spikes—both of which are transmitted as autosomal dominant traits with incomplete penetrance or perhaps in a more complicated manner. In the partial, or focal, epilepsies (which is the form that seizures take in two-thirds of adults and almost half of the children with epilepsy), the role of heredity is not nearly so clear. Yet in numerous studies there has been a greater-than-expected incidence of seizures, EEG abnormalities, or both among first-degree relatives. Among the familial cortical epilepsies, both a temporal and frontal lobe type are inherited in a polygenic fashion or in an autosomal dominant pattern. Undoubtedly also inherited is the tendency to develop simple febrile convulsions, though the mode of inheritance is uncertain.

The genetics of the epileptic disorders has been reviewed in detail by Steinlein, Delgado-Escueta and colleagues, Hirose and associates, Malafosse and Moulard, and Anderson and Hauser, whose articles are recommended.

CLINICAL APPROACH TO THE EPILEPSIES

The physician faced with a patient who seeks advice about an episodic disorder of nervous function must determine, first, whether the episode in question is indeed a seizure; if so, she must determine its pattern and other characteristics; and, finally, she must undertake a search for its cause. In the diagnosis of epilepsy, history is the key; in most adult cases the physical examination is relatively unrevealing. The examination in infants and children is of greater

Table 16-3
Monogenic epileptic disorders

	GENE	PROTEIN INVOLVED
Channelopathies		
Sodium channels		
Familial generalized seizures with febrile seizures “plus”; see text	SCN1A,B, (GABA _A)	Sodium channel subunits, less often, GABA receptor
Benign familial neonatal convulsions	SCN2A	Sodium channel subunits
Potassium channels		
Benign infantile epilepsy	KCNQ2,3	Potassium channel subunits
Episodic ataxia type 1 with partial epilepsy	KCNA1	
Ligand-gated channels		
Autosomal dominant nocturnal frontal seizures	CHRNA 2,4	Nicotinic acetylcholine receptor subunits
Familial generalized and febrile seizures	GABRG2	GABA _A receptor subunit
Juvenile myoclonic epilepsy	GABRA1 (CACNB4)	GABA _A receptor subunit, less often, calcium channel subunit
Calcium channels		
Episodic ataxia type 2 with spike-wave seizures	CACNA1A	Calcium channel subunit
Malformations of cortical development		
Holoprosencephaly, generalized epilepsy	SHH, PTCH, ZIC2, SIX3, TGIF	Sonic hedgehog, SHH receptor, transcription factors
Schizencephaly, generalized epilepsy	EMX2	Homeodomain protein
Tuberous sclerosis, generalized epilepsy	TSC1, 2	Hamartin, tuberin
Lissencephaly, generalized epilepsy	LIS1	Platelet-activating factor acid hydrolase
Double cortex syndrome, generalized epilepsy	DCX	Doublecortin
Heterotopia, generalized epilepsy	FLN1	Filamin 1
Fukuyama muscular dystrophy, lissencephaly, generalized epilepsy	FCMD	Fukutin
Walker-Warburg syndrome, generalized epilepsy	POMT1	O-mannosyl transferase
Muscle-eye-brain disease, generalized epilepsy	MEB	Lysosomal transferase, PMGnT1
Angelman syndrome: myoclonic, tonic-clonic, atonic seizures	UBE3A	Ubiquitin-protein ligase
Progressive myoclonic epilepsies (PME)		
Unverricht-Lundborg disease with PME	EPM1	Cystatin B
Laforda body disease with PME	EPM2A	Laforin, protein tyrosine phosphatase
Myoclonic epilepsy with ragged red fibers	tRNAlys	Mitochondrial lysine tRNA
Dentatorubro-pallidoluysian atrophy with PME	DRPLA	Atrophin-1
Gaucher disease	PSAP	β -glucocerebrosidase
Sialidosis type I	NEU1	Sialidase
Ceroid lipofuscinosis (CLN) and PME	CLN	CLN2, CLN3, CLN5, CLN6 also cause generalized, atonic and atypical absence seizures
Mixed seizure types		
Lipoid proteinosis and temporal lobe epilepsy	ECM1	Extracellular matrix protein 1
Temporal lobe epilepsy	LGI1	Leucine-rich glioma inactivated protein
CLN8; progressive non-myoclonic epilepsy with retardation	CLN8	Membrane protein in endoplasmic reticulum

value, since the finding of dysmorphic and cutaneous abnormalities allow the diagnosis of a large number of cerebral diseases that give rise to epilepsy.

Several laboratory studies should routinely be included in the initial diagnostic workup—complete blood count (CBC), blood chemistries, liver and thyroid function tests, EEG, and, most importantly, an imaging study of the brain, preferably MRI. CT scanning may be the only feasible study in an emergency or for very young children. Some patients may later need protracted video/

EEG monitoring, either in the hospital or with portable equipment at home. Other forms of testing—e.g., cardiac stress tests, Holter monitors, tilt-table testing, long-term patient-activated cardiac monitors, and sleep studies—are sometimes indicated in order to exclude some of the nonepileptic disorders listed below.

The conditions most likely to simulate a seizure are syncope and transient ischemic attacks, but also to be considered are migraine, unexplained falls (drop attacks), sleepwalking and rapid-eye-movement (REM) sleep behavior disorder, panic attacks, hy-

poglycemia, cataplexy, paroxysmal ataxia and choreoathetosis, recurrent transient global amnesia, and hysterical pseudoseizures. Often, in emergency departments, it is difficult to differentiate the postictal effects of an unwitnessed seizure from mild confusion following cerebral concussion or from a brief loss of consciousness produced by a subarachnoid hemorrhage.

The clinical differences between a seizure and a *syncopal attack* are considered in Chap. 18. Here it is emphasized that no single criterion stands inviolate. The authors have erred in mistaking akinetic seizures for simple faints and vasovagal and cardiac faints for seizures. If blood is tested after the episode in question, elevation in creatine kinase (persistent for hours) and prolactin (for up to 10 min) may be helpful in the diagnosis of a convulsive seizure. Postictal confusion, incontinence, and a bitten tongue clearly bespeak seizure rather than syncope. Absence attacks may be difficult to identify because of their brevity. Helpful maneuvers are to have the patient hyperventilate in order to evoke an attack or to observe the patient counting aloud for 5 min. Those with frequent absence attacks will pause or skip one or two numbers.

The diagnosis of *complex partial seizures* is the most difficult. These attacks are so variable and so often induce disturbances of behavior and psychic function—rather than obvious interruptions of consciousness—that they may be mistaken for temper tantrums, hysteria, sociopathic behavior, or acute psychosis. The careful questioning of witnesses of an attack is essential. Verbalizations that cannot be remembered, walking aimlessly, or inappropriate actions and social behavior are characteristic. As stated above, we have placed emphasis on amnesia for the events of at least part of the seizure as a crucial criterion for the diagnosis of temporal lobe epilepsy. In all obscure forms of epilepsy, prolonged EEG and video monitoring may prove diagnostic. A mild complex partial seizure, consisting of a brief loss of consciousness and lip-smacking, may be mistaken for an absence unless it is kept in mind that the former (but not the latter) is commonly followed by a period of confusion and dysphasia when the language areas are involved.

Epilepsy complicated by states of constitutional mental dullness and confusion poses special problems in diagnosis. Most epileptic patients seen in a general hospital or in office practice show no evidence of mental retardation, regardless of the type of seizure. Undoubtedly, seizures are more common in the mentally retarded, but recurrent seizures in themselves seldom cause intellectual deterioration (Ellenberg et al); when this does happen, one should suspect an underlying degenerative or hereditary metabolic disease. An exception to this statement is the patient with frequent and uncontrolled subclinical seizures (nonconvulsive status) who is drugged or in a postseizure psychotic state. Hospital admission and a systematic study of the seizure state and drug levels are necessary in the analysis of this problem.

Migraine should not be mistaken for a seizure, for reasons discussed on page 153. One feature of the focal neurologic disorder of classic migraine is particularly helpful—namely, the pace of the sequence of cerebral malfunction over a period of minutes rather than seconds, as in partial epilepsy. Even this criterion may fail occasionally, especially if both migraine and partial seizures are joined, e.g., as expressions of a vascular malformation of the brain.

Useful in the identification of a *transient ischemic attack* (TIA) and its separation from partial epilepsy are the patient's age, evidence of disease of the heart or carotid arteries, and the lack of disorder of consciousness or amnesia. Again, if the ischemic attack is marked by an evolution of symptoms, they tend to develop more

slowly than those of a seizure, and by their nature TIAs tend to produce a focal loss of function without convulsions. However, a “limb-shaking” TIA and convulsive phenomena at the outset of basilar artery occlusion may be nearly impossible to distinguish from epilepsy.

Drop attacks (falling to the ground without loss of consciousness) remain an enigma (page 329). In most cases, we have failed to substantiate their association with circulatory disturbances of the vertebrobasilar system and seldom have we observed them to be an expression of atonic or myoclonic epilepsy, but such an occurrence has been reported with the Lennox-Gastaut syndrome. In some instances they represent simple unexpected falls, especially in stout older women who are sedentary. The degenerative disease progressive supranuclear palsy may also present itself in this way (Chap. 39).

Regarding the distinction of narcolepsy, paroxysmal ataxia or choreoathetosis, transient global amnesia, hysterical fugues, panic attacks, and REM sleep behavior disorder from seizures, it is sufficient to be aware of the diagnostic criteria for each of these conditions.

The Probable Causes of Seizure(s) at Different Age Periods

(Table 16-4 and Fig. 16-3)

Having concluded that the neurologic disturbance under consideration is one of seizure, the next issue is to identify the type of seizure; indeed, this determines in most cases the nature of treatment. Since there are so many seizure types, especially in childhood and adolescence, each one tending to predominate in a certain age period, a clinical advantage accrues to considering seizure problems from just this point of view, i.e., the problem of epilepsy as it presents in each period of life, along with the neurologic and EEG findings, as well as the response to drugs, etiology, and prognosis.

Figure 16-3 displays the frequency of each seizure type and the main causes of seizures in each age group. These data are assembled from various sources and are approximate, but they highlight several points of clinical importance. First, implicit is the fact that the age of the patient greatly affects the incidence of certain seizure types; e.g., absence and myoclonic seizures are relatively more common in children and adolescents. Furthermore, the underlying causation varies greatly by age as discussed further on.

Neonatal Seizures The neonatologist is often confronted by an infant that begins to convulse in the first days of postnatal life. In most instances, the seizures are fragmentary—an abrupt movement or posturing of a limb, stiffening of the body, rolling up of the eyes, a pause in respirations, lip-smacking, chewing, or bicycling movements of the legs. Even the experienced observer may have difficulty at times in distinguishing seizure activity from the normal movements of the neonate. If manifest seizures are frequent, the diagnosis is less difficult. The seizures correlate with focal or multifocal cortical discharges; however, as is the case with most EEG changes in neonates, these are poorly formed and less distinct than seizure discharges in later life. Presumably the immaturity of the cerebrum prevents the development of a fully organized seizure pattern. The EEG is nonetheless helpful in diagnosis. Periods of EEG suppression may alternate with sharp or slow waves, or there may be discontinuous theta activity. Unfortunately, electrical seizure activity may be unattended by

Table 16-4

Causes of recurrent seizures in different age groups (see also Fig. 16-3)

AGE OF ONSET	PROBABLE CAUSE ^a
Neonatal	Congenital maldevelopment, birth injury, anoxia, metabolic disorders (hypocalcemia, hypoglycemia, vitamin B ₆ deficiency, biotinidase deficiency, phenylketonuria, and others)
Infancy (1–6 months)	As above; infantile spasms; West syndrome
Early childhood (6 months–3 years)	Infantile spasms, febrile convulsions, birth injury and anoxia, infections, trauma, metabolic disorders, cortical dysgenesis, accidental drug poisoning
Childhood (3–10 years)	Perinatal anoxia, injury at birth or later, infections, thrombosis of cerebral arteries or veins, metabolic disorders, cortical malformations, Lennox-Gastaut syndrome, “idiopathic,” probably inherited, epilepsy (Rolandic epilepsy)
Adolescence (10–18 years)	Idiopathic epilepsy, including genetically transmitted types, juvenile myoclonic epilepsy, trauma, drugs
Early adulthood (18–25 years)	Idiopathic epilepsy, trauma, neoplasm, withdrawal from alcohol or other sedative drugs
Middle age (35–60 years)	Trauma, neoplasm, vascular disease, alcohol or other drug withdrawal
Late life (over 60 years)	Vascular disease (usually postinfarction), tumor, abscess, degenerative disease, trauma

^a Meningitis or encephalitis and their complications may be a cause of seizures at any age. This is true also of severe metabolic disturbances. In tropical and subtropical countries, parasitic infection of the CNS is a common cause.

clinical manifestations. An early onset of myoclonic jerks, either fragmentary or massive, with an EEG pattern of alternating suppression and complex bursts of activity is particularly ominous according to Aicardi. Another extremely malignant form of neonatal seizure evolving later into infantile spasms and Lennox-Gastaut syndrome and leaving in its wake severe brain damage was described by Ohtahara. Most of the reported patients were left mentally retarded (Brett).

Neonatal seizures occurring within 24 to 48 h of a difficult birth are usually indicative of severe cerebral damage, usually anoxic, either antenatal or parturitional. Such infants often succumb, and about half of the survivors are seriously handicapped. *Seizures having their onset several days or weeks after birth* are more often an expression of acquired or hereditary metabolic disease. In this latter group, hypoglycemia is the most frequent cause; another, hypocalcemia with tetany, has become infrequent. A hereditary form of pyridoxine deficiency is a rare cause, sometimes also inducing seizures in utero and characteristically responding promptly to massive doses (100 mg) of vitamin B₆ given intravenously. Biotinidase deficiency is another rare but correctable cause. Nonketotic hyperglycemia, maple syrup urine disease, as well as other meta-

bolic disorders may lead to seizures in the first week or two of life and are expressive of a more diffuse encephalopathy.

Benign forms of neonatal seizures have also been identified. Plouin has described a form of benign neonatal clonic convulsions beginning on days 2 and 3, up to day 7, in which there were no specific EEG changes. The seizures then remit. The inheritance is autosomal dominant. There are other nonfamilial cases with onset on days 4 to 6, wherein the partial seizures may even increase to status epilepticus; the EEG consists of discontinuous theta activity. In both these groups, the outlook for normal development is good and seizures seldom recur later in life. There are also benign forms of polymyoclonus without seizures or EEG abnormality in this age period. Some occur only with slow-wave sleep or feeding. They disappear after a few months and require no treatment. A form of benign nocturnal myoclonus in the neonate has also been documented. When therapy is necessary, phenobarbital has been preferred.

Infantile Seizures (Occurring in the First Months, Up to 2 Years) Neonatal seizures may continue into the infantile period, or seizures may begin in an infant who seemed to be normal up to the time of the first convulsive attack. The most characteristic pattern at this age is the massive sudden myoclonic jerk of head and arms leading to flexion or, less often, to extension of the body (*infantile spasms*, salaam spasms). This form, known as the West syndrome as described earlier, is the most threatening of all infantile seizures. We have observed the same seizure type in infants with tuberous sclerosis (diagnosed in infancy by dermal white spots), phenylketonuria, or Sturge-Weber angiomas, but most often it is associated with other diseases beginning in this age period. West syndrome is probably a metabolic encephalopathy of unknown type or, in some cases, a cortical dysgenesis (Jellinger) and is identified by an EEG picture of large bilateral slow waves and multifocal spikes (*hypsarrhythmia*). Again, there is a benign form of infantile myoclonic epilepsy in which repetitive myoclonic jerking occurs in otherwise normal infants whose EEGs show only spike waves in early sleep.

However, when the myoclonus begins in infancy with fever and unilateral or bilateral clonic seizures or with partial seizures followed by focal neurologic abnormalities, there is a likelihood of developmental delay. The latter types are sometimes referred to as *complicated febrile seizures*, but, as indicated above, they must be distinguished from the benign familial febrile seizure syndrome. Infantile spasms cease by the fifth year and are replaced by partial and generalized grand mal seizures. They do not respond well to the usual anticonvulsant medications.

Seizures Presenting in Early Childhood (Onset during the First 5 to 6 Years) At this age, the first burst of seizures may take the form of status epilepticus and, if not successfully controlled, may end fatally. Or the convulsive state may present around the age of 4 years as a focal myoclonus with or without astatic seizures, atypical absence, or generalized tonic-clonic seizures. The EEG, repeated if initially normal, is most helpful in diagnosis; it reveals a paroxysmal 2- to 2.5-per-second spike-and-wave pattern on a background of predominant 4- to 7-Hz slow waves. Many of these cases qualify as the Lennox-Gastaut syndrome, are difficult to treat, and are likely to be associated with developmental retardation (see page 274). The MRI may be helpful in identifying a birth injury or cortical dysgenesis.

In contrast, the more typical absence, with its regularly recur-

ring three-per-second spike-and-wave EEG abnormality, also begins in this age period (rarely before 4 years) and carries a good prognosis. This seizure disorder responds well to medications, as indicated further on. Its features are fully described on page 274.

A number of partial epilepsies may appear for the first time during this age period and carry a good prognosis, i.e., the neurologic and intellectual capacities remain relatively unimpaired and seizures may cease in adolescence. These disorders begin between 3 and 13 years of age, and there is often a familial predisposition. Most are marked by distinctive focal spike activity that is greatly accentuated by sleep (see above, in reference to benign childhood epilepsy with centrotemporal or occipital spikes). In one form, unilateral tonic or clonic contractions of the face and limbs recur repeatedly with or without paresthesias; anarthria follows the seizure. There are central and temporal spikes in the EEG interictally. According to Gastaut, the focus may involve an occipital lobe with EEG spiking on eye closure. An acquired aphasia was noted by Landau and Kleffner to mark the beginning of an illness in which there are partial or generalized motor seizures and multifocal spike or spike-and-wave discharges in the EEG. Tumor and arteriovenous malformation are rare causes in this age group.

Rasmussen Encephalitis In other rare cases, a lesion, usually identified by biopsy, takes the form of a chronic focal encephalitis. In 1958, Rasmussen described three children in each of whom the clinical problem consisted of intractable focal epilepsy in association with a progressive hemiparesis. The cerebral cortex disclosed a mild meningeal infiltration of inflammatory cells and an encephalitic process marked by neuronal destruction, gliosis, neurorrhagia, some degree of tissue necrosis, and perivascular cuffing. Many additional cases were soon uncovered, and by 1991, in a publication devoted to this subject (edited by Andermann), Rasmussen was able to summarize the natural history of 48 personally observed patients.

The expanded view of the syndrome has added several interesting features. All the patients were children aged 3 to 15 years, more girls than boys. Half of them had epilepsia partialis continua. The progression of the disease led to hemiplegia or other deficits and brain atrophy in most cases. The CSF has shown pleocytosis and sometimes oligoclonal bands. Focal cortical and subcortical lesions have been well visualized by MRI and are bilateral in some cases. The neuropathology of five fully autopsied cases revealed extensive destruction of the cortex and white matter with intense gliosis but with lingering inflammatory reactions. The finding of antibodies to glutamate receptors in a proportion of patients has raised interest in an immune causation (see review by Antel and Rasmussen). An autoimmune hypothesis has been supported by the findings of Twyman and colleagues that these antibodies cause seizures in rabbits and lead to the release of the neurotoxin kainate in cell cultures. However, Wiendl's group and others have found these antibodies in many types of focal epilepsy and question their specificity for the Rasmussen type of encephalitis.

The unrelenting course of the disease has defied medical therapy. In some patients the process has eventually burned out, but in those with continuous focal epilepsy the seizures continued despite

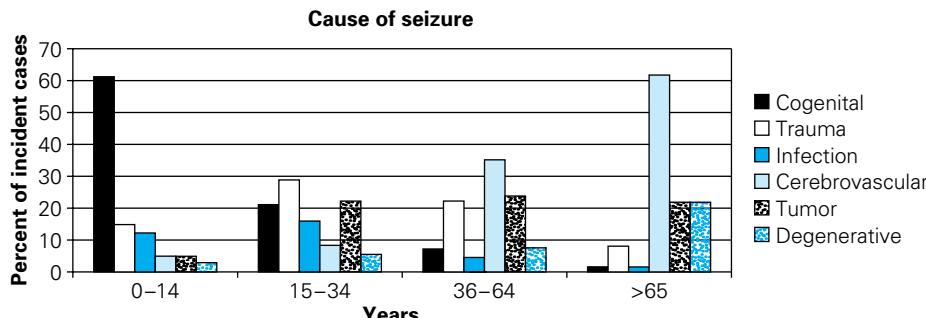

Figure 16-3. Distribution of the main causes of seizures at different ages. Evident is the prevalence of congenital causes in childhood and the emergence of cerebrovascular disease in older patients. (Adapted from several sources including Hauser and Annegers and the texts of Engel and of Pedley.)

all antiepileptic drugs. The use of full doses of corticosteroids, if started within the first year of the disease, proved beneficial in 5 of the 8 patients treated by Chinchilla and colleagues. Repeated plasma exchanges and immune globulin have been tried, but the results are difficult to interpret. When the disease is extensive and unilateral, neurosurgeons have in the past resorted to partial hemispherectomy. The authors have cared for a number of such patients with the same discouraging results.

Seizures in Later Childhood and Adolescence These represent the most common epileptic problem in general practice. Here, we face two different issues: one relates to the nature and management of the first seizure in an otherwise normal young person and the other to the management of a patient who has had one or more seizures at some time in the past. With respect to the first, a search for a cause by CT, MRI, CSF examination, and EEG rarely discloses a tumor or a vascular malformation and the epilepsy is then classed as idiopathic. The type of seizure that first brings the child or adolescent to medical attention is most likely to be a generalized tonic-clonic convulsion and often marks the beginning of a juvenile myoclonic epilepsy, as described on page 275. In the second type of case, in which there had been some type of seizure at an earlier period, one should suspect a developmental disorder, parturitional hypoxic-ischemic encephalopathy (birth injury), or one of the hereditary metabolic diseases.

Several groups of patients fall between these two distinct types. Development may have been slightly delayed, but reportedly no seizures had occurred earlier in life. Closer investigation may disclose absence seizures, not always recognized as such by parents or teachers, and a typical absence EEG, which points more directly to a genetic factor and to a more favorable prognosis.

When the seizures are an expression of a long-standing epileptic focus or foci that had been associated with mental backwardness, scholastic failure, and inadequacy of social adjustment, the diagnostic and therapeutic problem becomes much more difficult and demanding. Poor observations by the family, muddled thinking, and bizarre ideation on the part of the patient as well as poor compliance with therapy may pose problems as difficult as the seizures themselves. Some patients of this latter group will eventually fall into the category of epilepsy with complex partial seizures. In adulthood, the seizures may continue to interfere with work, marriage, and family relationships. In the interictal periods, the patients may exhibit bursts of bad temper, and they commonly have wide mood swings of sadness and anger or elation. As indicated earlier, paranoid ideation or a frank hallucinatory-delusional

psychosis sometimes appears and lasts for weeks after a single seizure, without any specific EEG changes.

In the large group with *intractable seizures in early life*, many of which are indiscriminately called febrile seizures, nearly half end up in the group identified as temporal lobe epilepsies. Huttelacher and Hapke, in a follow-up study of 145 infants and children with intractable epilepsy, found that the majority had borderline or subnormal intelligence. This group stands in contrast to the group of otherwise normal adolescents with a first seizure whose scholastic progress and social and emotional adjustment are little if at all affected.

Juvenile myoclonic epilepsy also has its onset during this age period. As described earlier, it is identified by intermittent myoclonic jerks when the patient is tired or after the ingestion of alcohol. Seizures are usually grand mal but are infrequent. The EEG shows a characteristic polyspike pattern, and treatment with certain anticonvulsants is very successful at suppressing the seizures and myoclonus (see page 295).

Finally, a first generalized seizure may bring to attention an adolescent who is abusing alcohol or another drug. Usually it is difficult from the clinical information alone to determine the type and quantity of the drug(s) and the setting in which the seizure occurred—whether in relation to overdose or withdrawal. While steps must be taken to exclude an infection of the nervous system, vascular occlusion, or trauma, the more important issue is generally not the seizure but the addiction and its control.

Regarding treatment, opinion is divided on whether treatment is required for the older child or adolescent who comes to medical attention because of a first seizure. When a large number of such cases have been left untreated, such as in the series reported by Hesdorfer and colleagues, the risk of another seizure over 10 years was 13 percent unless the first episode was status epilepticus, in which case the risk was 41 percent. Age, sex, and the circumstances of the seizure (withdrawal from drugs or alcohol, myoclonic episodes, family history, etc.) all figured into the risk.

Seizures with Onset in Adult Life and Secondary to Medical Disease Several primary diseases of the brain often announce themselves by an acute convulsive state, particularly *primary and metastatic brain tumors*; these are discussed further on in the section on seizures of late adult life. Here we focus on generalized medical disorders as causes of single and repeated seizures.

Withdrawal Seizures The possibility of abstinence seizures in patients who had chronically abused alcohol, barbiturates, or benzodiazepine sedative drugs must always be considered when seizures occur for the first time in adult life (or even in adolescence). Suspicion of this mechanism is raised by the stigmata of alcohol abuse or a history of prolonged nervousness and depression requiring sedation. Also, sleep disturbance, tremulousness, disorientation, illusions, and hallucinations are often associated with the convulsive phase of the illness. Seizures in this setting may occur singly, but more often in a brief flurry, the entire convulsive period lasting for several hours and rarely for a day or longer, during which time the patient may be unduly sensitive to photic stimulation. Alcohol and other drug-related seizures are discussed in more detail on pages 1008 and 1022.

Infections An outburst of seizures is also a prominent feature of all varieties of *bacterial meningitis*, more so in children than in adults. Fever, headache, and stiff neck usually provide the clues to diagnosis, and lumbar puncture yields the salient data. Myoclonic jerking and seizures appear early in acute *herpes simplex encephalitis* and other forms of viral, treponemal, and parasitic

encephalitis, including those derived from HIV infection, both directly and indirectly; with toxoplasmosis and brain lymphoma; and in subacute sclerosing panencephalitis. In tropical countries, cysticercosis and tuberculous granulomas of the brain are very common causes of epilepsy. Seizure(s) without fever or stiff neck may be the initial manifestation of syphilitic meningitis, a fact worth noting with the increasing incidence of this process in AIDS patients.

Endogenous Metabolic Encephalopathies *Uremia* is a condition with a strong convulsive tendency. Of interest is the relation of seizures to the development of anuric renal failure, generally from acute tubular necrosis but occasionally due to glomerular disease. Total anuria may be tolerated for several days without the appearance of neurologic signs, and then there is an abrupt onset of twitching, trembling, myoclonic jerks, and generalized motor seizures. Tetany may be added. The motor display, one of the most dramatic in medicine, lasts several days until the patient sinks into terminal coma or recovers, depending on the outcome of the renal disease and its treatment by dialysis. When this twitch-convulsive syndrome accompanies lupus erythematosus, seizures of undetermined cause, or generalized neoplasia, one should suspect it has its basis in renal failure.

Other *acute metabolic illnesses and electrolytic disorders* complicated by generalized and multifocal motor seizures are hyponatremia and its opposite, a hypernatremic hyperosmolar state, thyrotoxic storm, porphyria, hypoglycemia, hyperglycemia, hypomagnesemia, and hypocalcemia. In all these cases *rapidly evolving electrolyte abnormalities are more likely to cause seizures than those occurring gradually*. For this reason it is not possible to assign absolute levels of electrolyte, BUN, or glucose concentrations above or below which seizures are likely to occur. Lead (in children) and mercury (in children and adults) are the most frequent of the metallic poisons that cause convulsions.

In most cases of seizures due to metabolic and withdrawal states, treatment with anticonvulsants is usually not necessary as long as the underlying disturbance is rectified. Indeed, anticonvulsants are often ineffective if the metabolic disorder persists.

Generalized seizures, with or without twitching, may occur in the advanced stages of many other illnesses, such as *hypertensive encephalopathy*, sepsis—especially gram-negative septicemia with shock—hepatic stupor, and intractable congestive heart failure. Usually, seizures in these circumstances can be traced to an associated metabolic abnormality and are revealed by appropriate studies of the blood.

Medications as a Cause of Seizures A large number of medications can cause seizures, usually when toxic blood levels are attained. The antibiotic imipenem and excessive doses of other penicillin congeners will on occasion cause seizures, particularly if renal failure leads to drug accumulation. Cefapime, a fourth-generation cephalosporin, widely used for the treatment of gram-negative sepsis, can result in status epilepticus, especially if given in excessive dosage (Dixit et al). The tricyclic antidepressants, bupropion (Wellbutrin), and lithium may cause seizures, particularly in the presence of a structural brain lesion. Lidocaine and aminophylline are known to induce a single convolution if administered too quickly or in excessive doses. The use of the analgesic tramadol has also been associated with seizures. Curiously, the anesthetic propofol, which is discussed further on as a potent anticonvulsant in the treatment of status epilepticus, has caused seizure and marked myoclonic phenomena in some patients. These may occur during induction or emergence from anesthesia or as a delayed problem (Walder et al).

The list of medications that at one time or another have been

associated with a convulsion is long, and if no other explanation for a single seizure is evident, the physician is advised to look up in standard references the side effects of the drugs being given to the patient. In a few of our otherwise healthy adult patients, extreme *sleep deprivation* coupled with ingestion of large doses of antibiotics or adrenergic medications or other remedies that are used indiscriminately for the symptomatic relief of colds has been the only plausible explanation after extensive search for the cause of a single or doublet seizure.

Global Arrest of Circulation and Cerebrovascular Diseases
Cardiac arrest, suffocation or respiratory failure, carbon monoxide poisoning, or other causes of *hypoxic encephalopathy* tend to induce diffuse myoclonic jerking and generalized seizures as cardiac function is resumed. The myoclonic-convulsive phase of this condition may last only a few hours or days, in association with coma, stupor, and confusion; or it may persist indefinitely as an intention myoclonus-convulsive state (Lance-Adams syndrome).

Convulsive seizures are uncommon in the acute or evolving phases of an arterial stroke. The ischemic convulsive phenomena of a "limb-shaking TIA" and a burst of generalized clonic motor activity during basilar artery occlusion have been mentioned earlier but are uncommon. Only exceptionally will acute embolic infarction of the brain cause a focal fit at its onset. With these infrequent exceptions, a new seizure should not be attributed to an acute arterial occlusion in the cerebrum. More relevant is the fact that embolic infarcts involving the cortex later, after an interval of months or longer, become epileptogenic in almost 10 percent of cases. Thrombotic infarcts are almost never convulsive at their onset.

In contrast, *cortical venous thrombosis* with underlying ischemia and infarction is highly epileptogenic. The same is true for hypertensive encephalopathy and thrombotic thrombocytopenic purpura (TTP), which has a strong tendency to cause nonconvulsive status epilepticus. The rupture of a saccular aneurysm is sometimes marked by one or two generalized convulsions. Subcortical cerebral hemorrhages, spontaneous or traumatic, occasionally become sources of recurrent focal seizures.

Seizures with Acute Head Injury It is not uncommon for severe concussion to be followed by one or more brief convulsions (see Chap. 35). The appearance is similar in most cases to the clonic twitching and brief tonic phase that accompanies a faint. From time to time, a prolonged clonic convulsion occurs. The nature of this event, whether originating in the reticular formation as a component of concussion or from some disruption of cortical activity, is not clear. Almost invariably in our experience, the EEG recorded hours or a day later is normal, and imaging procedures are likewise normal or show a small contusion. There is little to guide one in treatment of these patients; we tend to give a course of anticonvulsant medications lasting several months. Another EEG is taken before discontinuing the medications.

Seizures during Pregnancy Here one contends with two types of problem: one, the woman with epilepsy who becomes pregnant; the other, the woman who has her first seizure during pregnancy. In respect to the first group, about half of the epileptic women who become pregnant have no change in seizure frequency or severity; in about 25 percent, the frequency increases; and in an equal number, it lessens. In a large cohort of such women, there was a slight increase in the number of stillbirths and a doubling in the expected incidence of mental retardation and nonfebrile seizures in their offspring.

Issues regarding a coagulopathy in the fetus exposed to phenobarbital and certain of the other drugs are well known to obstetricians and pediatric specialists and are treated with the oral ad-

ministration of vitamin K 20 mg/day during the eighth month or 10 mg IV 4 h before birth and 1 mg IM to the neonate. The conventional anticonvulsants also seem to be safe for the baby during breast-feeding in that only small amounts are excreted in lactated milk. For example, carbamazepine in human milk is found to be 40 percent of the mother's serum concentration, and this results in a neonatal blood level that is below the conventionally detectable amount. Phenytoin is excreted at 15 percent of maternal serum concentration, and valproate, being highly protein-bound, is virtually absent in breast milk. No adverse effects have been attributed to these small amounts of drug.

The special issue of the teratogenicity of antiepileptic drugs is addressed further on.

Eclampsia (See also Chap. 34.) This syndrome appears during the last trimester of pregnancy and may announce itself by hypertension and convulsions; the latter are generalized and tend to occur in clusters. The standard practice is to induce labor or perform cesarean section and manage the seizures as one would manage those of hypertensive encephalopathy (of which this is one type). The administration of magnesium sulfate continues to be the favored treatment by obstetricians for the prevention of eclamptic seizures; two randomized trials have re-established its value in preventing seizures in pre-eclamptic women (Lucas et al) and in avoiding a second convolution once one had occurred (Eclampsia Trial Collaborative Group). Magnesium sulfate, 10 g IM, followed by 5 g every 4 h, proved comparable to standard doses of phenytoin as prophylaxis for seizures. Our colleagues use a regimen of 4 g IV over 5 to 10 min followed by a maintenance dose of 5 g every 4 h IM or 1 to 2 g/h IV. Whether magnesium is as effective in the management of active convulsions of toxemia remains uncertain. In nontoxic gestational epilepsy, about 25 percent of patients are found to have some disease (neoplastic, vascular, or traumatic) that will persist.

Focal or Generalized Seizures in Late Adult Life

Hauser and Kurland have reported a marked increase in the incidence of seizures as the population ages—from 11.9 per 100,000 in the 40- to 60-year age group to 82 per 100,000 in those 60 years of age or older. A person in the latter age group who begins to have seizures of either partial or generalized type is always to be suspected of harboring a primary or secondary tumor or an infarct that had not declared itself clinically. This is a matter usually settled by the neurologic examination and by CT or MRI. Tumor, either primary or secondary, will be found to account for about half the cases of seizures occurring for the first time in late adult life. In our clinical material, almost 10 percent of patients with infarction involving the cerebral cortex later developed recurrent partial or generalized seizures, but most published series cite a lower proportion. According to Sung and Chu, previous infarcts are by far the most common lesions underlying status epilepticus in late adult life, but our experience has been that old trauma is as common. Cortical and subcortical encephalomalacia, the result of previous traumatic contusions, is a particularly important cause of seizures among alcoholics; the lesions are revealed by brain imaging and are typically located in the anterior frontal and temporal lobes. Brain abscess and other inflammatory and infectious illnesses are less common except in tropical regions. Seizures as a result of Alzheimer and other degenerative diseases do occur but are uncommon.

In the not infrequent cases of an adult with a first seizure that

Table 16-5
Common antiepileptic drugs

GENERIC NAME	TRADE NAME	USUAL DOSAGE		PRINCIPAL THERAPEUTIC INDICATIONS	SERUM HALF-LIFE, HOURS	EFFECTIVE BLOOD LEVEL, ^a μG/ML
		CHILDREN, MG/KG	ADULTS, MG/DAY			
Major anticonvulsants used as monotherapy						
Valproic acid	Depakote	30–60	1000–3000	Generalized tonic-clonic, partial, absence, myoclonic	6–15	50–100
Phenytoin	Dilantin	4–7	300–400	Generalized tonic-clonic, partial, absence, myoclonic	12–36	10–20
Carbamazepine	Tegretol	20–30	600–1200 ^b	Generalized tonic-clonic, partial	14–25	4–12
Phenobarbital	Luminal	3–5 (8 for infants)	90–200	Generalized tonic-clonic, partial	40–120	15–40
Lamotrigine	Lamictal	0.5	3–500	Generalized	15–60	
Adjunctive and special use anticonvulsants						
Topiramate	Topamax		400	Generalized tonic-clonic, atypical absence, myoclonic, partial	20–30	
Vigabatrin			4000	Partial and secondary generalized, Lennox-Gastaut	20–40	
Tiagabine	Gabitril		30–60	Partial and secondary generalized,	7–9	
Gabapentin	Neurontin	30–60	900–1800 ^b	Partial and secondary generalized,	5–7	
Primidone	Mysoline	10–25	750–1500 ^b	Generalized tonic-clonic, partial	6–18	5–12
Ethosuximide	Zarontin	20–40	750–1500	Absence	20–60	50–100
Methsuximide	Celontin	10–20	500–1000	Absence	28–50	40–100
ACTH		40–60 Units daily		Infantile spasms		
Clonazepam	Klonopin	0.01–0.2	2–10	Absence, myoclonus	18–50	0.01–0.07
Anticonvulsants for status epilepticus (initial loading or continuous infusion doses shown)^c—phenytoin and phenobarbital used in doses higher than shown above						
Diazepam	Valium	0.15–2	2–20	Status epilepticus		
Lorazepam	Ativan	0.03–0.22	2–20	Status epilepticus		
Midazolam	Versed		0.1–0.4 mg/kg/h	Status epilepticus		
Propofol	Diprivan	2.5–3.5	2–8 mg/kg/h	Status epilepticus		
Fosphenytoin	Cerebyx	30–50 mg	1000–1500	Status epilepticus		10–20

^a Average trough values.

^b May require slow dose escalation.

^c Administered intravenously.

remains unexplained after thorough evaluation, it has been our practice to administer an anticonvulsant and to re-evaluate the situation in a matter of 6 to 12 months, with the goal of eventually discontinuing medication. Usually, a second MRI and EEG are performed to exclude focal abnormalities that were not appreciated during the initial evaluation, but often these studies are again unrevealing. This approach has been prompted by data such as those of Hauser and colleagues, who found that about one-third of patients with a single unprovoked seizure will have another seizure within 5 years; the risk is even greater if there is a history of seizures in a sibling, a complex febrile convolution in childhood, or a spike-and-wave abnormality in the EEG. Moreover, the risk of recurrence is greatest in the first 24 months. In patients with two or three unexplained seizures, three-quarters have further seizures in the subsequent 4 years.

TREATMENT OF EPILEPSY

The treatment of epilepsy of all types can be divided into four parts: the use of antiepileptic drugs, the surgical excision of epileptic foci and other surgical measures, the removal of causative and precipitating factors, and the regulation of physical and mental activity.

The Use of Antiepileptic Drugs—General Principles

The use of antiepileptic drugs is the most important facet of treatment. In approximately 70 percent of all patients with epilepsy, the seizures are controlled completely or almost completely by the use of antiepileptic drugs; in an additional 20 to 25 percent, the attacks are significantly reduced in number and severity. The most commonly used drugs are listed in Table 16-5, along with their dosages, effective blood levels, and serum half-lives. Because of the long half-lives of phenytoin, phenobarbital, and ethosuximide, these drugs need be taken only once daily, preferably at bedtime. Valproate and carbamazepine have shorter half-lives, and their administration should be spaced during the day. It is also useful to be familiar with the serum protein-binding characteristics of antiepileptic drugs and the interactions among these drugs, and between antiepileptic and other drugs.

Certain drugs are somewhat more effective in one type of seizure than in another, and it is necessary to use the proper drugs in optimum dosages for different circumstances. Initially, only one drug should be used and the dosage increased until sustained therapeutic levels have been attained. If seizures are not controlled by

Table 16-6
Choices of antiepileptic drugs by type of adult seizure disorder

SEIZURE TYPE	INITIAL CHOICE	SECOND LINE
Tonic-clonic	Phenytoin, carbamazepine, valproate	Lamotrigine, oxcarbazepine
Myoclonic	Valproate	Lamotrigine
Partial	Carbamazepine, phenytoin	Valporate, lamotrigine, oxcarbazine
Absence	Valproate	Ethosuximide, lamotrigine
Unclassifiable	Valproate	Lamotrigine

the first drug, a different drug should be tried, but frequent shifting of drugs is not advisable; each should be given an adequate trial before another is substituted. A general approach to the choice of drug in certain common forms of epilepsy is given in Tables 16-6 for adults and 16-7 for children, but it must be noted that there are a number of drugs that may be appropriate in each circumstance. A guide to various combinations of drugs that are helpful in refractory cases is given in Table 16-8. In changing medication, the dosage of the new drug should be increased gradually to an optimum level while the dosage of the old drug is gradually decreased; the sudden withdrawal of a drug may lead to an increase in seizure frequency or status epilepticus, even though a new drug has been substituted. If seizures are still not controlled, a second drug can then be added. Seldom if ever are more than two drugs necessary; the physician should make an effort to succeed with one drug and with no more than two given in adequate dosage. Once an anticonvulsant or a combination of anticonvulsants is found to be effective, their use in most cases should be maintained for a period of years, or indefinitely if circumstances justify their long-term use.

Table 16-7
Choices of antiepileptic drugs in childhood seizure disorders

SEIZURE TYPE	INITIAL CHOICE	SECOND	THIRD
Tonic-clonic	Valproate, carbamazepine	Lamotrigine, oxcarbazine	Phenytoin
Myoclonic	Valproate	Lamotrigine	Phenobarbital, clobazam
Absence	Valproate	Lamotrigine, ethosuximide	Clobazam
Partial	Carbamazepine, phenytoin	Valproate, gabapentin, oxcarbazine	Lamotrigine, vigabatrin, topiramate
Infantile spasms	Vigabatrin, cortico-steroids	Valproate	Lamotrigine
Lennox-Gastaut	Valproate	Topiramate, lamotrigine	Felbamate

Topiramate and lamotrigine or levetiracetam	Numerous types

SOURCE: Adapted by permission from Brodie MJ, Schachter SC. *Epilepsy*, 2nd ed. Oxford, England, Health Press, 2001.

The therapeutic dose for any given patient must be determined, to some extent, by trial and error and by measurement of serum levels, as described below. Not uncommonly a drug is discarded as being ineffective, when a slight increase in dosage would have led to suppression of the attacks. It is, however, also an error to administer a drug to the point where the patient is so dull and stupefied that the toxic effects are more incapacitating than the seizures. It is highly doubtful that prolonged administration of anticonvulsant medication is a factor in the development of the mental deterioration that occurs in a small percentage of patients with convulsive seizures. In fact, improvement in mentation more often occurs following control of the seizures by the proper dosage of appropriate antiepileptic drugs.

The management of seizures with drugs is greatly facilitated by having patients chart their daily medication and the number, time, and circumstances of seizures. Some patients find it helpful to use a dispenser that is filled on Sunday, for example, with sufficient medication to last the week. This indicates to the patient whether a dose had been missed and whether the supply of medications is running low.

The proper use of anticonvulsant drugs is considerably enhanced by the measurement of their *serum levels*. The concentrations of almost all the commonly used drugs can be measured on a single specimen by immunoassay or by the older gas-liquid chromatography method. These measurements are helpful in regulating dosage, detecting irregular drug intake, identifying the toxic agent in patients taking more than one drug, and assuring patient compliance. Blood for serum levels is ideally drawn in the morning before breakfast and the first ingestion of anticonvulsants (“trough levels”), a practice that introduces consistency in the measurement of drug concentrations.

The effective serum levels for each of the commonly used anticonvulsant drugs are indicated in Table 16-5. The upper and lower levels of the “therapeutic range” are not to be regarded as immutable limits within which the serum values must fit. In some patients, seizures are controlled at serum levels below the therapeutic range; in others, the seizures continue despite serum values within this range. In the latter patients, seizures are sometimes controlled by raising levels above the therapeutic range but not to the point of producing clinical toxicity. In general, higher serum concentrations of drugs are necessary for the control of simple or complex partial seizures than for the control of tonic-clonic seizures alone. It is to be noted that the blood level is not a precise measure of the amount of drug entering the brain, because—in the case of the most widely used anticonvulsants—the larger proportion of

drug is bound to albumin and does not penetrate nervous tissue. Laboratory measurements of the serum concentration, however, detect only the protein-bound fraction. In patients who are malnourished or chronically ill or who have a constitutional reduction in proteins, this may lead to intoxication at low total serum levels. Certain anticonvulsants also have active metabolites that may produce toxicity but are not measured by methods ordinarily used to determine serum concentrations of antiepileptic drugs. This is particularly true for the epoxide of carbamazepine. The situation may be further complicated by interactions between one anticonvulsant and the metabolites of another, as, for example, the inhibition of epoxide hydrolase by valproic acid, leading to toxicity through the buildup of carbamazepine epoxide. In circumstances of unexplained toxicity in the face of conventionally obtained serum levels that are normal, it is therefore important to measure the levels of free drug and the concentration of active metabolites by chromatographic techniques. Drugs in common use for which tests of serum levels are not easily available include levetiracetam, lamotrigine, topiramate, tiagabine, gabapentin and others; this requires an empiric dosing schedule based on recommended amounts and dose escalations for each age group.

Finally, the pharmacokinetics of each drug plays a role in toxicity and the serum level that is achieved with each alteration in the dose. This is particularly true of phenytoin, which has nonlinear kinetics once serum concentrations reach 10 mg/mL, as the result of saturation of liver enzymatic capacity. For this reason, the typical increase in dose from 300 to 400 mg daily often results in a disproportionate elevation of the serum level and toxic side effects. These elevations are also accompanied by a prolongation of the serum half-life, which increases the time to reach a steady-state phenytoin concentration after dosage adjustments. Contrariwise, carbamazepine is known to induce its own metabolism, so that doses adequate to control seizures at the outset of therapy are no longer effective several weeks later.

Always to be considered in the use of an antiepileptic drug, as already mentioned, is its possible interactions with other drugs. Many such interactions have been demonstrated, but only a few are of clinical significance, requiring adjustment of drug dosages (Kutt). Important drugs in this respect are chloramphenicol, which causes the accumulation of phenytoin and phenobarbital, and erythromycin, which causes the accumulation of carbamazepine. Antacids reduce the blood phenytoin concentration, whereas cimetidine does the opposite. Salicylates may reduce the plasma levels of anticonvulsant drugs. Among anticonvulsant drugs, valproate often leads to accumulation of phenytoin and of phenobarbital by displacing them from serum proteins; equally important, warfarin levels are decreased by the addition of phenobarbital or carbamazepine and may be increased by phenytoin. Enzyme-inducing drugs such as phenytoin, carbamazepine, and barbiturates can greatly increase the chance of breakthrough menstrual bleeding in women taking oral contraceptives, and adjustments in the amount of estradiol must be made.

Hepatic failure can seriously affect antiepileptic anticonvulsant drug concentrations, since most of these drugs are metabolized in the liver. Serum levels must be checked frequently, and if there is hypoalbuminemia, it is advisable to obtain free drug levels for reasons just mentioned. Renal failure has only an indirect effect on the concentrations of the commonly used anticonvulsants, but some newer agents, such as vigabatrin and gabapentin, are excreted through the kidneys. The main renal effects have to do with alterations in protein binding that are induced by uremia. In end-stage

renal failure, serum levels are not an accurate guide to therapy, and the goal should be to attain free phenytoin concentrations of 1 to 2 mg/mL. In addition, uremia causes the accumulation of phenytoin metabolites, which are measured with the parent drug by enzyme-multiplied immunoassay techniques. In patients who are being dialyzed, total blood levels of phenytoin tend to be low because of decreased protein binding; in this situation it is also necessary to track free (unbound) phenytoin levels. Because dialysis removes phenobarbital and ethosuximide, dosage of these drugs may have to be increased. Decreased phenytoin levels are also known to occur during viral illnesses, and supplementary doses are occasionally necessary.

Once an effective anticonvulsant regimen has been established, it must usually be continued for many years. Because of the long-term toxic effects of such a regimen, many neurologists choose not to institute anticonvulsant therapy after the occurrence of a single generalized seizure in an otherwise normal child or adult (normal EEG and MRI and no family history of seizures). Our more conservative approach of administering an anticonvulsant for 6 to 12 months and then re-evaluating the patient has already been mentioned.

Discontinuation of Anticonvulsants Withdrawal of anticonvulsant drugs may be undertaken in patients who have been free of seizures for a prolonged period. There are few firm rules to guide the physician in this decision. A safe plan, applicable to most forms of epilepsy, is to obtain an EEG whenever withdrawal of medication is contemplated. We have taken the approach that if the tracing is abnormal by way of showing paroxysmal activity, it is generally better to continue treatment. A prospective study by Callaghan and colleagues has shown that in patients who had been seizure-free during 2 years of treatment with a single drug, one-third relapsed after discontinuation of the drug, and this relapse rate was much the same in adults and children and whether the drug was reduced over a period of weeks or months. The relapse rate was lower in patients with absence and generalized-onset seizures than in those with complex partial seizures and secondary generalization. A recent study by Specchio and colleagues gave results similar to those of the large Medical Research Council Antiepileptic Drug Withdrawal Study—namely, that after 2 years on a single anticonvulsant during which no seizures had occurred, the rate of relapse was 40 percent 2 1/2 years later and 50 percent at 5 years after discontinuation; this compared to the seizure recurrence rate of 20 percent for patients remaining on medication. Other authors have suggested that a longer seizure-free period is associated with a lesser rate of relapse (see reviews of Todd and of Pedley and comments above, under “Focal or Generalized Seizures in Late Adult Life”). Patients with juvenile myoclonic epilepsy, even those with long seizure-free periods, should probably continue with medication lifelong, but there have been no thorough studies to our knowledge to support this dictum. The appropriate duration of treatment for post-infarction epilepsy has not been studied, and most neurologists continue to use one drug indefinitely. Interestingly, epilepsy caused by military brain wounds tends to wane in frequency or to disappear in 20 to 30 years, then no longer requiring treatment (Caveness).

The Use of Specific Drugs in Treatment of Seizures

General Comments *Phenytoin, carbamazepine, and valproate* are more or less equally effective in the treatment of both gener-

alized and partial seizures (see Table 16-5 for typical initial dosages). Valproate is probably less effective in the treatment of complex partial seizures. The first two of these drugs putatively act by blocking sodium channels, thus preventing abnormal neuronal firing and seizure spread.

Since carbamazepine has somewhat fewer side effects, it is preferred as the initial drug by many neurologists, but phenytoin and valproate have very similar therapeutic and side-effect profiles. Carbamazepine and valproate are probably preferable to phenytoin for epileptic children because they do not coarsen facial features and do not produce gum hypertrophy or breast enlargement. In many cases, phenytoin or carbamazepine alone will control the seizures. If not, the use of valproate (which facilitates GABA activity) alone or the combined use of phenytoin and carbamazepine produces better control. In others, the addition of valproate to carbamazepine may prove effective. Because of the high incidence of myoclonic epilepsy in adolescence, it has been our practice to use valproate as the first drug in this age group. Weight gain and menstrual irregularities (see below) during the period of initiation of valproate may also figure into the decision regarding the choice of initial drug for otherwise uncomplicated seizures in women.

Finally, it should be said that most of the commonly used antiepileptic drugs cause, to varying degrees, a decrease in bone density and an increased risk of fracture from osteoporosis in older patients, particularly in women. Several mechanisms are probably active, among them, induction of the cytochrome P450 system, which enzymatically degrades vitamin D. No specific recommendations have been offered to counteract this effect of bone loss. Calcium supplements or one of the bisphosphonates are advised if there is no contraindication.

Phenytoin Both oral and intravenous forms are available. Rash, fever, lymphadenopathy, eosinophilia and other blood dyscrasias, and polyarteritis are manifestations of an idiosyncratic *phenytoin hypersensitivity*; their occurrence calls for discontinuation of the medication. *Overdose with phenytoin* causes ataxia, diplopia, and stupor. The prolonged use of phenytoin often leads to hirsutism (mainly in young girls), hypertrophy of gums, and coarsening of facial features in children. Chronic phenytoin use over several decades may occasionally be associated with peripheral neuropathy and probably with a form of cerebellar degeneration (Lindvall and Nilsson); it is not clear if these are strictly dose-related effects or if there is an idiosyncratic reaction. An antifolate effect on blood and interference with vitamin K metabolism have also been reported, for which reason pregnant women taking phenytoin should be given vitamin K before delivery and the newborn infant should receive vitamin K as well to prevent bleeding. Phenytoin should not be used together with disulfiram (Antabuse), chloramphenicol, sulfamethizole, phenylbutazone, or cyclophosphamide, and the use of either phenobarbital or phenytoin is not advisable in patients receiving warfarin (Coumadin) because of the undesirable interactions already described. Choreoathetosis is a rare idiosyncratic side effect.

Carbamazepine This drug causes many of the same side effects as phenytoin, but to a slightly lesser degree. Leukopenia is common, and there have been rare instances of pancytopenia, hyponatremia, and diabetes insipidus as idiosyncratic reactions. It is essential, therefore, that a complete blood count be done before treatment is instituted and that the white cell count be checked regularly. A more recently introduced analogue of carbamazepine *oxcarbazepine* is said to have even fewer of these side effects than the parent drug, but its long-term therapeutic value still has to be

established. Hyponatremia has been reported in 3 percent of patients taking the latter drug. Should drowsiness or increased seizure frequency occur, this complication should be suspected.

Valproate All preparations of this drug may be occasionally hepatotoxic, an adverse effect that is usually (but not invariably) limited to children 2 years of age and younger. The use of valproate with hepatic enzyme-inducing drugs increases the risk of liver toxicity. However, mild elevations of serum ammonia and mild impairments of liver function tests in an adult do not require discontinuation of the drug. An increasingly emphasized problem with valproate has been weight gain during the first months of therapy. In one study there was an average addition of 5.8 kg, and even more in those disposed to obesity. In addition, menstrual irregularities and polycystic ovarian syndrome may appear in young women taking the drug, perhaps as a consequence of the aforementioned weight gain.

An intravenous form of valproate is available. The maximum recommended rate of administration is 20 mg/min.

Phenobarbital Introduced as an antiepileptic drug in 1912, phenobarbital is still highly effective, but because of its toxic effects—drowsiness and mental dullness, nystagmus, and staggering—is seldom used as a first-line drug. The adverse effects of *primidone* are much the same. Both drugs may provoke behavioral problems in retarded children. It is still used to advantage as an adjunctive anticonvulsant and as primary therapy in infantile seizures.

Newer and Ancillary Antiepileptic Drugs *Lamotrigine* closely resembles phenytoin in its antiseizure activity and toxicity and is thought to have less risk of teratogenic effects, as mentioned below. It functions by selectively blocking the slow sodium channel, thereby preventing the release of the excitatory transmitters glutamate and aspartate. It is effective as a first-line and adjunctive drug for generalized and focal seizures and may be an alternative to valproate in young women because it does not provoke weight gain and ovarian problems. The main limitation to its use has been a serious rash in about 1 percent of patients, always requiring discontinuation of the drug, and lesser dermatologic eruptions in 12 percent. It should be pointed out that certain registries have reported far lower rates. The slow introduction of the medication may reduce the incidence of drug eruptions (see below). Rare cases of reversible chorea have been reported, especially with the concurrent use of phenytoin. Combined use with valproate greatly increases the serum level of lamotrigine.

Levetiracetam is a novel sodium channel blocker that has been useful in the treatment of partial seizures, mainly as an adjunctive drug. It is very well tolerated if initiated slowly but produces considerable sleepiness and dizziness otherwise and if used at high doses. There are no important interactions with other antiepileptic drugs.

Felbamate, a drug similar to meprobamate, has shown promise as an adjunctive form of treatment of generalized seizures, complex partial seizures, and Lennox-Gastaut syndrome, but its use has been greatly limited because of the rare occurrence of bone marrow suppression and liver failure.

Two other drugs, *gabapentin* and *vigabatrin*, were synthesized specifically to enhance the intrinsic inhibitory system of gamma-aminobutyric acid (GABA) in the brain. Gabapentin is chemically similar to GABA, but actually its anticonvulsant mechanism is not known. It is moderately effective in partial and secondary generalized seizures and has the advantage of not being metabolized by the liver. Vigabatrin and the related drugs *progabide* and *tiagabine* are inhibitors of GABA transaminase and are effective in the treatment of partial seizures and, to a lesser extent, primary generalized sei-

zures. Neither is bound to plasma protein, and they have the advantage of few toxic effects and no known adverse drug interactions.

Topiramate, another new antiepileptic agent, has much the same mode of action and degree of effectiveness as tiagabine. It may cause serious dermatologic side effects, especially if used with valproate, and appears to induce renal stones in 1.5 percent of patients. Angle-closure glaucoma has also been reported as a complication. A minor problem has been the development of hyperchloremic metabolic acidosis.

Ethosuximide (Zarontin) and valproate are equally effective for the treatment of absence seizures, the latter one being used mainly in children more than 4 years of age. It is good practice, in order to avoid excessive sleepiness, to begin with a single dose of 250 mg of ethosuximide per day and to increase it every week until the optimum therapeutic effect is achieved. *Methsuximide* (Celon-tin) is useful in individual cases where ethosuximide and valproate have failed. In patients with benign absence attacks that are associated with photosensitivity, myoclonus, and clonic-tonic-clonic seizures (including juvenile myoclonic epilepsy), valproate is the drug of choice. Valproate is particularly useful in children who have both absence and grand mal attacks, since the use of this drug alone often permits the control of both types of seizure. The concurrent use of valproate and clonazepam has been known to produce absence status.

Teratogenic Effects of Antiepileptic Medications Since it is essential to prevent convulsions in the pregnant epileptic woman, anticonvulsant medication should not be discontinued or arbitrarily reduced, particularly if there have been a number of convulsions in the recent past. The conventional drugs (phenytoin, carbamazepine, phenobarbital, valproate) are all appropriately tolerated in pregnancy. Plasma levels of most anticonvulsant drugs, both the free and protein-bound fractions, fall slightly in pregnancy and are cleared more rapidly from the blood. The main practical issue is the potential teratogenicity of many of the anticonvulsant drugs. The most common recorded teratogenic effects has been cleft lip and cleft palate, but infrequently a subtle facial dysmorphism ("fetal anticonvulsant syndrome"), similar to the fetal alcohol syndrome, has also been described. In general, the risk of major congenital defects is low; it increases to 4 to 5 percent in women taking anticonvulsant drugs during pregnancy, in comparison to 2 to 3 percent in the overall population of pregnant women. These statistics are essentially confirmed in the large study by Holmes and colleagues, conducted among several Boston hospitals. When all types of malformations were included, both major and minor, 20 percent of infants born to mothers who took anticonvulsants during pregnancy showed abnormalities compared to 9 percent of mothers who had not taken medications. However, similar to other large surveys, major malformations appeared in only 5 percent of infants exposed to anticonvulsants, in contrast to 2 percent in the nonexposed. These authors identified "midface hypoplasia" (shortened nose, philtrum, or inner canthal distance) and finger hypoplasia as characteristic of anticonvulsant exposure; these changes were found in 13 and 8 percent of exposed infants, respectively. The infants born of a group of women with epilepsy who had not taken anticonvulsants during pregnancy showed an overall rate of dysmorphic features comparable to that in control infants, but there was still a 2 to 3 percent rate of facial and finger hypoplasia. This risk is shared more or less equally by all the major anticonvulsants.

The risk of neural tube defects is also slightly increased by anticonvulsants, and greatest is for the use of valproate; it can be reduced by giving folate before pregnancy has begun, but some

epilepsy experts prefer to avoid the use of valproate during pregnancy altogether. Also, these risks are greater in women taking more than one anticonvulsant, so that monotherapy is a desirable goal. Furthermore, the risk is disproportionately increased in families with a history of these defects. Some of the newer anticonvulsants should probably be used cautiously until greater experience has been obtained. For example, claims have been made of safety in this regard for lamotrigine and many specialists have changed from the more conventional drugs to this one in women who anticipate becoming pregnant.

If a woman with seizure disorder has been off epilepsy medications for a time before getting pregnant and seizes during the pregnancy, the best choice of medications is probably phenytoin. Exposure of the fetus late in gestation poses few teratogenic risks. The special case of eclamptic seizures is managed by infusion of magnesium.

It should also be mentioned that most anticonvulsants induce the activity of hepatic enzymes, and this may result in the failure of contraceptive pills due to the accelerated metabolism of steroids. Epileptic women of childbearing age should be advised that higher doses of the estradiol component are required.

Skin Eruptions from Antiepileptic Drugs As mentioned in the discussion above, these are the most common idiosyncratic reactions to the drugs used to treat epilepsy. The aromatic compounds (phenytoin, carbamazepine, phenobarbital, primidone, and lamotrigine) are the ones most often responsible. Furthermore, *there is a high degree of cross-reactivity within this group*, particularly between phenytoin, carbamazepine and phenobarbital, and possibly lamotrigine. The problem arises most often in the first month of use. The typical eruption is maculopapular, mainly on the trunk; it usually resolves within days of discontinuing the medication. More severe rashes may develop, sometimes taking the form of erythema multiforme and Stevens-Johnson syndrome, or even toxic epidermal necrolysis. A rare hypersensitivity syndrome is one of high fever, rash, lymphadenopathy, and pharyngitis. Eosinophilia and hepatitis (nephritis) may follow.

If any of these reactions require that one of the aromatic drugs be replaced, valproate, gabapentin, topiramate, or levetiracetam are reasonable substitutes, depending, of course, on the nature of the seizures.

Treatment of Seizures in the Neonate Treatment of the *special types of convulsions in the neonatal period* and in infancy and childhood is discussed by Fenichel and by Volpe. In general, phenobarbital is preferred for seizure control in infancy.

Probably the form of epilepsy that is most difficult to treat is the childhood *Lennox-Gastaut* syndrome. Some of these patients have as many as 50 or more seizures per day, and every combination of anticonvulsant medications may have no effect. Valproic acid (900 to 2400 mg/day) will reduce the frequency of spells in approximately half the cases. The newer drugs—lamotrigine, topiramate, vigabatrin—are each beneficial in about 25 percent of cases. Clonazepam also has had limited success.

In the treatment of infantile spasms, ACTH or adrenal corticosteroids have been effective, but vigabatrin is now found to be as effective, including in patients with underlying tuberous sclerosis (see Elterman et al).

Status Epilepticus

Recurrent generalized convulsions at a frequency that prevents regaining of consciousness in the interval between seizures (grand mal status) constitute the most serious therapeutic problem (an

overall mortality of 20 to 30 percent, according to Towne and colleagues, but probably lower in recent years). Most patients who die of epilepsy do so because of uncontrolled seizures of this type, complicated by the effects of the underlying illness or an injury sustained as a result of a seizure. Rising temperature, acidosis, hypotension, and renal failure from myoglobinuria is a sequence of life-threatening events that may be encountered in cases of status epilepticus. Prolonged convulsive status (for longer than 30 min) also carries a risk of serious neurologic sequelae ("epileptic encephalopathy"). The MRI during and for days after a bout of status epilepticus frequently shows signal abnormalities in the region of a focal seizure or in the hippocampi, most often reversible, but we have had several such patients who awakened and were left in a permanent amnesia state. The MRI changes are most evident in FLAIR sequences. With regard to acute medical complications, from time to time a case of neurogenic pulmonary edema is encountered during or just after the convulsions, and some patients may become extremely hypertensive, then making it difficult to distinguish the syndrome from hypertensive encephalopathy.

Treatment (Table 16-9) The many regimens that have been proposed for the treatment of status attest to the fact that no one of them is altogether satisfactory and none is clearly superior (Treiman et al). The present authors have had the most success with the following program: when the patient is first seen, an initial assessment of cardiorespiratory function is made and an oral airway es-

tablished. A large-bore intravenous line is inserted; blood is drawn for glucose, blood urea nitrogen, electrolytes, and a metabolic and drug screen. A normal saline infusion is begun and a bolus of glucose is given (with thiamine if malnutrition and alcoholism are factors).

To rapidly suppress the seizures, diazepam is given intravenously at a rate of about 2 mg/min until the seizures stop or a total of 20 mg has been given. Or lorazepam, 0.1 mg/kg given by intravenous push at a rate not to exceed 2 mg/min, may be administered, being marginally more effective than diazepam because lorazepam putatively has a longer duration of action in the CNS (see Tables 16-2 and 16-9).

Immediately thereafter, a loading dose (15 to 18 mg/kg) of phenytoin is administered by vein at a rate of less than 50 mg/min. More rapid administration risks hypotension and heart block; it is therefore recommended that the blood pressure and electrocardiogram be monitored during the infusion. Phenytoin must be given through a freely running line with normal saline (it precipitates in other fluids) and should not be injected intramuscularly. A large study by Treiman and colleagues has demonstrated the superiority of using lorazepam instead of phenytoin as the first drug to control status, but this is not surprising considering the longer latency of action of phenytoin. Alldredge and colleagues have shown that diazepines can even be administered by paramedical workers with good effect in status epilepticus, terminating the seizures in about half of these patients. Nonetheless, a long-acting anticonvulsant such as phenytoin is given immediately after diazepam has controlled the initial seizures. An alternative is the water-soluble drug fosphenytoin, which is administered in the same doses as phenytoin but can be injected at twice the maximum rate. Moreover, it can be given intramuscularly in cases where venous access is difficult. However, the delay in hepatic conversion of fosphenytoin to active phenytoin makes the latency of clinical effect approximately the same for both drugs.

In an epileptic patient known to be taking anticonvulsants chronically but in whom the serum level of drug is unknown, it is probably best to administer the full recommended dose of phenytoin or fosphenytoin. If it can be established that the serum phenytoin is above 10 mg/mL, a lower loading dose is advisable. If seizures continue, an additional 5 mg/kg is indicated. If this fails to suppress the seizures and status has persisted for 20 to 30 min, an endotracheal tube should be inserted and O₂ administered.

Several approaches have been suggested to control status that persists after these efforts. The conventional and still dependable one is infusion of either thiopental, starting with 5 mg/kg, or phenobarbital, at a rate of 100 mg/min until the seizures stop or a total dose of 20 mg/kg is reached. In our experience, a long period of stupor must be anticipated after seizure control is obtained, but some epileptologists still prefer this as the initial treatment. Hypotension often limits the continued use of the barbiturates, but Parvainen and colleagues were able to manage this problem by fluid infusions, dopamine, and neosynephrine (we tend to depend on neosynephrine). Alternatively, at this stage, we have resorted to the approach of Kumar and Bleck, of giving high doses of midazolam (0.2 mg/kg loading dose followed by an infusion of 0.1 to 0.4 mg/kg/h as determined by clinical and EEG monitoring). If seizures continue, the dose can be raised as blood pressure permits. We have had occasion to use in excess of 20 mg/h because of a diminishing effect over days. This regimen of midazolam and phenytoin may be maintained for several days without major ill effect in previously healthy patients. Propofol given in a bolus of

Table 16-9
Approach to the treatment of status epilepticus in adults
(see text)

Initial assessment

- Assure adequate ventilation, oxygenation, blood pressure
- Intubate if necessary, based on low oxygen saturation and labored breathing
- Insert intravenous line
- Administer glucose and thiamine in appropriate circumstances
- Send toxic screen
- Assess quickly for cranial and cervical injury if onset of seizures is unwitnessed

Immediate suppression of convulsions

- Lorazepam or diazepam, 2 to 4 mg/min IV to a total dose of 10 to 15 mg with blood pressure monitoring when higher rates or doses are used

Initiation or reloading with anticonvulsants

- Phenytoin 15–18 mg/kg IV at 25–50 mg/min in normal saline or fosphenytoin at 50 to 75 mg/min

General anesthetic doses of medication for persistent status epilepticus

- Midazolam 0.2-mg/kg loading dose followed by infusion at 0.1 to 0.4 mg/kg/h or propofol 2 mg/kg/h

Further treatment if convulsions or electrographic seizures persist after several hours

- May add valproate or phenobarbital 10 mg/min to total dose of 20 mg/kg as additional anticonvulsants intravenously, or carbamazepine or levetiracetam by nasogastric tube if there is gastric and bowel activity

- Consider neuromuscular paralysis with EEG monitoring if convulsions persist

- Pentobarbital 10 mg/kg/h

- Inhalational anesthetics (isoflurane)

2 mg/kg and then as an intravenous drip of 2 to 8 mg/kg/h is an effective alternative to midazolam, but after 24 h the drug behaves like a high dose of barbiturate and there may be difficulty due to hypotension.

If none of these measures controls the seizures, all medication except phenytoin should be discontinued and a more aggressive approach taken to subdue all brain electrical activity by the use of general anesthesia. The preferred medications for this purpose have been pentobarbital and propofol, which, despite their poor record as primary anticonvulsants, are easier to manage than the alternative inhalational anesthetic agents. An initial intravenous dose of 5 mg/kg pentobarbital or 2 mg/kg propofol is given slowly to induce an EEG burst-suppression pattern, which is then maintained by the administration of 0.5 to 2 mg/kg/h pentobarbital or up to 10 mg/kg/h of propofol. Every 12 to 24 h, the rate of infusion is slowed to determine whether the seizures have stopped. The experience of Lowenstein and colleagues, like our own, is that most instances of status epilepticus that cannot be controlled with the standard anticonvulsants and midazolam will respond to high doses of barbiturates or propofol, but that these infusions cause hypotension and cannot be carried out for long periods.

Should the seizures continue, either clinically or electrographically, despite all these medications, one is justified in the assumption that the convulsive tendency is so strong that it cannot be checked by reasonable quantities of anticonvulsants. A few patients in this predicament have survived and awakened, even at times with minimal neurologic damage. Isoflurane (Forane) has been used in these circumstances with good effect, as we have reported (Ropper et al), but the continuous administration of such inhalational agents is impractical in most critical care units. Halothane has been ineffective as an anticonvulsant, but ether, although impractical, has in the past been effective in some cases. In the end, in these patients with truly intractable status, one usually depends on phenytoin, 0.5 g, and phenobarbital, 0.4 g/day (smaller doses in infants and children, as shown in Tables 16-9), and on measures that safeguard the patient's vital functions. Valproate is available as an intravenous preparation, making it suitable for administration in status, but its potential role in this circumstance has not been extensively studied.

A word must be added concerning neuromuscular paralysis and continuous EEG monitoring in status epilepticus. With failure of aggressive anticonvulsant and anesthetic treatment, there may be a temptation to paralyze all muscular activity, an effect easily attained with drugs such as pancuronium, while neglecting the underlying seizures. The use of such neuromuscular blocking drugs without a concomitant attempt to suppress seizure activity is inadvisable. If such measures are undertaken, continuous or frequent intermittent EEG monitoring is essential; this may also be also helpful in the early stages of status epilepticus in that it guides the dosages of anticonvulsants required to suppress the seizures.

In the related but less serious condition of *acute repetitive seizures*, in which the patient awakens between fits, a diazepam gel, which is well absorbed if given rectally, is available and has been found useful in institutional and home care of epileptic patients, although it is quite expensive. A similar effect has been attained by the nasal or buccal (transmucosal) administration of midazolam, which is absorbed from these sites (5 mg/mL, 0.2 mg/kg nasally; 2 mL to 10 mg buccally). These approaches have found their main use in children with frequent seizures who live in supervised environments, where a nurse or parent is available to administer the medication.

Petit mal status should be managed by intravenous lorazepam, valproic acid, or both, followed by ethosuximide. Nonconvulsive status is treated along the lines of grand mal status, usually stopping short of using anesthetic agents.

Surgical Treatment of Epilepsy

The surgical excision of epileptic foci in simple and complex partial epilepsies that have not responded to intensive and prolonged medical therapy is being used with increasing effectiveness in a growing number of specialized epilepsy units. At these centers, it has been estimated that approximately 25 percent of all patients with epilepsy are candidates for surgical therapy and more than half of these may benefit from surgery. With increasing experience and standardized approaches, especially in patients with temporal lobe epilepsy, it has been suggested that many patients are waiting too long before the surgical option. A perspective that may promote surgery in even more patients is the observation that about 60 percent of patients with partial seizures will respond to a conventional anticonvulsant but that among the remainder, few will respond to the addition of a second or third drug.

To locate the discharging focus requires a careful analysis of clinical and EEG findings, often including those obtained by long-term video/EEG monitoring and, sometimes, intracranial EEG recording by means of intraparenchymal depth electrodes, subdural strip electrodes, and subdural grids. Recently, functional imaging and specialized EEG analysis have been introduced to supplement these methods.

The most favorable candidates for surgery are those with complex partial seizures and a unilateral temporal lobe focus, in whom rates of cure and significant improvement approach 90 percent in some series, but overall, are probably closer to 50 percent after 5 years. A randomized trial conducted by Wiebe and colleagues gave representative results after temporal lobectomy of 58 percent of 40 carefully studied patients remaining seizure-free after 1 year, in contrast to 8 percent on medication alone. Furthermore, as reported by Yoon and colleagues, among those patients who remain free of seizures for 1 year after surgery, over half are still free of seizures after 10 years and most of the remainder had one or fewer episodes per year. It should be emphasized that most patients undergoing surgery in all these studies still require some anticonvulsant medication. Excision of cortical tissue outside of the temporal lobe accomplishes complete seizure-free states in about 50 percent. Taking all seizure types together, only about 10 percent of patients obtain no improvement at all and less than 5 percent are worse.

Other surgical procedures of value in selected cases are section of the corpus callosum and hemispherectomy. The most encouraging results with callosotomy have been obtained in the control of intractable partial and secondarily generalized seizures, particularly when tonic drop attacks are the most disabling seizure type. Removal of the entire cortex of one hemisphere, in addition to the amygdala and hippocampus, has been of value in children and also in some adults with severe and extensive unilateral cerebral disease and intractable contralateral motor seizures and hemiplegia. Rasmussen encephalitis, Sturge-Weber disease, and large porencephalic cysts at times fall into this category. Surgical, focused radiation, or endovascular reduction of arteriovenous malformations may reduce the frequency of seizures, but the results in this regard are somewhat unpredictable (see Chap. 34).

Driving and Epilepsy Only a few states in the United States and most provinces of Canada mandate that physicians report patients

with seizures under their care to the state Motor Vehicle Bureau. Physicians should nonetheless counsel such a patient regarding the obvious danger to himself and others if a seizure should occur (the same holds for the risks of swimming unattended). What little data are available suggest that accidents caused directly by a seizure are rare and, in any case, 15 percent have been due to a first episode of seizure that could not have been anticipated. In some states where a driver's license has been suspended on the occurrence of a seizure, there is usually some provision for its reinstatement—such as a physician's declaration that the patient is under medical care and has been seizure-free for some period of time (usually 6 months or 1 to 2 years). The Epilepsy Foundation website can be consulted for updated information regarding restrictions on driving, and this serves as an excellent general resource for patients and their families (www.epa.org).

Regulation of Physical and Mental Activity

The most important factors in seizure breakthrough, next to the abandonment of medication, are loss of sleep and abuse of alcohol or other drugs. The need for moderation in the use of alcohol must be stressed, as well as the need to maintain regular hours of sleep. These seemingly anachronistic suggestions in an age of many available anticonvulsants are still valid.

A moderate amount of physical exercise is desirable. With proper safeguards, even potentially more dangerous sports, such as swimming, may be permitted. However, a person with incompletely controlled epilepsy should not be allowed to drive an automobile, operate unguarded machinery, climb ladders, or take tub baths behind locked doors; such a person should swim only in the company of a good swimmer and wear a life preserver when boating.

Psychosocial difficulties must be identified and addressed early. Simple advice and reassurance will frequently help to prevent or overcome the feelings of inferiority and self-consciousness of many epileptic patients. Patients and their families may benefit from more extensive counseling, and proper family attitudes should be cultivated. Oversolicitude and overprotection should be discouraged. It is important that the patient be allowed to live as nor-

mal a life as possible. Every effort should be made to keep children in school, and adults should be encouraged to work. Many communities have vocational rehabilitation centers and special social agencies for epileptics, and advantage should be taken of such facilities.

Other Therapeutic Measures

Ketogenic Diet Since the 1920s, interest in this form of seizure control has varied, being revived periodically in centers caring for many children with intractable epilepsy. Despite the absence of controlled studies showing its efficacy or a reasonable hypothesis for its mechanism, several trials in the first half of the twentieth century and again more recently have demonstrated a reduction in seizures in half of the patients, including handicapped children with severe and sometimes intractable fits. The regimen is initiated during hospitalization by starvation for a day or two in order to induce ketosis, followed by a diet in which 80 to 90 percent of the calories are derived from fat (Vining). The difficulties in making such a diet palatable leads to its abandonment by about one-third of children and their families. A summary of experience from the numerous trials of the ketogenic diet can be found in the review by Lefevre and Aronson. They concluded that, despite the lack of a controlled trial, the diet can be effective in refractory cases of epilepsy in childhood. It has also been commented that some benefit persists even after the diet has been stopped.

Vagal Nerve Stimulation This experimental technique has found favor in cases of intractable partial and secondarily generalizing seizures. A pacemaker-like device is implanted in the anterior chest wall and stimulating electrodes are connected to the vagus at the left carotid bifurcation. The procedure is well tolerated except for hoarseness in some cases. Several trials have demonstrated an average of one-quarter reduction in seizure frequency among patients who were resistant to all manner of anticonvulsant drugs (see Chadwick for a discussion of recent trials). The mechanism by which vagal stimulation produces its effects is unclear, and its role in the management of seizures is still being defined. Cerebellar stimulation has also been used in the control of seizures, with no clear evidence of success.

CHAPTER 17

COMA AND RELATED DISORDERS OF CONSCIOUSNESS

In hospital neurology, the clinical analysis of unresponsive and comatose patients becomes a practical necessity. There is always an urgency about such medical problems—a need to determine the underlying disease process and the direction in which it is evolving and to protect the brain against more serious or irreversible damage. When called upon, the physician must therefore be prepared to implement a rapid, systematic investigation of the comatose patient; the need for prompt therapeutic and diagnostic action allows no time for deliberate, leisurely investigation.

Some idea of the dimensions of this category of neurologic disease can be obtained from published statistics. Many years ago, in two large municipal hospitals, it was estimated that 3 percent of all admissions to the emergency wards were for diseases that had caused coma. Alcoholism, cerebral trauma, and cerebrovascular diseases were the most common causes, accounting for 82 percent of the comatose patients admitted to the Boston City Hospital in past years (Solomon and Aring). Epilepsy, drug intoxication, diabetes, and severe infections were the other major causes for admission. It is surprising to learn that recent figures from municipal hospitals are much the same; they emphasize that the common conditions underlying coma are relatively invariant in general medical practice. In university hospitals, which tend to attract more obscure cases, the statistics are somewhat different. For example, in the series collected by Plum and Posner (Table 17-1), only one-quarter proved to have cerebrovascular disease, and in only 6 percent was coma the consequence of trauma. Indeed, all “mass lesions”—such as tumors, abscesses, hemorrhages, and infarcts—made up less than one-third of the coma-producing diseases. A majority were the result of exogenous (drug overdose) and endogenous (metabolic) intoxications and hypoxia. Subarachnoid hemorrhage, meningitis, and encephalitis accounted for another 5 percent of the total. Thus the order is, relatively speaking, reversed, but still intoxication, stroke, and cranial trauma stand as the “big three” of coma-producing conditions. Equally common in some series, albeit obvious and usually transient, is the coma that follows seizures or resuscitation from cardiac arrest.

The terms *consciousness*, *confusion*, *stupor*, *unconsciousness*, and *coma* have been endowed with so many different meanings that it is almost impossible to avoid ambiguity in their usage. They are not strictly medical terms but literary, philosophic, and psychologic ones as well. The word *consciousness* is the most difficult of all. William James once remarked that everyone knows what consciousness is until he attempts to define it. To the psychologist, consciousness denotes a state of continuous awareness of one's self and environment. Knowledge of self includes all “feelings, attitudes and emotions, impulses, volitions, and the active or striving aspects of conduct,” in short, a near continuous awareness of all one's own mental functioning, particularly of the cognitive processes, and their relation to past memories and experience. These can be judged only by the patient's verbal account of his introspections and, indirectly, by his actions. Physicians, being more

practical and objective for the most part, give greater credence to the patient's behavior and reactions to overt stimuli than to what the patient says. For this reason they usually give the term *consciousness* its commonest and simplest operational meaning—namely, the state of the patient's awareness of self and environment and his responsiveness to external stimulation and inner need. This narrow definition has an advantage in that *unconsciousness* has the opposite meaning—a state of unawareness of self and environment

Table 17-1

Final diagnosis in 500 patients admitted to hospital with “coma of unknown etiology”

	326 (65%)
Metabolic and other diffuse disorders	
Drug poisoning	149
Anoxia or ischemia	87
Hepatic encephalopathy	17
Encephalomyelitis and encephalitis	14
Subarachnoid hemorrhage	13
Endocrine disorders (including diabetes)	12
Acid-base disorders	12
Temperature regulation	9
Uremic encephalopathy	8
Pulmonary disease	3
Nutritional	1
Nonspecific metabolic coma	1
Supratentorial mass lesions	101 (20%)
Intracerebral hematoma	44
Subdural hematoma	26
Cerebral infarct	9
Brain tumor	7
Brain abscess	6
Epidural hematoma	4

or a suspension of those mental activities by which people are made aware of themselves and their environment, coupled with a diminished responsiveness to environmental stimuli. Some authors make a distinction between the level of consciousness—meaning the state of arousal or the degree of variation from normal alertness as judged by the appearance of facial muscles, fixity of gaze, and body posture—and the content of consciousness, i.e., the quality and coherence of thought and behavior. For medical purposes, the loss of normal arousal is by far the more important and dramatic aspect of disordered consciousness and the one identified by laypersons and physicians as being the central issue in coma. To add to the ambiguity, psychoanalysts have given the word *unconscious* a still different meaning; for them it is a repository of impulses and memories of previous experiences that cannot immediately be recalled to the conscious mind.

Much more could be said about the history of our ideas concerning consciousness and the theoretical problems with regard to its definition. Historically, there has been considerable controversy as whether it will ever be possible to understand mind and consciousness in terms of reductionist physical entities such as cellular and molecular neural systems. While it serves little practical purpose to review these subjects in detail, we note that contemporary investigations indicate that a constructive approach is to define the neurobiological correlates of well-defined elements of consciousness. Importantly, these controversies are being informed to some degree by analyses of unusual neurologic disorders, such as those that disturb perception and consciousness of perception (phantom limb, “blindsight,” etc.). The interested reader is referred to the discussions of consciousness by Crick and Koch, Plum and Posner, Young, and Zeman listed in the references.

States of Normal and Impaired Consciousness

The following definitions, though probably not acceptable to all psychologists, are of service to clinicians and will provide the student and practitioner with a convenient terminology for describing the states of awareness and responsiveness of their patients.

Normal Consciousness This is the condition of the normal person when awake. In this state the individual is fully responsive to a thought or perception and indicates by his behavior and speech the same awareness of self and environment as that of the examiner. This normal state may fluctuate during the day from one of keen alertness or deep concentration with a marked constriction of the field of attention to one of mild general inattentiveness, but even in the latter circumstances, the normal individual can be brought immediately to a state of full alertness and function.

Confusion The term *confusion* lacks precision, but in general it denotes an inability to think with customary speed, clarity, and coherence. All states of confusion are marked by some degree of inattentiveness and disorientation. In this condition the patient does not take into account all elements of his immediate environment. This state also implies a degree of imperceptiveness and distractibility, referred to traditionally as “clouding of the sensorium.” Here one difficulty is to define *thinking*, a term that refers variably to problem solving or to coherence of ideas and formation of memories. Confusion results most often from a process that influences the brain globally, such as a toxic or metabolic disturbance or a dementia. Any condition that causes drowsiness or stupor, includ-

ing the natural state that comes from sleep deprivation, results in some degradation of mental performance and inattentiveness. A confusional state can also accompany focal cerebral disease in various locations, particularly in the right hemisphere, or result from disorders that disturb mainly language, memory, or visuospatial orientation, but these are readily distinguished from the global confusional state. These matters are discussed further in Chap. 20, “Delirium and Other Confusional States,” and Chap. 23, in relation to focal cerebral lesions.

The mildest degree of confusion may be so slight that it can be overlooked unless the examiner searches for deviations from the patient’s normal behavior and liveliness of conversation. The patient may even be roughly oriented as to time and place, with only occasional irrelevant remarks betraying an incoherence of thinking. Moderately confused persons can carry on a simple conversation for short periods of time, but their thinking is slow and incoherent, their responses are inconsistent, attention span is reduced, and they are unable to stay on one topic and to inhibit inappropriate responses. Usually they are variably disoriented in time and place. They are distractible and at the mercy of every stimulus. Periods of irritability and excitability may alternate with drowsiness and diminished vigilance. Movements are often tremulous, jerky, and ineffectual. Sequences of movement also reveal impersistence.

Severely confused and inattentive persons are usually unable to do more than carry out the simplest commands, and these only inconsistently and in brief sequence. Few if any thought processes are in operation. Their speech is usually limited to a few words or phrases; infrequently the opposite pertains—namely, some individuals are voluble. They are unaware of much that goes on around them, are often disoriented in time and place, do not grasp their immediate situation, and may misidentify people or objects. Illusions may lead to fear or agitation. Occasionally, hallucinatory or delusional experiences impart a psychotic cast to the clinical picture, obscuring the deficit in attention.

The degree of confusion often varies from one time of day to another. It tends to be least pronounced in the morning but increases as the day wears on and peaks in the early evening hours (“sundowning”) when the patient is fatigued and environmental cues are less clear-cut. Many events that involve the confused patient leave no trace in memory; in fact, the capacity to recall events of the past hours or days is one of the most delicate tests of mental clarity. So is the use of so-called working memory, which requires the temporary storage of the solution of one task for use in the next. This deficit in working memory, which is such a common feature of the confusional states, can be demonstrated by tests of serial subtraction and the spelling of words (or repeating a phone number) forward and then backward. Careful analysis will show these defects to be tied to inattention and impaired perception or registration of information rather than a fault in retentive memory.

In some medical writings, particularly in the psychiatric literature, the terms *delirium* and *confusion* are used interchangeably, the former connoting nothing more than a nondescript confusional state in which hyperactivity may be prominent. However, in the syndrome of delirium tremens (observed most often but not exclusively in alcoholics), the vivid hallucinations; inaccessibility of the patient to events other than those to which he is reacting at the moment; extreme agitation; tendency to tremble, startle easily, and convulse; and the signs of overactivity of the autonomic nervous system [as well as a normal electroencephalographic (EEG) tracing] suggest to us that the term *delirium* should be reserved for a highly distinctive confusional syndrome (elaborated in Chap. 20).

The clearest evidence of the relationship of inattention, confusion, stupor, and coma is that patients may pass through each of these states as they become comatose or emerge from coma. The authors have not observed such a relationship between coma and delirium except possibly in patients suffering from bacterial meningitis, certain drug intoxications or withdrawal states, or hepatic stupor and coma, which in some few instances may be preceded by a brief period of delirium.

Drowsiness and Stupor In these states, mental, speech, and physical activity are reduced. *Drowsiness* denotes an inability to sustain a wakeful state without the application of external stimuli. Inattentiveness and mild confusion are the rule, both improving with arousal. The patient shifts positions in bed or chair. The lids droop without closing completely; there may be snoring, the jaw and limb muscles are slack, and the limbs are relaxed. This state is indistinguishable from light sleep, with slow arousal elicited by speaking to the patient or applying a tactile stimulus.

Stupor describes a state in which the patient can be roused only by vigorous and repeated stimuli, at which time he opens his eyes, looks at the examiner, and does not appear to be unconscious; response to spoken commands is either absent or slow and inadequate. Restless or stereotyped motor activity is common in stuporous patients and there is a reduction in the natural shifting of positions. When left unstimulated, these patients quickly drift back into a sleep-like state. The eyes move outward and upward, a feature that is shared with sleep (see further on). Tendon and plantar reflexes and breathing pattern may or may not be altered, depending on how the underlying disease has affected the nervous system. In psychiatry, the term *stupor* has been used in a second sense—to denote an uncommon condition in which the perception of sensory stimuli is presumably normal but activity is suspended and motor activity is profoundly diminished (catatonic stupor).

Coma The patient who appears to be asleep and is at the same time incapable of being aroused by external stimuli or inner need is in a state of coma. There are variations in the degree of coma; in its deepest stages, no reaction of any kind is obtainable: corneal, pupillary, pharyngeal, tendon, and plantar reflexes are in abeyance, and tone in the limb muscles is diminished. With lesser degrees of coma, pupillary reactions, reflex ocular movements, and corneal and other brainstem reflexes are preserved in varying degree, and muscle tone in the limbs may be increased. Respiration may be slow or rapid, periodic, or deranged in other ways (see further on). In still lighter stages, sometimes referred to by the ambiguous term *semicomma*, most of the above reflexes can be elicited, and the plantar reflexes may be either flexor or extensor (Babinski sign). Moreover, vigorous stimulation of the patient or distention of the bladder may cause a stirring or moaning and a quickening of respiration. These physical signs vary somewhat depending on the cause of coma. For example, patients with alcoholic coma may be areflexic and unresponsive to noxious stimuli, even when respiration and other vital functions are not threatened. The depth of coma and stupor, when compared in serial examinations, is most useful in assessing the direction in which the disease is evolving.

Relationship of Sleep to Coma Persons in sleep give little evidence of being aware of themselves or their environment; in this respect they are unconscious. Sleep shares a number of other features with the pathologic states of drowsiness, stupor, and coma. These include yawning, closure of the eyelids, cessation of blinking and swallowing, upward deviation or divergence or roving move-

ments of the eyes, loss of muscular tone, decrease or loss of tendon reflexes, and even the presence of Babinski signs and irregular respirations, sometimes Cheyne-Stokes in type. Upon being awakened from deep sleep, a normal person may be confused for a few moments, as every physician knows. Nevertheless, sleeping persons may still respond to unaccustomed stimuli and at times are capable of some mental activity in the form of dreams that leave traces of memory, thus differing from persons in stupor or coma. The most important difference, of course, is that persons in sleep, when stimulated, can be roused to normal consciousness. There are important physiologic differences as well. Cerebral oxygen uptake does not decrease during sleep, as it usually does in coma. Recordable electrical activity—EEG and cerebral evoked responses—and spontaneous motor activity differ in the two states, as indicated later in this chapter and in Chap. 19. The anatomic and physiologic bases for these differences are only partly known.

The Persistent Vegetative and Minimally Conscious States, Locked-in Syndrome, and Akinetic Mutism

With increasing refinements in the treatment of severe systemic diseases and cerebral injury, more and more patients who formerly would have died have survived for indefinite periods without regaining any meaningful mental function. For the first week or two after the cerebral injury, these patients are in a state of deep coma. Then they begin to open their eyes, at first in response to painful stimuli and later spontaneously and for increasingly prolonged periods. The patient may blink in response to threat or to light and intermittently the eyes move from side to side, seemingly following objects or fixating momentarily on the physician or a family member and giving the erroneous impression of recognition. Respiration may quicken in response to stimulation, and certain automatisms—such as swallowing, bruxism, grimacing, grunting, and moaning—may be observed (Zeman). However, the patient remains totally inattentive, does not speak, and shows no signs of awareness of the environment or inner need; responsiveness is limited to primitive postural and reflex movements of the limbs. In brief, there is arousal or wakefulness and alternating arousal-nonarousal cycles may be established, but the patient regains neither awareness nor purposeful behavior of any kind. This state is characterized by one of a number of EEG abnormalities. There may be predominantly low-amplitude delta-frequency background activity, burst suppression, widespread alpha and theta activity, an alpha coma pattern, and sleep spindles, all of which have been described in this syndrome, as summarized by Hansotia (see Chap. 2). One common feature is a lack of—or minimal change in—the background EEG activity after stimulating the patient. Moreover, the transition from coma to a state of partial awakening (the minimally responsive state described below) is generally not marked by a change in the EEG pattern.

If lasting, the syndrome described above is appropriately referred to as the *persistent vegetative state* or PVS (Jennett and Plum). This term has gained wide acceptance and applies to this clinical situation whatever the underlying cause. The most common pathologic bases of this state are diffuse cerebral injury due to closed head trauma, widespread laminar necrosis of the cortex after cardiac arrest, and thalamic necrosis from a number of causes. Most often, and contrary to the notion held by most neurologists, the most prominent pathologic changes are usually in the thalamic and subthalamic nuclei, as in the celebrated Quinlan case (Kinney et

al) rather than solely in the cortex; this holds for postanoxic as well as traumatic cases. A review by H Adams and colleagues found these thalamic changes but attributed them to secondary degeneration from white matter and cortical lesions. However, in several of our cases the thalamic damage stood almost alone as the cause of persistent “awake coma.” In traumatic cases, the pathologic findings are of diffuse subcortical white matter degeneration (described as *diffuse axonal injury*), prominent thalamic degeneration, and ischemic damage in the cortex. These anatomic findings suggest the concept that PVS is a state in which the cortex is either diffusely injured or effectively disconnected and isolated from the thalamus. In either the traumatic or anoxic types of PVS, atrophy of the white matter may lead to ventricular enlargement and thinning of the corpus callosum.

It is also noteworthy that a PVS may be the terminal phase of progressive cortical degenerative processes such as Alzheimer and Creutzfeldt-Jakob disease (where the pathologic changes may include the thalamus).

In all these clinical states, the profound and widespread dysfunction of the cerebrum is reflected by extreme reductions in cerebral blood flow and metabolism, measured with positron emission tomography (PET) and other techniques. On the basis of PET studies in a patient with carbon monoxide poisoning, Laureys and colleagues observed that the main difference between the PVS and the recovered state was the degree of hypometabolism in the parietal lobe association areas. The finding in this PET study that noxious somatosensory stimulation fails to activate the association cortices is consistent with the concept that large regions of cortex are isolated from thalamic input. This view notwithstanding, there is little doubt that the neuroanatomic and neurophysiologic basis of the vegetative state will prove to be complex.

Additional terms that have been used to describe this syndrome of preserved autonomic and respiratory function without cognition include *apallic syndrome* and *neocortical death*. A position paper has codified the features of the PVS and suggests dropping a number of related ambiguous terms, although some, such as *akinetic mutism*, discussed further on, have a more specific neurologic meaning and still find use (see Multi-Society Task Force on PVS).

The condition of PVS blends into a state of profound dementia that has been recently termed the “minimally conscious state,” wherein the patient is capable of some rudimentary behavior such as following a simple command, gesturing, or producing single words or brief phrases, always in an inconsistent way from one examination to another (see Giacino and colleagues). Here there is preservation of the ability to carry out basic motor behaviors that demonstrate a degree of alertness at least at some times. The minimally conscious state is found as either a transitional or permanent condition and is difficult to separate from akinetic mutism discussed further on. Any notion of such a patient’s self-awareness is purely conjectural. The causes and pathologic changes underlying the minimally conscious state are identical to those of the vegetative state, including the frequent finding of thalamic and multiple cerebral lesions, and the distinction between them is one of degree.

It is difficult to predict which patients will fall permanently into the PVS category (see page 961). Plum and Posner have reported that of 45 patients with signs of the vegetative state at 1 week after onset, 13 had awakened and 5 of these had satisfactory outcomes; after being vegetative for close to 2 weeks, only 1 recovered to a level of moderate disability. After 2 weeks, the prognosis was uniformly poor. Larger studies by Higashi and colleagues

have given similar results. As a rough guide to prognosis in head injury, Braakman and colleagues found that among a large group of comatose patients, 59 percent regained consciousness within 6 h; but of those in a vegetative state at 3 months, none became independent. At no time was it possible to distinguish patients who would remain in a vegetative state from those who would die. A study by the Multi-Society Task Force concluded that the outcome from a vegetative state is better in traumatic as compared to non-traumatic cases. H Adams and coworkers have proposed that this reflects differences in the state of thalamic neurons in the two situations. They propose that after acute hypoxia, neurons subjected to ischemic necrosis are liable to be permanently lost; by contrast, in trauma, the loss of thalamic neurons is more frequently secondary to transsynaptic degeneration following diffuse axonal injury, allowing a greater potential for recovery if there is improvement of early axonal injury. We find many of these ideas speculative.

If one allows the term *vegetative state* to be applied soon after the onset of coma, rather than requiring coma to persist for several months, then fewer cases would be “persistent.” For this reason and because of the anxiety created for families by such a final diagnosis, it has been suggested that the term be abandoned (Kennard and Illingworth); a more meaningful goal would be to insist on strict adherence to the clinical diagnostic criteria.

It is useful to maintain a critical view of news reports of remarkable recuperation after months or years of prolonged coma or the vegetative state. When the details of such cases become known, it is evident that recovery might reasonably have been expected. There are, however, numerous reported instances of partial recovery in patients—particularly children—who display vegetative features for several weeks or, as Andrews describes, even several months after injury. Such observations cast doubt on unqualified claims of success with various therapies, such as sensory stimulation. Nevertheless, the occurrence of rare instances of very late recovery in adults must be acknowledged [see Andrews; Higashi et al; and Rosenberg et al (1977)].

The states of coma described above and the PVS must be clearly distinguished from a clinical state in which there is little or no disturbance of awareness (consciousness) but only an inability of the patient to respond adequately. The latter is referred to as the *locked-in syndrome* or the *de-efferent state*. The term *pseudocoma* as a synonym for this state is best avoided, since it is used by some physicians to connote the feigned unconsciousness of the hysterical or malingerer. The locked-in syndrome is due most often to a lesion of the ventral pons (basis pontis) as a result of basilar artery occlusion. Such an infarction spares both the somatosensory pathways and the ascending neuronal systems responsible for arousal and wakefulness as well as certain midbrain elements that allow the eyelids to be raised and give the appearance of wakefulness; the lesion essentially interrupts the corticobulbar and corticospinal pathways, depriving the patient of speech and the capacity to respond in any way except by vertical gaze and blinking. Severe motor neuropathy (e.g., Guillain-Barré syndrome), pontine myelinolysis, or periodic paralysis may have a similar effect.

One could logically refer to the locked-in state as *akinetic mutism* insofar as the patient is akinetic (motionless) and mute, but this is not the sense in which the term was originally used by Cairns and colleagues. They described a patient who appeared to be awake but was unresponsive (actually their patient was able to answer in whispered monosyllables). Following each of several drainings of a third ventricular cyst, the patient would become aware and responsive but would have no memory for any of the events that had

taken place when she was in the akinetic mute state. This rare state of apparent vigilance in an imperceptive and unresponsive patient has been referred to by French authors as *coma vigile*, but the same term has been applied to the vegetative state. The term *akinetic mutism* has been applied to yet another group of patients who are silent and inert as a result of bilateral lesions of the anterior parts of the frontal lobes, leaving intact the motor and sensory pathways; the patient is profoundly apathetic, lacking to an extreme degree the psychic drive or impulse to action (abulia) (pages 359 and 394). However, the abulic patient, unlike Cairns's patient, registers most of what is happening about him and intensely stimulated, may speak normally, relating events observed in the recent and distant past.

The psychiatric patient with *catatonia* appears unresponsive, in a state that simulates stupor, light coma, or akinetic mutism. There are no signs of structural brain disease, such as pupillary or reflex abnormalities. Oculocephalic responses are preserved, as in the awake state—i.e., the eyes move concurrently as the head is turned. There is usually resistance to eye opening, and some patients display a waxy flexibility of passive limb movement that gives the examiner a feeling of bending a wax rod (*flexibilitas cerea*); there is also the retention for a long period of seemingly uncomfortable limb postures (*catalepsy*). Peculiar motor mannerisms or repetitive motions, seen in a number of these patients, may give the impression of seizures; choreiform jerking has also been reported, but the latter sign should suggest the possibility of seizure activity. The EEG shows normal posterior alpha activity that is attenuated by stimulation. Catatonia is discussed further on pages 359 and 1311.

Since there is considerable imprecision in the use of terms by which these states are designated, the physician would be better advised to supplement designations such as *coma* and *akinetic mutism* by simple descriptions indicating whether the patient appears awake or asleep, drowsy or alert, aware or unaware of his surroundings, and responsive or unresponsive to a variety of stimuli. This requires that the patient be observed more frequently or over a longer period than the several minutes usually devoted to this portion of the neurologic examination.

Brain Death

In the late 1950s European neurologists called attention to a state of coma in which the brain was irreversibly damaged and had ceased to function but pulmonary and cardiac function could still be maintained by artificial means. Mollaret and Goulon referred to this condition as *coma dépassé* (a state beyond coma). A Harvard Medical School committee, in 1968, called it *brain death* and established a set of clinical criteria by which it could be recognized (Beecher et al.). RD Adams, who was a member of the committee, defined the state as one of complete unresponsiveness to all modes of stimulation, respiratory arrest, and absence of all EEG activity for 24 h. The concept that a person is dead if the brain is dead and that death of the brain may precede the cessation of cardiac function has posed a number of important ethical, legal, and social problems as well as medical ones. The various aspects of brain death have since been the subject of close study by several professional committees, which have for the most part confirmed the 1968 guidelines for determining that the brain is dead. The monograph by our colleague Wijdicks is a thorough and modern source on the subject of brain death and also addresses the subject from an international perspective.

The central considerations in the diagnosis of brain death are (1) absence of cerebral functions; (2) absence of brainstem functions, including spontaneous respiration; and (3) irreversibility of the state. Following from the last criterion, it is necessary to demonstrate an irrefutable cause of the catastrophic brain damage (e.g., trauma, cardiac arrest, cerebral hemorrhage) and to exclude reversible causes such as drug overdose.

The absence of cerebral function is judged by the presence of deep coma and total lack of spontaneous movement and of motor and vocal responses to all visual, auditory, and cutaneous stimulation. Spinal reflexes may persist in some cases, and the toes often flex slowly in response to plantar stimulation; but a well-developed Babinski sign is unusual in our experience (although its presence does not exclude the diagnosis of brain death). Extensor or flexor posturing is seen from time to time as a transitional phenomenon just after brain death becomes evident.

The absence of brainstem function is judged by the loss of spontaneous eye movements, midposition of the eyes, and lack of response to oculocephalic and caloric (oculovestibular) testing; presence of dilated or midposition fixed pupils (not smaller than 3 mm); paralysis of bulbar musculature (no facial movement or gag, cough, corneal, or sucking reflexes); an absence of motor and autonomic responses to noxious stimuli; and absence of respiratory movements. The clinical findings should show complete absence of brain function, not an approximation that might be reflected, for example, by small or poorly reactive pupils, slight eye deviation with oculovestibular stimulation, posturing of the limbs, and the like.

As a final test of this last component, it has become customary to perform an "apnea test" to demonstrate an unresponsiveness of the medullary centers to a high carbon dioxide tension. This test is conducted by first employing preoxygenation for several minutes with 90% inspired oxygen, the purpose of which is to displace nitrogen from the alveoli and create a reservoir of oxygen that will diffuse down a gradient into the pulmonary blood. The patient can then be disconnected from the respirator for a few minutes (during which time 100% oxygen is being delivered by cannula); this allows the P_{CO_2} to rise to 50 to 60 mmHg (typically, carbon dioxide rises 2.5 mmHg per minute at normal body temperature—slower if the patient is hypothermic). If no breathing is observed and examination of the blood gases shows that an adequate level of P_{CO_2} has been attained, the presence of this component of brain death is corroborated.

Most but not all patients have the signs of diabetes insipidus when the other criteria for brain death are fulfilled, reflecting the imprecision of clinical features in detecting the total loss of brain function. Other ancillary bedside tests may be conducted. Among the ones we use from time to time is an absence of pulse response to the injection of atropine; this reflects the loss of innervation of the heart by vagal neurons.

The authors have observed a number of dramatic spontaneous movements when severely hypoxic levels are attained by apnea testing or terminal disconnection from the ventilator for several minutes. These include opisthotonus with chest expansion that simulates a breath, raising the arms and crossing them in front of the chest or neck (which we have termed the Lazarus sign), head-turning, shoulder-shrugging, and variants of these posturing-like movements (Ropper 1984). For this reason it is advisable that the family not be in attendance immediately after mechanical ventilation has been discontinued.

The EEG provides confirmation of cerebral death, and most institutions prefer corroboration of the clinical features by the dem-

onstration of electrocerebral silence (“flat” or, more accurately, iso-electric EEG, shown first by Schwab), which is considered to be present if there is no electrical potential of more than 2 mV during a 30-min recording (except for artifacts created by the ventilator, ECG, or surrounding electrical devices). We still follow this practice in almost all cases.

There are cases on record in which a patient with an isolectric EEG has had preserved brainstem reflexes. It must also be emphasized that cerebral unresponsiveness and a flat EEG do not always signify brain death; both may occur and may be reversible in states of profound hypothermia or intoxication with sedative-hypnotic drugs and immediately following cardiac arrest. For this reason, it has been recommended that the diagnosis of brain death not be entertained until several hours have passed from the time of initial observation. If the examination is performed at least 6 h after the ictus and there is *prima facie* evidence of overwhelming brain injury from trauma, anoxia, or massive cerebral hemorrhage (the most common conditions causing brain death), there is no need for serial testing. If cardiac arrest was the antecedent event, or the cause of neurologic damage is unclear, or drug or alcohol intoxication could reasonably have played a role in suppressing the brainstem’s reflexes, it is advisable to wait about 24 h before pronouncing the patient dead. Toxicologic screening of the serum or urine is requisite in the latter circumstances.

Evoked potentials show interesting but variable abnormalities in brain-dead patients but are not of primary value in the diagnosis. Some centers use nuclide brain scanning or cerebral angiography to demonstrate an absence of blood flow to the brain, equating this with brain death; but there are technical pitfalls in the use of these methods, and it is preferable to keep the diagnosis of death primarily clinical. The same can be said for transcranial Doppler sonography, which in brain death shows a to-and-fro “*pendelfluss*” blood-flow pattern in the basal vessels.

In our experience, the main difficulties that arise in relation to brain death are not the technical issues but those involving the sensitive conversations and relationships with the family of the patient and, to a lesser extent, with other medical professionals. These tasks often fall to the neurologist. From our experience, it is best not to embark on clinical or EEG testing for brain death unless there is a clear intention on the part of the physician to remove the ventilator or request organ donation at the end of the process. The process and its intended outcome should be explained to the family. The family’s desires regarding organ transplantation should be sought after adequate time has passed for them to absorb the shock of the circumstances. Neurologists must, of course, resist pressures from diverse sources that might lead them to the premature designation of a state of brain death. At the same time, it should be clarified that while brain death is an operational state that allows transplantation to proceed and mandates withdrawal of ventilation and blood pressure support, patients with overwhelming brain injuries need not fulfill these absolute criteria in order for medical support to be withdrawn.

A task force for the determination of *brain death in children* has recommended the adoption of essentially the same criteria as for adults. Because of the great difficulty in evaluating the status of nervous function in relation to perinatal insults, they have suggested that a diagnosis of brain death not be made before the seventh postnatal day and that the period of observation be extended to 48 h. As with adults, the possibility of reversible brain dysfunction from toxins, drugs, hypothermia, and hypotension must always be considered.

The Electroencephalogram and Disturbances of Consciousness

One of the most delicate confirmations of the fact that the states of impaired consciousness are expressions of neurophysiologic changes in the cerebrum is the altered EEG. Some change of brain waves occurs in all disturbances of consciousness except the milder degrees of confusion, in most cases of delirium tremens, and in catatonia. These alterations usually consist of a disorganization of the EEG background pattern, including disappearance of alpha rhythm and replacement by random slow waves of low to moderate voltage in the initial stages of confusion; a more regular pattern of slow, two- to three-per-second waves of high voltage in stupor; slow low-voltage waves or intermittent suppression of organized electrical activity in the deep coma of hypoxia and ischemia; and ultimately a complete absence of electrical activity in brain death.

In some deeply comatose patients, the EEG may transiently show diffuse and variable (8- to 12-Hz) activity, which may be mistaken for physiologic alpha rhythm. However, the former pattern (so-called *alpha coma*) is not limited to the posterior cerebral regions, is not monorhythmic like normal alpha activity, and displays no reactivity to sensory stimuli. This alpha-like activity pattern may be associated with pontine or diffuse cortical lesions and has a poor prognosis (Iragui and McCutchen; page 29). A rarer EEG abnormality is “spindle coma,” in which sleep spindles dominate the record (page 341).

The EEG accurately reflects the depth of certain metabolic comas, particularly those due to hepatic or renal failure. In these conditions the slow waves become higher in amplitude as coma deepens, ultimately assuming a high-voltage rhythmic delta pattern and a triphasic configuration. There is also a general correspondence between the intensity of stimuli required to elicit motor activity and the degree of slowing of the background rhythm. Not all cerebral disorders that cause confusion, stupor, and coma have the same effects on the EEG. In cases of intoxication with sedatives, exemplified by barbiturates, fast activity initially replaces normal rhythms. Coma in which myoclonus or twitching is a major clinical feature may show frequent sharp waves or a sharpness to the background slowing of the EEG. The differences in EEG changes among metabolic derangements probably represent important biologic distinctions at the neuronal level that have not yet been elucidated (see also Chap. 2).

The Anatomy and Neurophysiology of Alertness and Coma

Our current understanding of the anatomy and physiology of alertness comes largely from the elegant experiments of Bremer and of Magoun and Moruzzi in the 1930s and 1940s. Observing cats in whom he had sectioned the brainstem between the pons and midbrain and at the level of the lower medulla, Bremer found that the rostral section caused a sleep-like state and “synchronized” EEG rhythms that were characteristic of sleep; animals with the lower section remained awake, with appropriate “desynchronized” EEG rhythms. He interpreted this to mean, in large part correctly, that a constant stream of sensory stimuli, provided by trigeminal and other cranial sources, was required to maintain the awake state. Several years later, Morrison and Dempsey demonstrated a system of “nonspecific” projections from the thalamus to all cortical regions, independent of any specific sensory nucleus. A critical refinement of this concept resulted from the observation by Mor-

ruzzi and Magoun that electrical stimulation of the medial midbrain tegmentum and adjacent areas just above this level caused a lightly anesthetized animal to become suddenly alert and its EEG to change correspondingly, i.e., to become “desynchronized,” in a manner identical to normal arousal by sensory stimuli. The sites at which stimulation led to arousal consisted of a series of points extending from the nonspecific medial thalamic nuclei down through the caudal midbrain. These points were situated along the loosely organized core of neurons that anatomists had referred to as the reticular system or formation. The anatomic studies of the Scheibels have described widespread innervation of the reticular formation by multiple bifurcating and collateral axons of the ascending sensory systems, implying that this area was maintained in a tonically active state by ascending sensory stimulation. Because this region, especially the medial thalamus, projects widely to the cerebral hemispheres, there arose the concept of a reticular activating system (RAS) that maintained the alert state and the inactivation of which led to an unarousable state. In this way, despite a number of experimental inconsistencies (see Steriade) the paramedian upper brainstem tegmentum and lower diencephalon came to be conceived as the locus of the alerting system of the brain.

The anatomic boundaries of the upper brainstem reticular activating system are somewhat indistinct. This system is interspersed throughout the paramedian regions of the upper (rostral) pontine and midbrain tegmentum; at the thalamic level, it includes the functionally related posterior paramedian, parafascicular, and medial portions of the centromedian and adjacent intralaminar nuclei. In the brainstem, nuclei of the reticular formation receive collaterals from the spinothalamic and trigeminal-thalamic pathways and project not just to the sensory cortex of the parietal lobe, as do the thalamic relay nuclei for somatic sensation, but to the whole of the cerebral cortex. Thus, it would seem that sensory stimulation has a double effect—it conveys information to the brain from somatic structures and the environment and also activates those parts of the nervous system on which the maintenance of consciousness depends. The cerebral cortex not only receives impulses from the ascending reticular activating system but also modulates this incoming information via corticofugal projections to the reticular formation. Although the physiology of the reticular activating system is far more complicated than this simple formulation would suggest, it nevertheless, as a working idea, retains a great deal of clinical credibility and makes comprehensible some of the neuropathologic observations noted further on, under “Pathologic Anatomy of Coma.”

Although for many years it has been taught that arousal causes a desynchronization of brainwave activity (in distinction to the synchronized activity of sleep), it has become apparent that during wakefulness, there is also a widespread low-voltage fast rhythm (a gamma rhythm that has a frequency of 30 to 60 Hz). This activity, coordinated by the thalamus, has been theorized to synchronize widespread cortical activity and to account perhaps for the unification of modular aspects of experience (color, shape, motion) that are processed in different cortical regions. In this way the rhythm has been theorized to “bind” various aspects of a sensory experience or a memory. This fast and widespread electrographic activity is not easily appreciable with EEG surface recordings but it can be extracted by sophisticated mathematical tools. Using such electrophysiologic methods, Meador and colleagues have shown that the rhythm can be detected over the primary somatosensory cortex after an electrical stimulus on the contralateral hand is perceived, but

not if the patient fails to perceive it. The clinical meaning of the rhythm is controversial, but it has elicited great interest because it may give insight into several intriguing questions about the states of consciousness.

Metabolic Mechanisms that Disturb Consciousness

In a number of disease processes that disturb consciousness, there is direct interference with the metabolic activities of the nerve cells in the cerebral cortex and the central nuclei of the brain. Hypoxia, global ischemia, hypoglycemia, hyper- and hypo-osmolar states, acidosis, alkalosis, hypokalemia, hyperammonemia, hypercalcemia, hypercarbia, drug intoxication, and severe vitamin deficiencies are well-known examples (see Chap. 40 and Table 40-1). In general, the loss of consciousness in these conditions parallels the reduction in cerebral metabolism or blood flow. For example, in the case of global ischemia, an acute drop in cerebral blood flow (CBF) to 25 mL/min/100 g brain tissue from its normal 55 mL/min/100 g causes slowing of the EEG and syncope or impaired consciousness; a drop in CBF below 12 to 15 mL/min/100 g causes electrocerebral silence, coma, and cessation of most neuronal metabolic and synaptic functions. Lower levels are tolerated if arrived at more slowly, but neurons cannot survive when flow is reduced below 8 to 10 mL/min/100 g. There is a corresponding reduction in the cerebral metabolic rate. In other types of metabolic encephalopathy or with widespread anatomic damage to the hemispheres, blood flow stays near normal levels while metabolism is greatly reduced. Oxygen consumption of 2 mg/min/100 g (approximately half of normal) is incompatible with an alert state. An exception to these statements is the coma that arises from seizures, in which metabolism and blood flow are greatly increased during the seizure. Extremes of body temperature (above 41°C or below 30°C) also induce coma through a nonspecific effect on the metabolic activity of neurons. These metabolic changes are probably epiphenomena reflecting, in each particular encephalopathy, a specific type of dysfunction in neurons and their supporting cells.

The endogenous metabolic toxin(s) that are responsible for coma cannot always be identified. In diabetes, acetone bodies (acetocetate acid, β -hydroxybutyric acid, and acetone) are present in high concentration; in uremia, there is probably an accumulation of dialyzable small molecular toxins, notably phenolic derivatives of the aromatic amino acids. In hepatic coma, elevation of blood NH₃ to five to six times normal levels corresponds roughly to the level of coma. Lactic acidosis may affect the brain by lowering arterial blood pH to less than 7.0. The impairment of consciousness that accompanies pulmonary insufficiency is related mainly to hypercapnia (see page 964). In hyponatremia (Na < 120 meq/L) of whatever cause, neuronal dysfunction is probably due to the intracellular movement of water, leading to neuronal swelling and loss of potassium chloride from the cells. The mode of action of bacterial toxins is not fully understood.

Drugs such as general anesthetics (see below), alcohol, opiates, barbiturates, phenytoin, antidepressants, and diazepines induce coma by their direct effects on neuronal membranes in the cerebrum and reticular activating system or on neurotransmitters and their receptors. Others, such as methyl alcohol and ethylene glycol, act by producing a metabolic acidosis. Although the coma of toxic and metabolic diseases usually evolves through stages of drowsiness, confusion, and stupor (and the reverse sequence occurs during emergence from coma), each disease imparts its own char-

acteristic clinical features. Probably this means that each disease has a distinctive mechanism and that the locus of the metabolic effect is somewhat different from one disease to another.

The sudden and excessive neuronal discharge that characterizes an epileptic seizure is a common coma-producing mechanism. Usually focal seizure activity has little effect on consciousness until it spreads from one side of the brain (and the body if there is a convulsion) to the other. Coma then ensues, presumably because the spread of the seizure discharge to deep central neuronal structures paralyzes their function. In other types of seizure, in which consciousness is interrupted from the very beginning, a diencephalic origin has been postulated (centrencephalic seizures of Penfield).

Concussion exemplifies another special pathophysiologic mechanism of coma. In “blunt”, or closed head injury, it has been shown that at the moment of the concussive injury there is an enormous increase in intracranial pressure, on the order of 200 to 700 lb/in², lasting a few thousandths of a second. The vibration set up in the skull and transmitted to the brain was for many years thought to be the basis of the abrupt paralysis of nervous function that characterizes concussive head injury. Instead, it is more likely that the sudden swirling motion of the brain induced by the blow to the head, producing a rotation (torque) of the cerebral hemispheres around the axis of the upper brainstem, is the proximate cause of loss of consciousness. These same physical forces, when extreme, cause multiple shearing lesions or hemorrhages in the diencephalon and upper brainstem. The subject of concussion is discussed fully in Chap. 35.

Yet another unique form of coma is that produced by inhalation anesthetics. The effects of general anesthesia had for many years been attributed to changes in the physical chemistry of neuronal membranes. More recently, it has been recognized that there are interactions with ligand-gated ion channels and alterations in neurotransmitter function that are of direct consequence in causing anesthesia-induced unconsciousness. Inhalation anesthetics are unusual among coma-producing drugs in respect to the sequence of inhibitory and excitatory effects that they produce at different concentrations. During anesthesia, sufficient inhibition of brainstem activity can be attained to eliminate the pupillary responses and the corneal reflex. Both return to normal by the time the patient is able to speak. Sustained clonus, exaggerated tendon reflexes, and Babinski signs are common during the process of arousal. These findings have been studied systematically by Rosenberg et al. Pre-existing focal cerebral deficits from strokes often worsen transiently with the administration of anesthetics, as is true to a lesser extent with other sedatives, metabolic encephalopathies, and hyperthermia.

Recurring Stupor and Coma Aside from repeated drug overdose, recurring episodes of stupor are usually due to the decompensation of an encephalopathy from an underlying biochemical derangement, hepatic failure being the most common. A similar condition of periodic hyperammonemic coma in children and adults can come about from urea cycle enzyme defects, such as ornithine transcarbamylase deficiency. These are discussed in Chap. 37, in the section on inherited hyperammonemias.

Under the title of idiopathic recurring stupor, a rare condition has been described in adult men who displayed a prolonged state of deep sleepiness lasting from hours to days intermittently over a period of many years. Despite the impression of a sleep disorder related to narcolepsy, the EEG showed widespread fast (beta) ac-

tivity, and both the stupor and EEG changes were promptly reversed by flumazenil, a benzodiazepine receptor antagonist. During the bouts, a hundredfold increase of circulating endozepine-4, a naturally occurring diazepine agonist, was found in the serum and spinal fluid. Subsequently, the authors of the original reports (Lugaresi et al) found, by the use of more advanced techniques, that intoxication with lorazepam may have accounted for at least some of the cases. Although cases such as this—in which diazepine antagonists reverse episodes of recurrent coma (Huberfeld et al)—continue to be reported, the status of this entity is ambiguous. The vigilance-producing drug, modafinil, has also been effective in one report (Scott and Ahmed).

It is unclear to us whether migraine can cause a similar syndrome, as suggested in the study of familial hemiplegic migraine by Fitzsimmons and Wolfenden. Basilar migraine may exceptionally cause transient stupor and coma. Catatonic stupor and Kleine-Levin syndrome of periodic hypersomnolence and behavioral changes (page 344) also need to be considered.

Pathologic Anatomy of Coma

Coma is produced by one of two broad groups of problems: The first is clearly morphologic, consisting either of discrete lesions in the upper brainstem and lower diencephalon (which may be primary or secondary to compression) or of more widespread changes throughout the hemispheres. The second is metabolic or submicroscopic, resulting in suppression of neuronal activity. The clinical examination in coma is designed to separate these various mechanisms and to gauge the depth of brain dysfunction.

The study of a large number of human cases in which coma preceded death by several days has disclosed three types of lesions, each of which ultimately deranges the function of the reticular activating system directly or indirectly. In the *first type*, a readily discernible mass lesion—chiefly a tumor, abscess, massive edematous infarct, or intracerebral, subarachnoid, subdural, or epidural hemorrhage—is demonstrable. Usually the lesion involves only a portion of the cortex and white matter, leaving much of the cerebrum intact, but nonetheless it distorts deeper structures. In most instances, these mass lesions in or surrounding the hemispheres cause coma by a lateral displacement of deep central structures, sometimes with herniation of the temporal lobe into the tentorial opening, resulting in compression of the midbrain and subthalamic region of the reticular activating system (see below and also Chap. 31). Likewise, a cerebellar lesion may secondarily compress the adjacent upper brainstem reticular region by displacing it forward and perhaps upward. A detailed clinical record will show the coma to have coincided with these displacements and herniations. The anatomic displacements caused by herniations are discussed in more detail below.

In a *second type* of anatomic lesion, less frequent than the first, a destructive lesion is located in the thalamus or midbrain, in which case the neurons of the reticular activating are involved directly. This pathoanatomic pattern characterizes brainstem stroke from basilar artery occlusion, thalamic and upper brainstem hemorrhages, as well as some forms of traumatic damage.

In a *third type*, widespread bilateral damage to the cortex and cerebral white matter is found—the result of traumatic damage (contusions, diffuse axonal injury), bilateral infarcts or hemorrhages, viral encephalitis, meningitis, hypoxia, or ischemia, as occurs after cardiac arrest. The coma in these cases results from interruption of thalamocortical impulses or from generalized

destruction of cortical neurons. Only if the cerebral lesions are bilateral and extensive is consciousness markedly impaired. It should be mentioned, however, that in many of the diseases in this category there is severe thalamic damage, as mentioned earlier, and it is the latter that is responsible for coma.

Thus, the pathologic changes found in cases of coma are compatible with physiologic deductions—namely that the state of prolonged coma correlates with lesions of all parts of the cortical-diencephalic system of neurons; but it is only in the upper brainstem that coma-producing lesions are small and discrete. Recent studies by Parvizi and Damasio suggesting that lesions in the pons may cause coma are, in our opinion, subject to alternative interpretation, but further study is justified.

It should be noted again that in the largest group of cases of coma, no lesion is divulged by any technique of pathology; the lesion, caused by a metabolic or toxic abnormality or a generalized electrical discharge (seizure), is presumably subcellular or molecular, or the visible microscopic lesions are too diffuse for clinicoanatomic correlation.

Pathoanatomy of Brain Displacement

and Herniations (See also Chap. 31)

As pointed out above, large, destructive, and space-consuming lesions of the cerebrum—such as hemorrhage, tumor, abscess, or infarction with brain swelling—impair consciousness in one of two ways. One is by direct extension of the lesion into the diencephalon and midbrain. The other, more frequent in clinical practice, is by lateral and downward displacement of the subthalamic—upper brainstem structures with or without herniation of the medial part of the temporal lobe (uncus, hippocampus) into the opening in the tentorium. One consequence of lateral displacement is that the upper midbrain, particularly the cerebral peduncle, is crushed against the opposite free edge of the tentorium (the resulting creasing of the lateral edge of the peduncle is called *Kernohan's notch* or, more properly, the *Kernohan-Woltman phenomenon*); this causes a Babinski sign ipsilateral to the hemispherical lesion. The posterior cerebral artery may also be compressed at the edge of the tentorium, leading to hemorrhagic infarction of the occipital lobe (see also page 581).

It follows from the foregoing discussion that unilateral destructive lesions of the hemispheres, such as infarcts or hemorrhages, do not cause coma unless they create some degree of mass effect, usually delayed in onset, which secondarily compresses the upper brainstem. There are exceptions in which patients with massive strokes affecting the territory of the internal carotid artery are drowsy and inattentive from the onset, even before brain swelling occurs, but more often they are simply apathetic with a tendency to keep their eyes closed, a state that may be misinterpreted as stupor.

The term *herniation*, as in neurology and neurosurgery, refers to the dislocation of a portion of the cerebral or cerebellar hemisphere from its normal position to an adjacent compartment, a phenomenon that is evident at the autopsy table and may be appreciated by imaging of the brain. Thus, herniations are termed *transfalcine* (across the falx) or *transtentorial* (through the tentorial aperture) or are named by the structure that is displaced—*cerebellar, uncal*, etc. These herniations between dural compartments are illustrated in Fig. 17-1 and Table 17-2. Plum and Posner, following from earlier observations by McNealy and Plum, subdivided the transtentorial brainstem displacements into two groups: one a central

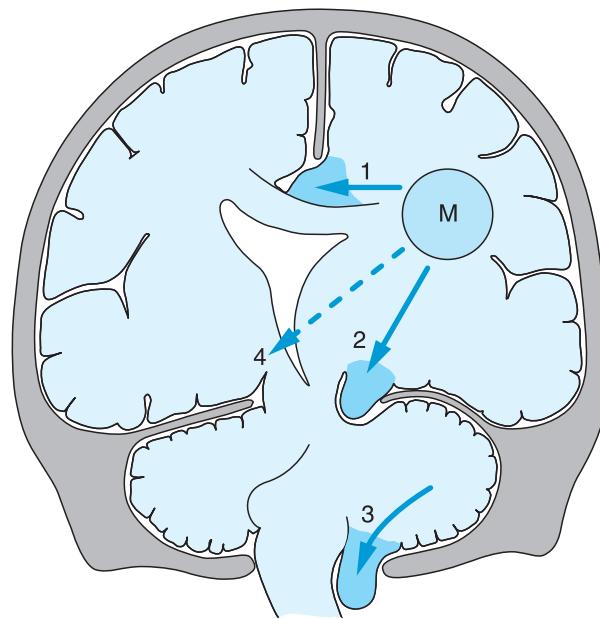

Figure 17-1. Schematic depiction of brain herniations between dural compartments. Transfalcial (1), transtentorial uncal-parahippocampal (2), cerebellar tonsillar (3), and horizontal (4), causing Kernohan-Woltman notch phenomenon. Herniations are shown in blue.

herniation syndrome with downward displacement and bilateral compression of the upper brainstem and the other a unilateral displacement of the medial temporal lobe, including the uncus gyrus, into the tentorial opening. Both are types of transtentorial herniation.

According to these authors, the *central syndrome* takes the form of a rostral-caudal deterioration of function: there is first confusion, apathy, and drowsiness and often Cheyne-Stokes respiration (CSR); following this, the pupils become small and react very little to light; “doll’s-head” (oculocephalic) eye movements are still elicitable, as are deviations of the eyes in response to cold-water caloric testing. Bilateral Babinski signs can be detected early; later, grasp reflexes and decorticate postures appear. These signs give way to a downward gradient of brainstem signs—coma, central hyperventilation, medium-sized fixed pupils, bilateral decerebrate postures, loss of oculovestibular (caloric) responses, slow, irregular breathing, and death.

The *uncal syndrome*, considered to be the result of herniation of the medial temporal lobe into the tentorial opening, differs mainly in that drowsiness in the early stages is accompanied or preceded by unilateral pupillary dilatation, most often on the side of the mass, as a result of compression of the third nerve by the advancing uncal gyrus.

Our own experience does not fully accord with this distinction between the two syndromes, and seldom have we been able to follow such an orderly sequence of neural dysfunction from the diencephalic to the medullary level. With lateral shift and uncal herniation, one sometimes observes smallness of the pupils, rather than ipsilateral pupillary dilatation, as drowsiness develops. Or, infrequently, the contralateral pupil may dilate before the ipsilateral one. Nor is it clear that the dilatation of one pupil is always due to compression of the oculomotor nerve by the herniated uncus, as traditionally taught. As often in pathologic material, the third nerve is stretched and angulated over the clivus or compressed under the

Table 17-2
Clinicopathologic features of temporal lobe–transtentorial herniation

PATHOLOGIC CHANGE	MECHANISM	CLINICAL DISORDERS
Injury to outer fibers of ipsilateral oculomotor nerve	Strangulation of nerve between herniating tissue and medial petroclinoid ligament; stretching of nerve over clivus from lateral displacement of midbrain; entrapment of nerve between posterior cerebral and superior cerebellar arteries from downward displacement of midbrain	Pupillary dilatation (Hutchinson pupil), ophthalmoplegia later
Creasing of contralateral cerebral peduncle (Kernohan's notch)	Pressure of laterally displaced midbrain against sharp edge of tentorium	Hemiplegia ipsilateral to herniation (<i>false localizing sign</i>) and bilateral corticospinal tract signs
Lateral flattening of midbrain and zones of necrosis and secondary hemorrhages in tegmentum and base of subthalamus, midbrain, and upper pons (Duret hemorrhages)	Crushing of midbrain between herniating temporal lobe and opposite leaf of tentorium and vascular occlusion (hemorrhages around arterioles and veins)	Cheyne-Stokes respirations; stupor-coma; bipyramidal signs; decerebration; dilated, fixed pupils and alterations of gaze (facilitated oculocephalic reflex movement giving way to loss of all response to head movement and labyrinthine stimulation)
Unilateral or bilateral infarction (hemorrhagic) of occipital lobes	Compression of posterior cerebral artery against the tentorium by herniating temporal lobe	Usually none detectable during coma; hemianopia (unilateral or bilateral) with recovery
Rising intracranial pressure and hydrocephalus	Lateral flattening of aqueduct and third ventricle and blockage of perimesencephalic subarachnoid space	Increasing coma, rising blood pressure, bradycardia

descended posterior cerebral artery. Involvement of the third nerve nucleus or its fibers of exit may be responsible for the dilatation of the opposite pupil, the usual occurrence after the pupil on the side of the mass has become fixed (Ropper 1990). In our serial study of 12 patients with brain edema and lateral diencephalic-mesencephalic shifts due to hemispherical infarcts, 4 patients initially had no ipsilateral pupillary enlargement; in 1 patient, the pupillary enlargement was contralateral; in 3 patients, the pupils were symmetrical when drowsiness gave way to stupor or coma (Ropper and Shafran). Cyclic Cheyne-Stokes breathing was an early sign of deterioration. In one patient, the first motor sign was an ipsilateral decerebrate rigidity rather than decorticate posturing; most of the patients had bilateral Babinski signs by the time they became stuporous. Indeed, the appearance of a Babinski sign on the nonhemiparetic side has been one of the best sentinels of secondary brain tissue shift. These signs usually progressed to deep coma and decerebration within hours, and they fluctuated.

From our observations of computed tomography (CT) and magnetic resonance imaging (MRI) scans obtained soon after the onset of coma, we have favored a mechanism of predominantly lateral displacement that causes compression of subthalamic and mesencephalic structures. This is often, but not invariably associated with temporal lobe herniation. The resulting neural dysfunction of deep structures is probably due to ischemia. Moreover, the early disturbances of consciousness (drowsiness and stupor) dependably follow the degree of lateral displacement of high brainstem and subthalamic structures (judged by shifts in the position of midline structures such as the pineal body and, with less accuracy, the septum pellucidum), all of which can occur in the absence of transtentorial herniation, which arises later. The important elements of secondary compression of the upper brainstem, in fact,

occur above the plane of the tentorium. With acute masses, a 3- to 5-mm horizontal displacement of the pineal calcification is associated with drowsiness; 5 to 8 mm, with stupor; and greater than 8 or 9 mm, with coma (Ropper, 1986). Although in some cases the downward shift predominates and in others it is horizontal, on MRI the latter is usually disproportionate to vertical displacement, and the clinical state corresponds more closely to the degree of lateral shift. Possibly, the configuration differs entirely between cases, such as the one reported by Pleasure and colleagues, in which a syndrome of low CSF pressure caused purely downward herniation and stupor that could be corrected by the infusion of fluid into the spinal canal. Others, notably Reich and colleagues, find the evidence for vertical shift to be more compelling than for horizontal displacement.

The location as well as the size of a mass determines the degree of brain distortion and displacement of crucial structures in the lower diencephalon and upper midbrain. Andrews and colleagues have pointed out that frontal and occipital hemorrhages are less likely to displace deep structures and to cause coma than are clots of equivalent size in the parietal or temporal lobes. Nor is it surprising that slowly enlarging masses, such as brain tumors, may sometimes cause massive shifts of brain tissue yet result in few clinical changes. In other words, all of the above comments pertain only to structural changes that are acute.

CLINICAL APPROACH TO THE COMATOSE PATIENT

Coma is always a symptomatic expression of an underlying disease. Sometimes the primary disorder is perfectly obvious, as with severe cranial trauma. All too often, however, the patient is brought to the hospital in a state of coma and little pertinent medical in-

formation is immediately available. The need for efficiency in reaching a diagnosis and providing appropriate acute care demands that the physician have a methodical approach that leaves none of the common and treatable causes of coma unexplored.

When the comatose patient is first seen, one must quickly make sure that the patient's airway is clear and blood pressure is adequate; if trauma has occurred, one must check for bleeding from a wound or ruptured organ (e.g., spleen or liver). If hypotension is present, certain therapeutic measures—placement of a central venous line and administration of fluids and pressor agents, oxygen, blood, or glucose solutions (preferably after blood is drawn for glucose determinations and thiamine is administered)—take precedence over diagnostic procedures. If respirations are shallow or labored or if there is emesis with a threat of aspiration, tracheal intubation and mechanical ventilation are required. An oropharyngeal airway is usually adequate in a comatose patient who is breathing normally. Deeply comatose patients with shallow respirations require endotracheal intubation. The patient with a head injury may also have suffered a fracture of the cervical vertebrae, in which case caution must be exercised in moving the head and neck as well as in intubation, lest the spinal cord be inadvertently damaged. These matters are discussed in greater detail further on, under "Management of the Acutely Comatose Patient."

There must then be an inquiry as to the previous health of the patient—whether there was a history of diabetes, a head injury, a convulsion, alcohol or drug use, or a prior episode of coma or attempted suicide—and the circumstances in which the person was found. Persons who accompany the comatose patient to the hospital should be encouraged not to leave until they have been questioned.

When one is assessing stupor and coma that has developed in a hospitalized patient who does not display localizing findings, it is instructive to review the patient's medications closely. A large category of compounds may reduce alertness to the point of profound somnolence or stupor, particularly if there are underlying medical problems (especially liver failure). Prominent in lists of iatrogenic drug intoxications are anesthetics, sedatives, anticonvulsants, opiates, antidepressants, and some antipsychotic compounds. Chronic administration of nitroprusside for hypertension can induce stupor from cyanide toxicity. From an initial survey, many of the common causes of coma—such as severe head injury, alcoholic or other forms of drug intoxication, and hypertensive brain hemorrhage—are readily recognized.

General Examination

Alterations in vital signs—temperature, pulse, respiratory rate, and blood pressure—are important aids in diagnosis. *Fever* is most often due to a systemic infection such as pneumonia or to bacterial meningitis or viral encephalitis. An excessively high body temperature (42 or 43°C) associated with dry skin should arouse suspicion of heat stroke or intoxication by a drug with anticholinergic activity. Fever should not be ascribed to a brain lesion that has disturbed the temperature-regulating center—so-called central fever, which is a rare occurrence. Hypothermia is observed in patients with alcoholic or barbiturate intoxication, drowning, exposure to cold, peripheral circulatory failure, and myxedema.

Slow breathing points to opiate or barbiturate intoxication and occasionally to hypothyroidism, whereas deep, rapid breathing (Kussmaul respiration) should suggest the presence of pneumonia, diabetic or uremic acidosis, pulmonary edema, or the less common occurrence of an intracranial disease that causes central neurogenic

hyperventilation. Diseases that elevate intracranial pressure or damage the brain often cause slow, irregular, or cyclic Cheyne-Stokes respiration (see further on). The various disordered patterns of breathing and their clinical significance are described further on and on page 474. *Vomiting* at the outset of sudden coma, particularly if combined with pronounced hypertension, is highly characteristic of cerebral hemorrhage within the hemispheres, brainstem, cerebellum, or subarachnoid space. The *pulse rate*, if exceptionally slow, should suggest heart block from medications such as tricyclic antidepressants or anticonvulsants, or—if combined with periodic breathing and hypertension—an increase in intracranial pressure that reflects the presence of a mass lesion. A myocardial infarction of the inferior wall may also be the cause of bradycardia. Marked *hypertension* is observed in patients with cerebral hemorrhage and hypertensive encephalopathy and sometimes in those with greatly increased intracranial pressure. *Hypotension* is the usual finding in states of depressed consciousness due to diabetes, alcohol or barbiturate intoxication, internal hemorrhage, myocardial infarction, dissecting aortic aneurysm, septicemia, Addison disease, or massive brain trauma.

Inspection of the skin may yield valuable information. Cyanosis of the lips and nail beds signifies inadequate oxygenation. Cherry-red coloration is typical of carbon monoxide poisoning. Multiple bruises (particularly a bruise or boggy area in the scalp), bleeding, CSF leakage from an ear or the nose, or periorbital hemorrhage greatly raises the likelihood of cranial fracture and intracranial trauma. Telangiectases and hyperemia of the face and conjunctivae are the common stigmata of alcoholism; myxedema imparts a characteristic puffiness of the face, and hypopituitarism an equally characteristic sallow complexion. Marked pallor suggests internal hemorrhage. A maculohemorrhagic rash indicates the possibility of meningococcal infection, staphylococcal endocarditis, typhus, or Rocky Mountain spotted fever. Excessive sweating suggests hypoglycemia or shock, and excessively dry skin, diabetic acidosis or uremia. Skin turgor is reduced in dehydration. Large blisters, sometimes bloody, may form over pressure points such as the buttocks if the patient has been motionless for a time; they are particularly characteristic of acute barbiturate, alcohol, and opiate intoxication. Thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, and fat embolism may cause diffuse petechiae.

The *odor of the breath* may provide a clue to the etiology of coma. Alcohol is easily recognized (except for vodka, which is odorless). The spoiled-fruit odor of diabetic coma, the uriniferous odor of uremia, the musty fetor of hepatic coma, and the burnt almond odor of cyanide poisoning are distinctive enough to be identified by physicians who possess a keen sense of smell.

Neurologic Examination of the Stuporous or Comatose Patient

Although limited in many ways, the neurologic examination of the comatose patient is of crucial importance. Simply watching the patient for a few moments often yields considerable information. The predominant postures of the limbs and body; the presence or absence of spontaneous movements on one side; the position of the head and eyes; and the rate, depth, and rhythm of respiration should be noted. The state of responsiveness is then estimated by noting the patient's reaction to calling his name, to simple commands, or to noxious stimuli such as supraorbital or sternal pressure, pinching the side of the neck or inner parts of the arms or thighs, or applying

pressure to the knuckles. By gradually increasing the strength of these stimuli, one can roughly estimate both the degree of unresponsiveness and changes from hour to hour. Vocalization may persist in stupor and is the first response to be lost as coma appears. Grimacing and deft avoidance movements of the stimulated parts are preserved in light coma; their presence substantiates the integrity of corticobulbar and corticospinal tracts. Yawning and spontaneous shifting of body positions indicate a minimal degree of unresponsiveness. These various signs have been elegantly summarized by Fisher based on his own observations. The Glasgow Coma Scale, constructed originally as a quick and simple means of quantitating the responsiveness of patients with severe cerebral trauma, can be used in the grading of other acute coma-producing diseases but is of little use in diagnosis (see Chap. 35).

It is usually possible to determine whether coma is associated with meningeal irritation. In all but the deepest stages of coma, meningeal irritation—from either bacterial meningitis or subarachnoid hemorrhage—will cause resistance to passive flexion of the neck but not to extension, turning, or tilting of the head. It should be noted that in some patients the signs of meningeal irritation do not develop for 12 to 24 h after the onset of subarachnoid hemorrhage. Resistance to movement of the neck in all directions may be part of generalized muscular rigidity (as in phenothiazine intoxication) or indicate disease of the cervical spine. In the infant, bulging of the anterior fontanel is at times a more reliable sign of meningitis than stiff neck. A temporal lobe or cerebellar herniation or decerebrate rigidity may also limit passive flexion of the neck and be confused with meningeal irritation.

A lesion in a cerebral hemisphere can usually be detected, even though the patient is comatose, by careful observation of the patient's spontaneous movements, responses to stimulation, prevailing postures, respiratory rate and rhythm, and by examination of the cranial nerves. A *hemiplegia* is revealed by a lack of restless movements of the limbs and by inadequate protective movements in response to painful stimuli on only one side. The paralyzed limbs are usually slack; they tend to remain in passive positions and, if lifted from the bed, they "fall flail." The hemiplegic leg lies in a position of external rotation (this may also be due to a fractured femur), and the affected thigh may appear wider and flatter than the nonhemiplegic one. In expiration, the cheek and lips puff out on the paralyzed side. With hemispheric lesions, the eyes are often turned away from the paralyzed side (toward the lesion, as described below); the opposite may occur with brainstem lesions. In most cases, a hemiplegia and an accompanying Babinski sign are indicative of a contralateral hemispherical lesion; but with lateral mass effect and compression of the opposite cerebral peduncle against the tentorium, extensor rigidity, a Babinski sign, and weakness of arm and leg may also occur ipsilateral to the lesion (the above described Kernohan-Woltman sign). A moan or grimace may be provoked by painful stimuli on one side but not on the other, reflecting the presence of a hemianesthesia; also during grimacing, facial weakness may be noted.

Of the various indicators of brainstem function, the most useful are pupillary size and reactivity, ocular movements, oculovestibular reflexes, and, to a lesser extent, the pattern of breathing. These functions, like consciousness itself, are to a large extent dependent on the integrity of structures in the midbrain and rostral pons.

Pupillary Reactions These are of great diagnostic importance in the comatose patient. A unilaterally enlarged pupil (5.5 mm diameter) is an early indicator of stretching or compression of the

third nerve and reflects the presence of an ipsilateral hemispherical mass. A loss of light reaction alone usually precedes enlargement of the pupil. As a transitional phenomenon, the pupil may become oval or pear-shaped or appear to be off center (*corectopia*) due to a differential loss of innervation of a portion of the pupillary sphincter. The light-unreactive pupil continues to enlarge to a size of 6 to 9 mm diameter and is soon joined by a slight outward deviation of the eye, as noted below. In unusual instances, for unknown reasons, the pupil contralateral to the mass may enlarge first; this is the case in 10 percent of subdural hematomas but has been far less frequent in our experience with other mass lesions. As midbrain displacement continues, both pupils dilate and become unreactive to light probably as a result of compression of the oculomotor nuclei in the rostral midbrain (Ropper, 1990). The last step in the evolution of brainstem compression tends to be a slight reduction in pupillary size, to 5 to 7 mm. Normal pupillary size, shape, and light reflexes indicate integrity of midbrain structures and a cause of coma other than a mass lesion.

Pontine tegmental lesions cause extremely miotic pupils (<1 mm in diameter) with barely perceptible reaction to strong light; this is characteristic of the early phase of pontine hemorrhage. The ipsilateral pupillary dilatation from pinching the side of the neck (the ciliospinal reflex, page 242) is also lost in brainstem lesions. A Horner syndrome (miosis, ptosis, and reduced facial sweating) may be observed ipsilateral to a lesion of the brainstem or hypothalamus or as a sign of dissection of the internal carotid artery.

With coma due to drug intoxications and metabolic disorders, pupillary reactions are usually spared, but there are notable exceptions. Opiates cause pinpoint pupils with a constriction to light that is so slight that it can be seen only with a magnifying glass. High-dose barbiturates may act similarly, but the pupillary diameter tends to be 1 mm or more. Poisoning with atropine or with drugs that have atropinic qualities, especially the tricyclic antidepressants, is characterized by wide dilation and fixity of pupils; these features are partially reversed by intravenous physostigmine. Hippus, or fluctuating pupillary size, is said by some observers to be characteristic of the metabolic encephalopathies.

Movements of Eyes and Eyelids and Corneal Responses These may be altered in a variety of ways. In light coma of metabolic origin, the eyes rove conjugately from side to side in random fashion, sometimes resting briefly in an eccentric position. These movements disappear as coma deepens, and the eyes then remain motionless in slightly exotropic positions.

A lateral and slight downward deviation of one eye suggests the presence of a third nerve palsy, and a medial deviation, a sixth nerve palsy. There may be a persistent conjugate deviation of the eyes to one side—away from the side of the paralysis with a large cerebral lesion (looking toward the lesion) and toward the side of the paralysis with a unilateral pontine lesion (looking away from the lesion). "Wrong-way" conjugate deviation may sometimes occur with thalamic and upper brainstem lesions (page 226). During a one-sided seizure, the eyes turn or jerk toward the convulsing side (opposite to the irritative focus). The eyes may be turned down and inward (looking at the nose) with hematomas or ischemic lesions of the thalamus and upper midbrain (a variant of Parinaud syndrome; see page 225). Retraction and convergence nystagmus and "ocular bobbing," described on page 239, occur with lesions in the tegmentum of the midbrain and pons, respectively. "Ocular dipping," in which the eyes move down slowly and return rapidly to the meridian, may be observed with coma due to anoxia and drug intoxications; horizontal eye movements are preserved (page

239). The coma-producing structural lesions of the brainstem abolish most if not all conjugate ocular movements, whereas metabolic disorders generally do not (except for instances of deep hepatic coma and anticonvulsant drug overdose).

Oculocephalic reflexes (doll's-eye movements), are elicited by briskly turning or tilting the head. The response in coma of metabolic origin or that due to bihemispherical structural lesions consists of conjugate movement of the eyes in the opposite direction. Elicitation of these reflexes in a comatose patient provides two pieces of information: (1) evidence of unimpeded function of the oculomotor nerves and of the midbrain and pontine tegmental structures that integrate ocular movements and (2) loss of the cortical inhibition that normally holds these movements in check. The presence of unimpaired reflex eye movements implies that coma is not due to compression or destruction of the upper midbrain. Instead, there must be widespread cerebral dysfunction, such as occurs with cerebral anoxia or metabolic-toxic suppression of cortical activity. It must be conceded, however, that sedative or anticonvulsant intoxication serious enough to cause coma may obliterate the brainstem mechanisms for oculocephalic reactions and, in extreme cases, even the oculovestibular responses as noted below. Asymmetry in elicited eye movements remains a dependable sign of focal brainstem disease. In instances of coma due to a large mass in one cerebral hemisphere that secondarily compresses the upper brainstem, the oculocephalic reflexes are usually present, but the movement of the eye on the side of the mass may be impeded in adduction as a result of a third nerve paresis.

Irrigation of each ear with 10 mL of cold water (or room-temperature water if the patient is not comatose) normally causes slow conjugate deviation of the eyes toward the irrigated ear, followed in a few seconds by compensatory nystagmus (fast component away from the stimulated side). This is the *oculovestibular* or *caloric* test (page 259). The ears are irrigated separately several minutes apart. In comatose patients, the fast "corrective" phase of nystagmus is lost and the eyes are tonically deflected to the side irrigated with cold water or away from the side irrigated with warm water; this position may be held for 2 to 3 min. With brainstem lesions, these vestibulo-ocular reflexes are lost or disrupted. If only one eye abducts and the other fails to adduct, one can conclude that the medial longitudinal fasciculus has been interrupted (on the side of adductor paralysis). The opposite, abducens palsy, is indicated by an esotropic resting position and a lack of outward deviation of one eye with the reflex maneuvers. The complete absence of ocular movement in response to oculovestibular testing indicates a severe disruption of brainstem tegmental pathways in the pons or midbrain or, as mentioned, a profound overdose of sedative or anesthetic drugs.

Reduction in frequency and eventual loss of spontaneous blinking, then loss of blink in response to touching the eyelashes, and finally a lack of response to corneal touch (afferent limb–trigeminal nerve; efferent limb–both facial nerves) are among the most dependable signs of deepening coma. A marked asymmetry in corneal responses indicates either an acute lesion of the opposite hemisphere or, less often, an ipsilateral lesion in the brainstem.

Spontaneous Limb Movements Restless movements of both arms and both legs and grasping and picking movements signify that the corticospinal tracts are more or less intact. Variable oppositional resistance to passive movement (paratonic rigidity), complex avoidance movements, and discrete protective movements have the same meaning; if these movements are bilateral, the coma is usually not profound. The occurrence of focal motor epilepsy

indicates that the corresponding corticospinal pathway is intact. With massive destruction of a cerebral hemisphere, as occurs in hypertensive hemorrhage or internal carotid–middle cerebral artery occlusion, focal seizures are seldom seen on the paralyzed side, however, seizure activity may be manifest solely in the ipsilateral limbs, the contralateral limbs being prevented from participating by the hemiplegia. Often, elaborate forms of semivoluntary movement are present on the "good side" in patients with extensive disease in one hemisphere; they probably represent some type of disequilibrium or disinhibition of cortical and subcortical movement patterns. Definite choreic, athetotic, or hemiballistic movements indicate a disorder of the basal ganglionic and subthalamic structures, just as they do in the alert patient.

Posturing in the Comatose Patient One of these abnormal postures is *decerebrate rigidity*, which in its fully developed form consists of opisthotonus, clenching of the jaws, and stiff extension of the limbs, with internal rotation of the arms and plantar flexion of the feet (see Chap. 3). This postural pattern was first described by Sherrington, who produced it in cats and monkeys by transecting the brainstem at the intercollicular level. The decerebrate pattern was noted to be ipsilateral to a one-sided lesion, hence not due to involvement of the corticospinal tracts. Such a precise correlation is rarely possible in patients who develop stereotyped extensor posturing since it arises in a variety of settings—with midbrain compression due to a hemispherical mass; with cerebellar or other posterior fossa lesions; with certain metabolic disorders, such as anoxia and hypoglycemia; and rarely with hepatic coma and profound intoxication. Patients with an acute lesion of one cerebral hemisphere may show a similar type of extensor posturing of the contralateral and sometimes ipsilateral limbs, and this may coexist with the ability to make purposeful movements of the same limbs. Extensor postures, unilateral or bilateral, may seemingly occur spontaneously, but more often they are in response to manipulation of the limbs or a tactile or noxious stimulus. Another pattern is the extensor posturing of arm and leg on one side and flexion and abduction of the opposite arm. This reaction is analogous to the tonic reflexes described by Magnus in decerebrate animals.

In some patients with the foregoing postural changes the lesions are clearly in the cerebral white matter or basal ganglia, which is difficult to reconcile with the classic physiologic explanation of decerebrate posturing; presumably there is a functional derangement of structures in the midbrain. Decerebrate posturing, either in experimental preparations or in humans, is usually not a persistent steady state but an intermittent and transient one. Hence the term *decerebrate state*, as suggested by Feldman, is preferable to *decerebrate rigidity*, which implies a fixed, tonic extensor attitude.

Decorticcate rigidity, with arm or arms in flexion and adduction and leg(s) extended, signifies lesions at a higher level—in the cerebral white matter or internal capsule and thalamus. Bilateral decorticcate rigidity is essentially a bilateral spastic hemiplegia. Diagonal postures, e.g., flexion of one arm and extension of the opposite arm and leg, usually indicate a supratentorial lesion. Forceful extensor postures of the arms and weak flexor responses of the legs are probably due to lesions at about the level of the vestibular nuclei. Lesions below this level lead to flaccidity and abolition of all postures and movements. The coma is then usually profound and often progresses to brain death.

Only in the most advanced forms of intoxication and metabolic coma, as might occur with anoxic necrosis of neurons throughout the entire brain, are coughing, swallowing, hiccuping, and spontaneous respiration all abolished. Further, the tendon

and plantar reflexes may give little indication of what is happening. Tendon reflexes are usually preserved until the late stages of coma due to metabolic disturbances and intoxications. In coma due to a large cerebral infarct or hemorrhage, the tendon reflexes may be normal or only slightly reduced on the hemiplegic side and the plantar reflexes may be absent or extensor. Plantar flexor responses, succeeding extensor responses, signify either a return to normalcy or, in the context of deepening coma, a transition to brain death.

Patterns of Breathing (See pages 437–474) Any massive supratentorial lesions, bilateral deep-seated cerebral lesions, or metabolic disturbances of the brain give rise to a characteristic pattern of breathing, in which a period of waxing and waning hyperpnea regularly alternates with a shorter period of apnea (*Cheyne-Stokes respiration*, or CSR). This phenomenon has been attributed to isolation of the brainstem respiratory centers from the cerebrum, rendering them more sensitive than usual to carbon dioxide (hyperventilation drive). It is postulated that as a result of overbreathing, the blood carbon dioxide drops below the concentration required to stimulate the centers, and breathing gradually stops. Carbon dioxide then reaccumulates until it exceeds the respiratory threshold, and the cycle then repeats itself. Alternatively, CSR has been attributed to the stimulating effect of a low arterial PO_2 on a depressed respiratory center. In either case, the presence of CSR signifies bilateral dysfunction of cerebral structures, usually deep in the hemispheres or diencephalon, and it is seen with states of drowsiness or stupor from a variety of causes. Coma with CSR is usually due to intoxication or to a severe metabolic derangement and occasionally to bilateral lesions, such as subdural hematomas. In itself, CSR is not a grave sign. It may occur during sleep in elderly individuals and can be a manifestation of cardiopulmonary disorders in awake patients. Only when it gives way to more irregular respiratory patterns that implicate structural damage of the brainstem is the patient in imminent danger, as discussed below.

A number of other aberrant breathing rhythms occur with brainstem lesions (these are reviewed in Chap. 26), but few are specifically localizing. The more conspicuous respiratory arrhythmias are associated with brainstem lesions below the level of the reticular activating system and are therefore found in the late stages of brainstem compression or with large brainstem lesions such as infarction, primary hemorrhage, or infiltrating tumor.

Lesions of the lower midbrain–upper pontine tegmentum, either primary or secondary to a tentorial herniation, may give rise to *central neurogenic hyperventilation* (CNH). This disorder is characterized by an increase in the rate and depth of respiration to the extent that respiratory alkalosis results. CNH is thought to represent a release of the reflex mechanisms for respiratory control in the lower brainstem. It must be distinguished from hyperventilation caused by medical illnesses, particularly pneumonia and acidosis. Mild degrees of hyperventilation are common after a number of acute neurologic events, notably head injury. The neurologic basis of CNH is uncertain. It has been observed with tumors of the medulla, lower pons, and midbrain. However, North and Jennett, in a study of respiratory abnormalities in neurosurgical patients, found no consistent correlation between tachypnea and the site of the lesion. It is also noteworthy that primary brain lymphoma without brainstem involvement has emerged as a curious cause of CNH (Pauzner et al.).

Low pontine lesions, usually due to basilar artery occlusion, sometimes cause *apneustic breathing* (a pause of 2 to 3 s in full inspiration) or so-called short-cycle CSR, in which a few rapid deep breaths alternate with apneic cycles. With lesions of the dorsome-

dial part of the medulla, the rhythm of breathing is chaotic, being irregularly interrupted and each breath varying in rate and depth (*Biot breathing*; also called “ataxia of breathing”—not an appropriate term.) This pattern progresses to one of intermittent prolonged inspiratory gasps that are recognized by all physicians as agonal in nature and finally to apnea; in fact, respiratory arrest is the mode of death of most patients with serious central nervous system (CNS) disease.

Probably all of these erratic patterns of breathing are interrelated in some manner; Webber and Speck have shown that apnea, Biot breathing, and gasping could be produced in the same animal with lesions in the dorsolateral pontine tegmentum by altering the depth of anesthesia. As pointed out by Fisher and by Plum and Posner, when certain supratentorial lesions progress to the point of temporal lobe and cerebellar herniation, one may observe a succession of respiratory patterns (CSR-CNH-Biot breathing), indicating an extension of the functional disorder from upper to lower brainstem; but again, such a sequence is not always observed. Rapidly evolving lesions of the posterior fossa may cause sudden respiratory arrest without any of the aforementioned abnormalities of breathing; presumably this results from fulminant pontomedullary compression by the cerebellar tonsils.

Clinical Signs of Increased Intracranial Pressure A history of headache before the onset of coma, vomiting, severe hypertension beyond the patient's static level, unexplained bradycardia, and subhyaloid retinal hemorrhages are immediate clues to the presence of increased intracranial pressure, usually from one of the types of cerebral hemorrhage. Papilledema develops within 12 to 24 h in cases of brain trauma and hemorrhage, but if it is pronounced, it usually signifies brain tumor or abscess—i.e., a lesion of longer duration. Increased intracranial pressure produces coma by impeding global cerebral blood flow; but this occurs only at extremely high levels of pressure. High pressure within one compartment produces shifts of central structures and a series of “false localizing” signs due to lateral displacements and herniations, as noted in the above discussion of herniation.

The syndrome of acute hydrocephalus, most often from subarachnoid hemorrhage or from rapid obstruction of the ventricular system by a tumor in the posterior fossa, induces a state of abulia (page 359) followed by stupor and then coma with bilateral Babinski signs. The pupils are small and tone in the legs is increased. These signs may be accompanied by headache and systemic hypertension. This subject is discussed further in Chap. 30.

Laboratory Procedures

Unless the diagnosis is established at once by history and physical examination, it is necessary to carry out a number of laboratory procedures. In patients with evidence of a cerebral mass or acute hydrocephalus, as manifest by signs of raised intracranial pressure or indications of brain displacements (asymmetry of limb movements, pupillary enlargement), a CT scan or MRI should be obtained as the primary procedure. As discussed in Chap. 2, lumbar puncture, although carrying a certain small risk of promoting further herniation, is nevertheless necessary in some instances to exclude bacterial meningitis or encephalitis. If poisoning is suspected, aspiration and analysis of the gastric contents is sometimes helpful, but greater reliance should be placed on chromatographic analysis of the blood and urine (“toxic screen”). Accurate means are available for measuring the blood concentrations of phenytoin and other anticonvulsants, opiates, diazepines, barbiturates, alcohol, and a

wide range of other toxic substances. A specimen of urine is obtained by catheter for determination of specific gravity and for glucose, acetone, and protein content. Proteinuria may also be found for 2 or 3 days after a subarachnoid hemorrhage or with high fever. Urine of high specific gravity, glycosuria, and acetonuria occur almost invariably in diabetic coma; but transient glycosuria and hyperglycemia may result from a massive cerebral lesion. Blood counts should be obtained, and in malarial districts a blood smear should be examined for parasites. Neutrophilic leukocytosis occurs in bacterial infections and also with brain hemorrhage and infarction, although the elevation of leukocytes in the latter conditions rarely exceeds 12,000/mm³. Venous blood should be examined for the concentrations of glucose, urea, carbon dioxide, bicarbonate, ammonia, sodium, potassium, chloride, calcium, and SGOT (serum glutamic oxaloacetic transaminase); analysis of blood gases and carboxyhemoglobin should be obtained in appropriate cases.

It should be kept in mind that disorders of water and sodium balance, reflected in hyper- or hyponatremia, may be the result of cerebral disease (excess ADH secretion, diabetes insipidus, atrial natriuretic factor release), as well as being the proximate cause of coma.

An EEG may be highly informative if no adequate explanation for coma is forthcoming from the initial examinations. This is the only way to reveal nonconvulsive status epilepticus as the cause of a stupor.

Classification of Coma and Differential

Diagnosis (See also Table 17-3)

The demonstration of focal brain disease or of meningeal irritation with abnormalities of the CSF is of particular help in the differential diagnosis of coma and serves to divide the diseases that cause coma into three classes, as follows:

- I. Diseases that cause no focal or lateralizing neurologic signs, usually with normal brainstem functions. CT scan and cellular content of the CSF are normal.
 - A. Intoxications: alcohol, barbiturates and other sedative drugs, opiates, etc. (Chaps. 42 and 43).
 - B. Metabolic disturbances: anoxia, diabetic acidosis, uremia, hepatic failure, nonketotic hyperosmolar hyperglycemia, hypo- and hypernatremia, hypoglycemia, addisonian crisis, profound nutritional deficiency, carbon monoxide, thyroid states including Hashimoto encephalopathy (Chaps. 40 and 41).
 - C. Severe systemic infections: pneumonia, peritonitis, typhoid fever, malaria, septicemia, Waterhouse-Friderichsen syndrome.
 - D. Circulatory collapse (shock) from any cause.
 - E. Postseizure states and convulsive and nonconvulsive status epilepticus (Chap. 16).
 - F. Hypertensive encephalopathy and eclampsia (Chap. 34).
 - G. Hyperthermia and hypothermia.
 - H. Concussion (Chap. 35).
 - I. Acute hydrocephalus (Chap 30).
 - J. Late stages of certain degenerative diseases and Creutzfeldt-Jakob disease.
- II. Diseases that cause meningeal irritation, with or without fever, and with an excess of WBCs or RBCs in the CSF, usually without focal or lateralizing cerebral or brainstem

signs. CT scanning or MRI (which preferably should precede lumbar puncture) may be normal or abnormal.

- A. Subarachnoid hemorrhage from ruptured aneurysm, arteriovenous malformation, occasionally trauma (Chaps. 34 and 35).
- B. Acute bacterial meningitis (Chap. 32).
- C. Some forms of viral encephalitis (Chap. 33).
- D. Neoplastic and parasitic meningitides.
- III. Diseases that cause focal brainstem or lateralizing cerebral signs, with or without changes in the CSF. CT scanning and MRI are usually abnormal.
 - A. Hemispherical hemorrhage or massive infarction (Chap. 34).
 - B. Brainstem infarction due to basilar artery thrombosis or embolism (Chap. 34).
 - C. Brain abscess, subdural empyema, Herpes encephalitis (Chap. 32).
 - D. Epidural and subdural hemorrhage and brain contusion (Chap. 35).
 - E. Brain tumor (Chap. 31).
 - F. Cerebellar and pontine hemorrhage.
 - G. Miscellaneous: cortical vein thrombosis, some forms of viral encephalitis (herpes), focal embolic infarction due to bacterial endocarditis, acute hemorrhagic leukoencephalitis, disseminated (postinfectious) encephalomyelitis, intravascular lymphoma, thrombotic thrombocytopenic purpura, diffuse fat embolism, and others.

Using the clinical criteria outlined above, one can usually ascertain whether a given case of coma falls into one of these three categories. Concerning the group without focal or lateralizing or meningeal signs (which includes most of the metabolic encephalopathies, intoxications, concussion, and postseizure states), it must be kept in mind that residua from previous neurologic disease may confuse the clinical picture. Thus, an earlier hemiparesis from vascular disease or trauma may reassert itself in the course of uremic or hepatic coma with hypotension, hypoglycemia, diabetic acidosis, or following a seizure. In hypertensive encephalopathy, focal signs may also be present. Occasionally, for no understandable reason, one leg may seem to move less, one plantar reflex may be extensor, or seizures may be predominantly or entirely unilateral in a metabolic coma, particularly in the hyperglycemic-hyperosmolar states. Babinski signs and extensor rigidity, conventionally considered to be indicators of structural disease, do sometimes occur in profound intoxications with a number of agents.

The diagnosis of concussion or of postictal coma depends on observation of the precipitating event or indirect evidence thereof. Often a convulsive seizure is marked by a bitten tongue, urinary incontinence, and an elevated CK-skeletal muscle fraction; it may be followed by another seizure or burst of seizures. The presence of small clonic or myoclonic convulsive movements of a hand or foot or fluttering of the eyelids requires that an EEG be performed to determine whether status epilepticus is the cause of coma. This state, called nonconvulsive status or spike-wave stupor and described in Chap. 16, must always be considered in the diagnosis of unexplained coma, especially in known epileptics (Table 17-3).

With respect to the second group in the above classification, the signs of meningeal irritation (head retraction, stiffness of neck on forward bending, Kernig and Brudzinski signs) can usually be elicited in both bacterial meningitis and subarachnoid hemorrhage. However, if the coma is profound, stiff neck may be absent in both

infants and adults. In such cases the spinal fluid must be examined in order to establish the diagnosis. In most cases of bacterial meningitis, the CSF pressure is not exceptionally high (usually less than 400 mmH₂O). However, in cases associated with brain swelling, the CSF pressure is greatly elevated; the pupils become fixed and dilated, and there may be signs of compression of the brainstem with arrest of respiration. Patients in coma from ruptured aneurysms also have high CSF pressure; the CSF is overtly bloody and the blood is invariably visible in the CT scan throughout the basal cisterns and ventricles if the bleeding has been severe enough to cause coma.

In the third group of patients, it is the focality of sensorimotor signs and the abnormal pupillary and ocular reflexes, postural states, and breathing patterns that provide the clues to serious structural lesions in the cerebral hemispheres and their pressure effects upon segmental brainstem functions. As the brainstem features become more prominent, they may obscure earlier signs of cerebral disease.

It is worth emphasizing once more that profound hepatic, hypoglycemic, hyperglycemic, and hypoxic states may resemble the coma due to a brainstem lesion in that asymmetrical motor signs, focal seizures, and decerebrate postures arise and deep coma from drug intoxication may obliterate reflex eye movements. Also, *certain structural lesions of the cerebral hemispheres are so diffuse as to produce a picture that simulates a metabolic disturbance*; thrombotic thrombocytopenic purpura (TTP), fat embolism, and the late effects of global ischemia-anoxia are examples of such states. At other times they cause a diffuse encephalopathy with superimposed focal signs.

Unilateral cerebral infarction due to anterior, middle, or posterior cerebral artery occlusion produces no more than drowsiness, as a rule; however, with massive unilateral infarction due to carotid artery occlusion, coma can occur if extensive brain edema and secondary tissue shift develop. Edema of this degree seldom develops before 12 or 24 h. Rapidly evolving hydrocephalus causes smallness of the pupils, rapid respiration, extensor rigidity of the legs, Babinski signs, and sometimes a loss of eye movements.

Finally, it should be restated that diagnosis has as its prime purpose the direction of therapy. The treatable causes of coma are drug and alcohol intoxications, shock due to infection, cardiac failure, or systemic bleeding, epidural and subdural hematomas, brain abscess, bacterial and fungal meningitis, diabetic acidosis or hyperosmolar state, hypoglycemia, hypo- or hypernatremia, hepatic coma, uremia, status epilepticus, Hashimoto encephalopathy, and hypertensive encephalopathy. Also treatable to a varying degree are uremia; putaminal and cerebellar hemorrhages, which can sometimes be evacuated successfully; edema from massive stroke, which may be ameliorated by hemicraniectomy; and hydrocephalus from any cause, which may respond to ventricular drainage.

Management of the Acutely Comatose Patient

Seriously impaired states of consciousness, regardless of their cause, are often fatal not only because they represent an advanced stage of many diseases but also because they add their own particular burdens to the primary disease. The physician's main objective, of course, is to find the cause of the coma and to treat it appropriately. It often happens, however, that the disease process is one for which there is no specific therapy; or, as in hypoxia or hypoglycemia, the acute, irreversible effects have already occurred

before the patient comes to the attention of the physician. Again, the problem may be highly complex, for the disturbance may be attributable not to a single cause but to several factors acting in unison, no one of which could account for the total clinical picture. Moreover, in certain circumstances two processes frequently contribute to depressing consciousness, particularly head injury combined with drug or alcohol intoxication. In lieu of specific therapy, supportive measures must be used; indeed, the patient's chances of surviving the original disease often depend on the effectiveness of these general medical measures.

The successful management of the insensate patient requires the services of a well-coordinated team of nurses under the close guidance of a physician. Necessary treatment must be instituted immediately, even before all the diagnostic steps have been completed; diagnosis and treatment may have to proceed concurrently. The following is a brief outline of the principles involved in the treatment of such patients. The details of management of shock, fluid and electrolyte imbalance, and other complications that threaten the comatose patient (pneumonia, urinary tract infections, deep venous thrombosis, etc.) are found in *Harrison's Principles of Internal Medicine*.

1. Shallow and irregular respirations, stertorous breathing (indicating obstruction to inspiration), and cyanosis require the establishment of a clear airway and delivery of oxygen. The patient should initially be placed in a lateral position so that secretions and vomitus do not enter the tracheobronchial tree. Secretions should be removed by suctioning as soon as they accumulate; otherwise they will lead to atelectasis and bronchopneumonia. Arterial blood gases should be measured and further observed by monitoring of oxygen saturation. A patient's inability to protect against aspiration and the presence of either hypoxia or hypoventilation dictates the use of endotracheal intubation and a positive-pressure respirator.
2. The management of shock, if present, takes precedence over all other diagnostic and therapeutic measures.
3. Concurrently, an intravenous line is established and blood samples are drawn for determination of glucose, intoxicating drugs, and electrolytes and for tests of liver and kidney function. Naloxone, 0.5 mg, should be given intravenously if a narcotic overdose is a possibility. Hypoglycemia that has produced stupor or coma demands the infusion of glucose, usually 25 to 50 mL of a 50% solution followed by a 5% infusion; this must be supplemented with thiamine. A urine sample is obtained for drug and glucose testing. If the diagnosis is uncertain, both naloxone and the glucose-thiamine combination should be administered.
4. With the development of elevated intracranial pressure from a mass lesion, mannitol, 25 to 50 g in a 20% solution, should be given intravenously over 10 to 20 min and hyper-ventilation instituted if deterioration occurs, as judged by pupillary enlargement or deepening coma. Repeated CT scanning allows the physician to follow the size of the lesion and degree of localized edema and to detect displacements of cerebral tissue. With massive cerebral lesions, it may be appropriate to place a pressure-measuring device in the cranium of selected patients (see Chap. 35 for details of intracranial pressure monitoring and treatment).
5. A lumbar puncture should be performed if meningitis or subarachnoid hemorrhage is suspected on the basis of head-

Table 17-3
Important points in the differential diagnosis of the common causes of coma

GENERAL GROUP	SPECIFIC DISORDER	IMPORTANT CLINICAL FINDINGS	IMPORTANT LABORATORY FINDINGS	REMARKS
Coma with focal or lateralizing signs	Cerebral hemorrhage	Hemiplegia, hypertension, cyclic breathing, specific ocular signs (See Chaps. 14 and 33)	CT scan +	Sudden onset, often with headache, vomiting; history of chronic hypertension; late pupillary enlargement
	Basilar artery occlusion (thrombotic or embolic)	Extensor posturing and bilateral Babinski signs; early loss of oculocephalic responses; ocular bobbing	Normal early CT; MRI shows cerebellar and brainstem or thalamic infarction, normal CSF	Onset subacute (thrombosis), or sudden (rostral basilar embolism)
	Massive infarction and edema in carotid territory Subdural hematoma	Hemiplegia, unilateral unresponsive or enlarged pupil Slow or cyclic respiration, rising blood pressure, hemiparesis, unilateral enlarged pupil Signs of cranial and facial injury	CT and MRI show massive edema of hemisphere CT scan; CSF xanthochromic with relatively low protein	Coma preceded by drowsiness for several days after stroke Signs or history of trauma, headache, confusion, progressive drowsiness
Trauma		Signs of cranial and facial injury	CT and MRI show brain contusions and other injuries	Unstable blood pressure, associated systemic injuries
Brain abscess		Neurologic signs depending on location	CT scan and MRI +	Systemic infection or neurosurgical procedure, fever
Hypertensive encephalopathy; eclampsia		Blood pressure $>210/110$ (lower in eclampsia and in children), headache, seizures, hypertensive retinal changes	CT \pm ; CSF pressure elevated	Acute or subacute evolution, use of aminophylline or catecholamine medications
Thrombotic thrombocytopenic purpura (TTP) Meningitis and encephalitis		Petechiae, seizures shifting focal signs Stiff neck, Kernig sign, fever, headache	Multiple small cortical infarctions; thrombocytopenia CT scan \pm ; pleocytosis, increased protein, low glucose in CSF	Similar to fat embolism; multifocal microvasculopathy Subacute or acute onset
Coma without focal or lateralizing signs, with signs of meningeal irritation	Subarachnoid hemorrhage	Stertorous breathing, hypertension, stiff neck, Kernig sign	CT scan may show blood and aneurysm; bloody or xanthochromic CSF under increased pressure	Sudden onset with severe headache

Coma without focal neurologic signs or meningeal irritation; CT scan and CSF normal	Alcohol intoxication	Hypothermia, hypotension, flushed skin, alcohol breath	Elevated blood alcohol	May be combined with head injury, infection, or hepatic failure
	Sedative intoxication	Hypothermia, hypotension	Drug in urine and blood; EEG often shows fast activity	History of intake of drug; suicide attempt
	Opioid intoxication	Slow respiration, cyanosis, constricted pupils	Carboxyhemoglobin CSF normal; EEG may be isoelectric or show high-voltage delta	Administration of naloxone causes awakening and withdrawal signs
	Carbon monoxide intoxication	Cherry-red skin		Pallid necrosis
	Global ischemia–anoxia	Rigidity, decerebrate postures, fever, seizures, myoclonus		Abrupt onset following cardiopulmonary arrest; damage permanent if anoxia exceeds 3–5 min
	Hypoglycemia	Same as in anoxia	Low blood and CSF glucose	Characteristic slow evolution through stages of nervousness, hunger, sweating, flushed face; then pallor, shallow respirations and seizures
	Diabetic coma	Signs of extracellular fluid deficit, hyperventilation with Kussmaul respiration, “fruity” breath	Glycosuria, hyperglycemia, acidosis; reduced serum bicarbonate; ketonemia and ketonuria, or hyperosmolarity	History of polyuria, polydipsia, weight loss, or diabetes
	Uremia	Hypertension; sallow, dry skin, uriniferous breath, twitch-convulsive syndrome	Protein and casts in urine; elevated BUN and serum creatinine; anemia, acidosis, hypocalcemia	Progressive apathy, confusion, and asterixis precede coma
	Hepatic coma	Jaundice, ascites, and other signs of portal hypertension; asterixis	Elevated blood NH ₃ levels; CSF yellow (bilirubin) with normal or slightly elevated protein	Onset over a few days or after paracentesis or hemorrhage from varices; confusion, stupor, asterixis, and characteristic EEG changes precede coma
	Hypercapnia	Papilledema, diffuse myoclonus, asterixis	Increased CSF pressure; PCO ₂ may exceed 75 mmHg; EEG theta and delta activity	Advanced pulmonary disease; profound coma and brain damage uncommon
	Severe infections (septic shock); heat stroke	Extreme hyperthermia, rapid respiration	Vary according to cause	Evidence of a specific infection or exposure to extreme heat
	Seizures	Episodic disturbance of behavior or convulsive movements	Characteristic EEG changes	History of previous attacks

- ache and meningismus (and fever in the case of infectious meningitis), keeping in mind the risks of this procedure and the means of dealing with them. A CT scan may have disclosed a primary subarachnoid hemorrhage, in which case lumbar puncture is not necessary. In the case of meningitis, broad spectrum antibiotics that penetrate the meninges may be instituted, especially if the lumbar puncture is delayed. The choice of drug is then determined by the principles set forth in Chap. 32.
6. Convulsions should be controlled by measures outlined in Chap. 16.
 7. As indicated above, gastric aspiration and lavage with normal saline may be diagnostically and therapeutically useful in some instances of coma due to drug ingestion. Salicylates, opiates, and anticholinergic drugs (tricyclic antidepressants, phenothiazines, scopolamine), all of which induce gastric atony, may be recovered many hours after ingestion. Caustic materials should not be lavaged because of the danger of gastrointestinal perforation. The administration of activated charcoal is indicated in certain drug poisonings. Measures to prevent gastric hemorrhage and excessive gastric acid secretion are usually advisable.
 8. The temperature-regulating mechanisms may be disturbed, and extreme hypothermia or hyperthermia should be corrected. In severe hyperthermia, evaporative-cooling measures are indicated in addition to antipyretics.
 9. The bladder should not be permitted to become distended; if the patient does not void, decompression should be carried out with an indwelling catheter. Needless to say, the patient should not be permitted to lie in a wet or soiled bed.
 10. Diseases of the CNS may disrupt the control of water, glucose, and sodium. The unconscious patient can no longer adjust the intake of food and fluids by hunger and thirst. Both salt-losing and salt-retaining syndromes have been described with brain disease (see Chap. 27). Water intoxication and severe hyponatremia may of themselves prove damaging. If coma is prolonged, the insertion of a nasogastric tube will ease the problems of feeding the patient and maintaining fluid and electrolyte balance. It is quite acceptable to leave the tube in place for long periods. Otherwise, approximately 35 mL/kg of isotonic fluid should be administered per 24 h (5% dextrose in 0.45% saline with potassium supplementation unless there is brain edema, in which case the use of isotonic normal saline is indicated).
 11. Aspiration pneumonia is avoided by prevention of vomiting (gastric tube and endotracheal intubation), proper positioning of the patient, and restriction of oral fluids. Should aspiration pneumonia occur, it requires treatment with appropriate antibiotics and aggressive pulmonary physical therapy.
 12. Leg vein thrombosis—a common occurrence in comatose and hemiplegic patients—often does not manifest itself by obvious clinical signs. An attempt may be made to prevent it by the subcutaneous administration of heparin, 5000 U q 12 h, or of low-molecular-weight heparin, and by the use of intermittent pneumatic compression boots.
 13. If the patient is capable of moving, suitable restraints should be used to prevent him from falling out of bed and to avert self-injury from convulsions.
 14. Regular conjunctival lubrication and oral cleansing should be instituted.

Prognosis of Coma (See also page 963)

As a general rule, recovery from coma of metabolic and toxic causes is far better than from anoxic coma, with head injury occupying an intermediate prognostic position. Most patients who are comatose as a result of a stroke will die; subarachnoid hemorrhage in which coma is due to hydrocephalus is an exception. In regard to all forms of coma, but particularly after cardiac arrest, if there are no pupillary, corneal, or oculovestibular responses within several hours of the onset of coma, the chances of regaining independent function are practically nil (see Levy et al). Other signs that predict a poor outcome are absence of corneal reflexes and eye-opening responses and atonia of the limbs at 1 and 3 days after the onset of coma and absence of the cortical component of the somatosensory evoked responses on both sides. It is the unfortunate survivor from this latter group who may remain in a vegetative state for months or years, breathing without aid and with preserved hypothalamopituitary functions. The frequency of this persistent vegetative state after head injury and the negligible chances of improvement if the condition persists for several weeks have already been discussed, and a discussion of the outcome of anoxic-ischemic coma can be found in Chap 40.

In all other cases, the nature of the underlying disease determines outcome; the reader should refer to the appropriate section of this book for further details.

CHAPTER 18

FAINTNESS AND SYNCOPES

The term *syncope* (Greek, *synkope*) literally means a “cessation,” a “cutting short” or “pause.” Medically, it refers to an episodic loss of consciousness and postural tone and an inability to stand due to a diminished flow of blood to the brain. It is synonymous in everyday language with *fainting*. *Feeling faint* and *a feeling of faintness* are also commonly used terms to describe the sudden loss of strength and other symptoms that characterize the impending or incomplete fainting spell. This latter state is referred to as *presyncope*. Relatively abrupt onset, brief duration, and spontaneous and complete recovery not requiring specific resuscitative measures are other distinguishing features.

Faintness and syncope are among the most common of all medical phenomena. Practically every adult has experienced some presyncopeal symptoms if not a fully developed syncopal attack or has observed such attacks in others. Description of these symptoms, as with other predominantly subjective states, is often ambiguous. The patient may refer to the experience as light-headedness, giddiness, dizziness, a “drunk feeling,” a weak spell, or, if consciousness was lost, a “blackout.” Careful questioning may be necessary to ascertain the exact meaning the patient has given to these words. In many instances the nature of the symptoms is clarified by the fact that they include a sensation of faintness and then a momentary loss of consciousness, which is easily recognized as a faint, or syncope. This sequence also informs us that under certain conditions any difference between faintness and syncope is only one of degree. These symptoms must be clearly set apart from certain types of epilepsy, the other major cause of episodic unconsciousness, and from disorders such as cataplexy, transient ischemic attacks (TIAs), “drop attacks,” and vertigo, which are also characterized by episodic attacks of generalized weakness or inability to stand upright but not by a loss of consciousness.

CLINICAL FEATURES OF SYNCOPES

The clinical manifestations of fainting attacks vary to some extent, depending on their mechanisms and the settings in which they occur.

The most common type of faint—namely, *vasodepressor* or *vasovagal syncope*, defined more precisely further on, conforms more or less to the following pattern. The patient is usually in the upright position at the beginning of the attack, either sitting or standing. Certain subjective symptoms, the prodrome, mark the onset of the faint. The person feels queasy, is assailed by a sense of giddiness and apprehension, may sway, and sometimes develops a headache. What is most noticeable at the beginning of the attack is pallor or an ashen-gray color of the face; often the face and body become bathed in cool perspiration. Salivation, epigastric distress, nausea, and sometimes vomiting may accompany these symptoms, and the patient tries to suppress them by yawning, sighing, or breathing deeply. Vision may dim or close in concentrically, the ears may ring, and it may be impossible to think clearly (“gray-out”). This serves to introduce the common faint that is known to all physicians and most laypersons; a more extensive discussion is given further on, under “Vasodepressor Syncope.”

The duration of the prodromal symptoms is variable, from a few minutes to only a few seconds, but it is doubtful that consciousness is ever abolished as abruptly as with a seizure. If, during the prodromal period, the person is able to lie down promptly, the attack can be averted before complete loss of consciousness occurs; otherwise, consciousness is lost and the patient falls to the ground. The more or less deliberate onset of this type of syncope enables patients to lie down or at least to protect themselves as they slump. A hurtful fall is exceptional in the young, though an elderly person may be injured.

The depth and duration of unconsciousness vary. Sometimes the person is not completely oblivious to his surroundings; he may still hear voices or see the blurred outlines of people. More often there is a complete lack of awareness and responsiveness. The patient lies motionless, with skeletal muscles fully relaxed. Sphincteric control is maintained in nearly all cases. The pupils are dilated. The pulse is thin and slow or cannot be felt; the systolic blood pressure is reduced (to 60 mmHg or less as a rule), and breathing is almost imperceptible. It is the brief period of hypotension and cerebral hypoperfusion that is the unifying feature of the syncopes. The depressed vital functions, striking facial pallor, and unconsciousness almost simulate death.

Once the patient is horizontal, the flow of blood to the brain is restored. The strength of the pulse soon improves and color begins to return to the face. Breathing becomes quicker and deeper. Then the eyelids flutter and consciousness is quickly regained. However, should unconsciousness persist for 15 to 20 s, convulsive movements may occur (*convulsive syncope*). These movements, which are often mistaken for a seizure, usually take the form of brief, mild, clonic jerks of the limbs and trunk and twitchings of the face or a tonic extension of the trunk and clenching of the jaw. Occasionally the extensor rigidity and jerking flexor movements are more severe, but very rarely is there urinary incontinence or biting of the tongue, features that characterize a generalized tonic-clonic convolution.

Gastaut and Fischer-Williams used the oculocardiac inhibitory reflex to study of the pattern of electroencephalographic (EEG) changes in syncope. They found that the heightened vagal discharge produced by compression of the eyeballs (oculovagal reflex, a cause of syncope in acute glaucoma) could produce brief periods of cardiac arrest and syncope. This effect was produced in 20 of 100 patients who had a history of syncopal attacks. These investigators found that after a 7- to 13-s period of cardiac arrest, there was a loss of consciousness, pallor, and muscle relaxation. Toward the end of this period, runs of bilaterally synchronous theta and delta waves appeared in the EEG, predominantly in the frontal lobes; in some patients there were one or more myoclonic jerks, synchronous with the slow waves. If the cardiac arrest persisted beyond 14 or 15 s, the EEG became flat. This period of electrical silence lasted for 10 to 20 s and was sometimes accompanied by a generalized tonic spasm with incontinence. Following the spasm, heartbeats and large-amplitude delta waves reappeared, and after another 20 to 30 s, the EEG reverted to normal. It is noteworthy that rhythmic clonic seizures or epileptiform EEG activity were not observed at any time during the periods of cardiac arrest, syncope, and tonic spasm.

From the moment that consciousness is regained, there is a correct perception of the environment. Confusion, headache, and drowsiness, the common sequelae of a convulsive seizure, do not follow a syncopal attack. Nevertheless, the patient often feels weak and groggy after a vasodepressor faint and, by arising too soon, may precipitate another faint.

The clinical features of *cardiac* and *carotid sinus syncope* are much the same as those described above except that the onset of these forms of syncope may be absolutely abrupt, without any warning symptoms, and is much less dependent upon the patient being in an upright posture. The clinical particulars of these and other forms of syncope are described further on.

CAUSES OF EPISODIC FAINTNESS AND SYNCOPES

From a clinical and pathophysiologic perspective, syncope is essentially of three main types, each of which may lead to a temporary reduction in the flow of blood to the brain:

1. Reflex loss of vascular sympathetic tone (vasodepressor effect), triggered by centrally mediated inhibition of the normal tonic sympathetic influences, often associated with excessive vagal effect and bradycardia (vasovagal effect). These are referred to generally as *vasovagal syncopes*, a special form of the neurogenic, or *neurocardiogenic syncopes*, by which is meant the withdrawal of sympathetic tone through a reflex neural mechanism. Neurocardiogenic syncope signifies that the inciting stimulus originates in neural receptors within the heart.
2. A failure of sympathetic innervation of blood vessels and of autonomically activated compensatory responses (reflex tachycardia and vasoconstriction), which occurs with assumption of the upright body position and leads to pooling of blood in the lower parts of the body—causing *orthostatic hypotension* and syncope. Typically, in individuals with these first two forms of syncope, there is no evidence of underlying cardiac disease.
3. Diminished cardiac output due to disease of the heart itself (as in the Stokes-Adams bradyarrhythmia attack or in severe aortic stenosis) or to greatly reduced blood volume from dehydration or blood loss.

As a rough guide to the relative frequency of the various causes of syncope, the large amount of information from the Framingham Heart Study accumulated by Soteriades and colleagues can be taken as representative; the leading cause was vasovagal, 21 percent, a cardiac cause was established in 9 percent, and orthostatic hypotension in 9 percent; fully 40 percent could not be categorized. Also notably, 7 percent of cases were attributed to medications, mainly those that interfered with sympathetic tone.

The three main types of syncope and several others that cannot readily be included within these categories can be further subdivided by their pathophysiologic mechanism, as follows:

- I. Neurogenic vasodepressor reactions
 - A. Elicited by *extrinsic signals* to the medulla from baro-receptors
 1. Vasodepressor (vasovagal)
 2. Neurocardiogenic
 3. Carotid sinus hypersensitivity

4. Vagoglossopharyngeal
5. Severe pain, especially if arising in a viscera (bowel, ovary, testicle, etc.)
- B. Coupled with diminished venous return to the heart
 1. Micturitional
 2. Tussive
 3. Valsalva, straining, breath-holding, weight lifting
 4. Postprandial
- C. Intrinsic psychic stimuli
 1. Fear, anxiety (presyncope more common)
 2. Sight of blood
 3. Hysterical
- II. Failure of sympathetic nervous system innervation (postural-orthostatic hypotension)
 - A. Peripheral nervous system autonomic failure
 1. Diabetes
 2. Pandysautonomia
 3. Guillain-Barré syndrome
 4. Amyloid neuropathy
 5. Surgical sympathectomy
 6. Antihypertensive medications and other blockers of vascular innervation
 - B. Central nervous system (CNS) autonomic failure
 1. Primary autonomic failure (idiopathic orthostatic hypotension)
 2. Multiple system atrophy (parkinsonism, ataxia, orthostatic hypotension)
 3. Spinal cord trauma, infarction, and necrosis
 4. Centrally acting antihypertensive and other medications
- III. Reduced cardiac output or inadequate intravascular volume (hypovolemia)
 - A. Reduced cardiac output
 1. Cardiac arrhythmias
 - a. Bradyarrhythmias
 - a. Atrioventricular (AV) block (second and third degree) with Stokes-Adams attacks
 - b. Ventricular asystole
 - c. Sinus bradycardia, sinoatrial block, sinus arrest, sick sinus syndrome
 - b. Tachyarrhythmias
 - a. Episodic ventricular tachycardia
 - b. Supraventricular tachycardia (infrequently causes syncope)
 2. Myocardial: infarction or severe congestive heart failure
 3. Obstruction to left ventricular or aortic outflow: aortic stenosis, hypertrophic subaortic stenosis, Takayasu arteritis
 4. Obstruction to pulmonary flow: pulmonic stenosis, tetralogy of Fallot, primary pulmonary hypertension, pulmonary embolism
 5. Pericardial tamponade
 - B. Inadequate intravascular volume (hemorrhage); dehydration
 - IV. Other causes of episodic faintness and syncope
 - A. Hypoxia
 - B. Anemia
 - C. Diminished CO₂ due to hyperventilation (faintness common, syncope rare)
 - D. Hypoglycemia (faintness frequent, syncope rare)
 - E. Anxiety (panic) attacks
 - F. Environmental overheating

This list of conditions causing faintness and syncope is deceptively long and involved. It will be recognized that the usual types are reducible to a few well-established mechanisms, all resulting in a temporary reduction of blood flow to the brain. In order not to obscure these mechanisms by too many details, only the varieties of fainting commonly encountered in clinical practice or those of particular neurologic interest are discussed below.

Neurogenic Syncope

This term refers to all forms of syncope that result directly from the vascular effects of neural signals coming from the CNS, primarily the nucleus tractus solitarius (NTS). A number of stimuli, mostly from the viscera but some of psychologic origin, are capable of eliciting this response, which consists of a reduction or loss of sympathetic vascular tone coupled with a heightened vagal activity. The NTS in the medulla integrates these afferent stimuli and normal baroreceptor signals with the efferent sympathetic mechanisms that maintain vascular tone (see further on and Chap. 26). Several lines of study suggest that there are disturbances of both sympathetic control of vascular tone and also of the responsiveness of baroreceptors.

By the use of microneurography, Wallin and Sundlof have demonstrated an increase in sympathetic outflow in peripheral nerves just prior to syncope as would be expected; this activity then ceases at the onset of fainting. Unmyelinated (postganglionic sympathetic) fibers cease firing during vasovagal fainting at a point when the blood pressure falls below 80/40 mmHg and the pulse below 60. This would signify that there is an initial attempt to compensate for the falling blood pressure, following which there is a centrally mediated withdrawal of sympathetic activity. Which one of these mechanisms (perhaps both) is responsible is not clear. More recently, Bechir has shown that muscle sympathetic activity as assessed using microneurography is increased in the resting state in patients with orthostatic hypotension and, importantly, does not increase further with venous pooling (induced by lower-body negative pressure). Moreover, in the same patients, the response of the cardiac baroreceptors to pooling was significantly diminished. These data are partially in agreement with those of Wallin and Sundlof, although they are not in accord with an initial increase in sympathetic activity prior to syncope. The clear implication of such studies is that the ability of the sympathetic nervous system to compensate for falling blood pressure is impaired, although it is not clear whether the primary defect is at the level of the baroreceptor afferents, the nucleus solitarius, or the sympathetic effector neurons. There is agreement that peripheral vascular resistance is greatly reduced just prior to and at the onset of fainting. This drop in resistance has been attributed by some to an initial adrenergic discharge that, at high levels, causes a vasodilation (rather than constriction) in intramuscular blood vessels. High levels of epinephrine and the vasodilating effects of nitric oxide acting on vascular endothelium as well as greatly augmented levels of circulating acetylcholine during syncope have also been invoked as additional or intermediary factors, but all remain speculative. In the current view, the drop in blood pressure is the result of a transient but excessive activity of sympathetic nerves that paradoxically leads to vascular dilatation in muscle and viscera.

It has been further suggested, on the basis of reasonable but not conclusive physiologic evidence, that the early sympathotonic attempt to maintain blood pressure leads to overly vigorous con-

tractions of the cardiac chambers and that this, in turn, acts as the afferent stimulus for withdrawal of sympathetic tone in common fainting (see “*Neurocardiogenic Syncope*,” below).

In essence all the following types of syncope are “*vasovagal*,” meaning a combination of vasodepressor and vagal effects in varying proportions; the only differences are in the stimuli that elicit the reflex response from the medulla.

Vasodepressor Syncope This is the common faint, fully described above and seen mainly in young individuals. A familial predisposition is known (Mathias et al). The evocative factors are usually strong emotion, physical injury—particularly to viscera (testicles, gut)—or other factors (see below). As described above, the vasodilatation of adrenergically innervated “resistance vessels” is postulated to lead to a reduction in peripheral vascular resistance, but cardiac output fails to exhibit the compensatory rise that normally occurs in hypotension. Some physiologic studies suggest that the dilatation of intramuscular vessels, innervated by beta-adrenergic fibers, may be more important than dilatation of the splanchnic ones. Skin vessels are constricted. Vagal stimulation may then occur (hence the term *vasovagal*), causing bradycardia and leading possibly to a slight further drop in blood pressure. Other vagal effects are perspiration, increased peristaltic activity, nausea, and salivation.

It should be emphasized that bradycardia probably contributes little to the hypotension and syncope. The term *vasovagal*, used originally by Thomas Lewis to designate this type of faint, is therefore not entirely apt and should be avoided as a synonym for *vasodepressor syncope*. As Lewis himself pointed out, atropine, “while raising the pulse rate up to and beyond normal levels during the attack, leaves the blood pressure below normal and the patient still pale and not fully conscious.”

In summary, the vasodepressor faint occurs (1) in normal health under the influence of strong emotion, particularly in some susceptible individuals (sight of blood or an accident) or in conditions that favor peripheral vasodilatation, e.g., hot, crowded rooms (“heat syncope”), especially if the person is hungry or tired or has had a few alcoholic drinks; (2) during a painful illness or after bodily injury (especially of the abdomen or genitalia), as a consequence of fright, pain, and other factors (where pain is involved, the vagal element tends to be more prominent in the genesis of the faint); and (3) during exercise in some sensitive persons (see further on).

Neurocardiogenic Syncope This entity, a component or perhaps a subtype of vasodepressor syncope, has received attention as a cause of otherwise unexplained fainting in healthy and athletic children and young adults. As mentioned above, it may be the final precipitant in the common vasodepressor faint, and the term is used synonymously with *vasovagal* or *vasodepressor syncope* by some authors (Kosinski et al).

Oberg and Thoren were the first to observe that the left ventricle itself can be the source of neurally mediated syncope in much the same way as the carotid sinus, when stimulated, produces vasodilation and bradycardia. During acute blood loss in cats, they noted a paradoxical bradycardia that was preceded by increased afferent activity in autonomic fibers arising from the ventricles of the heart, a reaction that could be eliminated by sectioning these nerves. This concept of the heart as a source of vasodepressor reflexes had been suggested earlier by Bezold as well as by Jarisch

and Zoterman and came to be known as the *Bezold-Jarisch reflex*. The inferoposterior wall of the left ventricle is the site of most of the subendocardial mechanoreceptors that are responsible for the afferent impulses.

In order for this mechanism to become active, very vigorous cardiac contractions must occur in the presence of deficient filling of the cardiac chambers (hence “neurocardiogenic”). In the simple faint, an initial burst of sympathetic activity is thought to precipitate these physiologic circumstances of excessive cardiac activity. Echocardiographic findings of a greatly diminished ventricular chamber size and vigorous contractions just prior to syncope support this notion (the “empty-heart syndrome”). However, the ability to induce a similar neurally mediated syncope in cardiac transplantation patients, whose hearts are denervated, leads one to question this concept. Perhaps the remaining baroreceptors in the aorta are responsible in this instance.

According to Kaufmann, a proclivity to primary neurocardiogenic syncope can be identified by the finding of delayed fainting when the patient is placed at a 60-degree upright position on a tilt table. After approximately 10 min of upright posture, the blood pressure drops below 100 mmHg; soon thereafter, the patient complains of dizziness and sweating and subsequently faints. In contrast, patients with primary sympathetic failure will faint soon after upward tilting. Half of patients with unexplained syncope display this delayed tilt-table reaction, but it is also seen in 5 percent of controls (see pages 330 and 459). The value of isoproterenol as a cardiac stimulant and peripheral vasodilator to enhance the effect of upright posture and expose neurocardiogenic syncope during the tilt-table test is controversial, as described further on, under “Special Methods of Examination.”

Exercise-Induced Syncope Aerobic exercise, particularly running, is known to induce fainting in some persons, a trait that may become apparent in late childhood or later and may be familial. There is nausea as well as other presyncope symptoms; the faint can be avoided by discontinuing exercise or not exceeding a threshold of effort set by the patient himself. Such persons do not seem unduly sensitive to nonaerobic exercise and have no recognizable electrocardiographic or structural heart problems. They have a predilection to faint with prolonged tilt-table testing and with isoproterenol infusion, suggesting that this represents a form of neurocardiogenic syncope. For this reason, these patients may benefit from beta-adrenergic blocking drugs if given under careful supervision. As discussed further on, exercise can also precipitate syncope in patients with a number of underlying cardiac conditions (myocardial ischemia, long QT syndrome, aortic outflow obstruction, cardiomyopathy, structural chamber anomalies, exercise-induced ventricular tachycardia, and less often supraventricular tachycardias).

Athletes who faint unpredictably during exercise pose a particularly difficult problem. Obviously those found to have serious heart disease should give up competitive sports, but the majority have no demonstrable cardiac abnormality. Subjecting these patients to intense exercise and other testing sometimes fails to elicit the faints, but many have varying degrees of hypotension when subjected to prolonged head-up tilt, again suggesting that the cause of fainting is essentially neurocardiogenic (see above). Standard pacemakers are not curative in these vasodepressor faints, since the main deficiency is in vascular resistance. Unless the results of tilt-table testing are unequivocal and reproducible, it is best to consider

the more serious causes of exercise-induced syncope and to treat the patient appropriately.

Carotid Sinus Syncope The carotid sinus is normally sensitive to stretch and gives rise to sensory impulses carried via the nerve of Hering, a branch of the glossopharyngeal nerve, to the medulla. Massage of one of the carotid sinuses or of both alternately, particularly in elderly persons, causes (1) a reflex cardiac slowing (sinus bradycardia, sinus arrest, or even atrioventricular block)—the *vagal type* of response, or (2) a fall of arterial pressure without cardiac slowing—the *vasodepressor type* of response. Another (“central”) type of carotid sinus syncope was in the past ascribed to cerebral arteriolar constriction, but such an entity has never been validated.

Faintness or syncope due to carotid sinus sensitivity has reportedly been initiated by turning of the head to one side while wearing a tight collar or even by shaving over the region of the sinus. However, the absence of a history of such an association does not exclude the diagnosis. The attack nearly always occurs when the patient is upright, usually standing. The onset is sudden, often with falling. Small convulsive movements occur quite frequently in both the vagal and vasodepressor types of carotid sinus syncope. The period of unconsciousness in carotid sinus syncope seldom lasts longer than 30 s, and the sensorium is immediately clear when consciousness is regained. The majority of the reported cases have involved men.

In a patient displaying faintness on massage of one carotid sinus, it is important to distinguish between the benign disorder (hypersensitivity of the carotid sinus) and a more serious condition—atheromatous narrowing of the basilar or opposite carotid artery (see Chap. 34). In the latter circumstance, it is important to avoid compression of the carotid artery, particularly if a carotid bruit is heard over either carotid vessel.

A number of other types of purely reflexive cardiac slowing can be traced to direct irritation of the vagus nerves (from esophageal diverticula, mediastinal tumors, gallbladder stones, carotid sinus disease, bronchoscopy, and needling of body cavities). Here, the reflex bradycardia is more often of sinoatrial than atrioventricular type. Weiss and Ferris called such faints *vagovagal*.

Through a similar mechanism, tumors or lymph node enlargements at the base of the skull or in the neck that impinge on the carotid artery, as well as postradiation fibrosis, are capable of causing dramatic syncopal attacks, sometimes preceded by unilateral head or neck pain. Often the episodes are unpredictable, but some patients find that turning the head stimulates an attack. The mechanism in one of our patients was primarily a vasodepressor response; patients with prominent bradycardia have generally had tumors that directly surrounded or infiltrated the glossopharyngeal and vagus nerves (Frank et al; see also MacDonald et al). If the tumor can be safely removed from the carotid region, the syncope often abates; in many cases, however, intracranial section of the ninth and upper rootlets of the tenth nerves on the side of the mass is necessary.

Syncope in Association with Glossopharyngeal Neuralgia *Glossopharyngeal neuralgia* (also referred to as *vagoglossopharyngeal neuralgia*) (see discussion in Chap. 47, “Diseases of Cranial Nerves,” page 1185) typically begins in the sixth decade with paroxysms of pain localized to the base of the tongue, pharynx or larynx, tonsillar area, or an ear. In only a small proportion of cases (estimated at 2 percent) are the paroxysms of pain complicated by

syncope. Always the sequence is pain, then bradycardia, and finally syncope. Presumably the pain gives rise to a massive volley of afferent impulses along the ninth cranial nerve, activating the medullary vasomotor centers via collateral fibers from the nucleus of the tractus solitarius. An increase in parasympathetic (vagal) activity slows the heart. Wallin and colleagues have demonstrated that, in addition to bradycardia, there is an element of hypotension due to inhibition of peripheral sympathetic activity. Here, the effects of the bradycardia exceed those of the vasodepressor hypotension, sometimes to the point of asystole, reflecting the opposite relationship from that seen in most other types of syncope.

The medical treatment of this type of syncope parallels that of trigeminal neuralgia (which is associated in approximately 10 percent of cases, usually on the same side). Anticonvulsants and baclofen are helpful in reducing both the pain and syncope in some patients. Intracranial vascular decompression procedures involving small branches of the basilar artery that impinge on the ninth nerve are said to be useful, but such patients have not been extensively studied. Conventional surgical treatment, which consists of sectioning the ninth cranial nerve and upper rootlets of the tenth, has proved to be effective in intractable cases.

The same mechanism is probably operative in so-called *deglutitional syncope*, in which consciousness is lost during or immediately after a forceful swallow. The administration of anticholinergic drugs (propantheline 15 mg tid) has abolished these attacks (Levin and Posner).

Micturition Syncope This infrequent condition is usually seen in men, sometimes in young adults but more often in the elderly, who arise from bed at night to urinate. The syncope occurs at the end of micturition or soon thereafter, and the loss of consciousness is abrupt, with rapid and complete recovery. Several factors are probably operative. A full bladder causes reflex vasoconstriction; as the bladder empties, this gives way to vasodilatation, which, combined with an element of postural hypotension, might be sufficient to cause fainting in some individuals. Vagus-mediated bradycardia and, in some cases, a mild Valsalva effect may also be factors, and alcohol ingestion, hunger, fatigue, and upper respiratory infection are common predisposing factors. In some instances, especially in the elderly, the nocturnal collapse has caused serious head injury.

Tussive and Valsalva Syncope Syncope as a result of a severe paroxysm of coughing was first described by Charcot in 1876. Affected patients are usually heavy-set males who smoke and have chronic bronchitis. Occasionally the problem occurs in children, particularly following paroxysmal coughing spells of pertussis and laryngitis. After sustained hard coughing, the patient suddenly becomes weak and may lose consciousness momentarily. This is mainly attributable to the greatly elevated intrathoracic pressure, which interferes with venous return to the heart. Increased cerebrospinal fluid (CSF) pressure and diminished PCO_2 , with resultant cerebral vasoconstriction, are possibly contributing factors.

Powerful efforts to exhale against a closed glottis (as occurs in tussive syncope) is referred to as the *Valsalva maneuver*. The unconsciousness that results from *breath-holding spells* in infants is probably based on this mechanism as well; the so-called pallid attacks in infants probably represent reflex vasodepression. Also, the loss of consciousness that occurs during competitive weight lifting ("weight lifters' blackout") is mainly the effect of a Valsalva maneuver, added to which are the effects of vascular dilatation

produced by squatting and hyperventilation. Lesser degrees of this phenomenon (faintness and light-headedness) not infrequently follow other kinds of strenuous activity, such as unrestrained laughing, straining at stool, heavy lifting, underwater diving, or effortful trumpet playing. Rarely, a brief faint may occur in each of these circumstances.

Syncope may occur occasionally in the course of prostatic or rectal examination, but only if the patient is standing (prostatic syncope). A Valsalva effect and reflex vagal stimulation appear to be contributing factors. *Postprandial hypotension* may occasionally lead to syncope in elderly persons, in whom impaired baroreflex function cannot compensate for pooling of blood in splanchnic vessels.

Primary Failure of the Sympathetic Nervous System

Postural (Orthostatic) Hypotension This type of syncope affects persons whose peripheral vasomotor system is defective. The effect of posture in its initiation is its most typical attribute. Standing still for prolonged periods or arising quickly from a recumbent position are the two circumstances under which it is most likely to happen. The patient, on assuming an upright position, shows a steady decline in blood pressure to a level at which the cerebral circulation cannot be supported. With few exceptions (see Chap. 26), peripheral autonomic failure precludes a compensatory tachycardia, and contrary to what happens in vasodepressor syncope, there are no autonomic responses such as pallor, sweating, nausea, or release of norepinephrine. Mild mental clouding with staggering or falling may precede unconsciousness or be the only evidence of the disorder.

The maintenance of blood pressure during various levels of activity and with postural changes depends on pressure-sensitive receptors (baroreceptors) in the aortic arch and carotid sinus and mechanoreceptors in the walls of the heart. These receptors, which are the sensory nerve endings of the glossopharyngeal and vagus nerves, send afferent impulses to the vasomotor centers in the medulla, more specifically the NTS. Axons from the NTS project to the reticular formation of the ventrolateral medulla, which, in turn, sends fibers to the intermediolateral cell column of the spinal cord, thereby controlling vasomotor tone in skeletal muscles, skin, and the splanchnic bed. A diminution of sensory impulses from baroreceptors increases the flow of excitatory signals, which raise the blood pressure and cardiac output, thus restoring cerebral perfusion. This subject is discussed further in relation to the regulation of blood pressure, in Chap. 26.

Postural syncope occurs under a wide variety of clinical conditions: (1) in otherwise normal individuals who, in certain circumstances, experience a failure of pressor-receptor reflex function, as described earlier; (2) as part of a chronic syndrome known as idiopathic orthostatic hypotension or primary autonomic insufficiency (see further on); (3) after a period of prolonged illness with recumbency, especially in elderly individuals with poor muscle tone; (4) in association with diseases of the peripheral nerves that involve autonomic nerve fibers—diabetes, tabes dorsalis, amyloidosis, Guillain-Barré syndrome, a primary idiopathic autonomic neuropathy, pandysautonomia, and several other polyneuropathies, all of which interrupt vasomotor reflexes; (5) after sympathectomy or high vagotomy; (6) in patients receiving L-dopa, antihypertensive agents, and certain sedative and antidepressant drugs; (7) in spinal cord transection above the T6 level, particularly in the acute stage; and (8) in patients with hypovolemia.

These conditions are easily understood if one keeps in mind that, on assuming the erect posture, the pooling of blood in the lower parts of the body is normally prevented by (1) reflex arteriolar and arterial constriction, through alpha- and beta-adrenergic effector mechanisms; (2) reflex acceleration of the heart by means of aortic and carotid reflexes, as described above; and (3) muscular activity, which improves venous return. Lipsitz has pointed out that aging is associated with a progressive impairment of these compensatory mechanisms, thus rendering the older person especially vulnerable to syncope. However, even in some younger persons, after the blood pressure has fallen slightly and stabilized at a lower level, the compensatory reflexes may also fail suddenly, with a precipitant drop in blood pressure.

The diagnosis of orthostatic hypotension from autonomic failure is established by measuring the blood pressure in the supine and then in the standing position and noting a substantial drop accompanied by symptoms of dizziness or syncope. *It should be emphasized that the bedside testing of orthostatic blood pressure is best performed by having the patient stand quickly and taking readings immediately and again at 1 and at 3 min, rather than using the lying-sitting-standing sequence.*

Postural Orthostatic Tachycardia Syndrome (“POTS”) The authors have limited experience with this syndrome and are uncertain about its validity as an entity apart from an aversion of the patient to assume an upright posture and the tendency to become weak and tremulous. As described by Low et al, it consists of intolerance of the standing position accompanied by tachycardia up to 120 beats per minute or more, but *without* orthostatic hypotension. Dyspnea, fatigue, and tremulousness and a complaint of “dizziness” accompany the assumption of an upright posture, and the same constellation of symptoms may be brought out by upright tilting. There is a frequent association with fatigue and with exercise intolerance. The situation is comparable to orthostatic intolerance in the chronic fatigue syndrome (page 435), with which POTS shares many features. An impairment of cerebral autoregulation has been hypothesized; others consider it to be a limited form of dysautonomia. In any case, it seems a valid entity.

Goldstein and associates recently compared a cohort of POTS patients with a group that experienced recurrent postural near-syncope and found that in the former group there was increased myocardial epinephrine release from intact cardiac sympathetic nerves. The basis for this is not known, although the researchers did exclude the possibility of defects in the cardiac norepinephrine transporter membrane and in norepinephrine synthesis.

Primary Autonomic Insufficiency (Idiopathic Orthostatic Hypotension) This presents in two forms. In one form (Bradbury-Eggleston), there is probably a selective degeneration of neurons in the sympathetic ganglia with denervation of smooth muscle vasculature and adrenal glands. The pathology has not been fully delineated, but lesions in other parts of the nervous system are not evident. In the second type (Shy-Drager), there is a degeneration of preganglionic neurons in the lateral columns of gray matter in the spinal cord, leaving postganglionic neurons isolated from spinal control. The latter lesion is often associated with degeneration of other systems of neurons in the CNS. Three such system degenerations have been identified, occurring singly or in combination: (1) degeneration of the substantia nigra and locus ceruleus (Parkinson disease), (2) striatonigral degeneration, and (3) olivopontocerebellar degeneration. In the first two syndromes, orthostatic

hypotension is combined with a parkinsonian syndrome; in the third, it is associated with cerebellar ataxia. Nonetheless, there are cases on record in which neuronal degeneration is limited to the sympathetic neurons of the intermediolateral cell columns. These forms of degenerative disease have their onset in adult life, and the associated hypotension and syncope are usually part of a more widespread autonomic dysfunction that includes other features such as a fixed cardiac rate, vocal cord paralysis, a loss of sweating in the lower parts of the body, atonicity of the bladder, constipation, and impotence in the male. As indicated on page 925, the symptoms of Parkinson disease, autonomic failure, and cerebellar atrophy are often associated in various combinations and degrees—a distinctive combination that has been subsumed under the term *multiple system atrophy*.

Syncope of Cardiac Origin

This is due to a sudden reduction in cardiac output, usually because of an arrhythmia, predominantly a bradycardia. Normally, a pulse as low as 35 to 40 beats per minute or as high as 150 beats per minute is well tolerated, especially if the patient is recumbent. Changes in pulse rate beyond these extremes impair cardiac output and may lead to syncope. Upright posture, anemia, and coronary, myocardial, and valvular disease all render the individual more susceptible to these alterations. Detailed discussions of the various valvular and myocardial abnormalities and arrhythmias that may compromise cardiac output and lead to syncope are to be found in the articles by Lipsitz, by Manolis, and by Kapoor and colleagues, listed in the References.

Syncope of cardiac origin occurs most frequently in patients with *complete atrioventricular block* and a pulse rate of 40 or less per minute (Adams-Stokes-Morgagni syndrome). The block may be persistent or intermittent; it is often preceded by fascicular or second-degree heart block. Ventricular arrest of 4 to 8 s, if the patient is upright, is enough to cause syncope; if the patient is supine, the asystole must last 12 to 15 s. After asystole of 12 s, according to Engel, the patient turns pale and becomes momentarily weak or may lose consciousness without warning; this may occur regardless of the position of the body. If the duration of cerebral ischemia exceeds 15 to 20 s, there are a few clonic jerks. With still longer asystole, the clonic jerks merge with tonic spasms and stertorous respirations and the ashen-gray pallor gives way to cyanosis, incontinence, fixed pupils, and bilateral Babinski signs. As heart action resumes, the face and neck become flushed. The report of this sequence of signs by a dependable observer helps to distinguish syncope from epilepsy. In cases of even more prolonged asystole (4 to 5 min), there may be cerebral injury, caused by a combination of hypoxia and ischemia. Coma may persist or may be replaced by confusion and other neurologic signs. Focal ischemic changes, often irreversible, may then be traced to the fields of occluded atherosclerotic cerebral arteries or the border zones between the areas of supply of major arteries. Cardiac faints of the Stokes-Adams type may recur several times a day. The heart block is usually intermittent at first, and between attacks the electrocardiogram (ECG) may show only evidence of myocardial disease. A continuous ECG using a Holter monitor or telemetry is then needed to demonstrate the arrhythmia (see further on).

Less easily recognized are faintness and syncope due to *dysfunction of the sinus node*, manifest by marked sinus bradycardia, sinoatrial block, or sinus arrest (“sick sinus syndrome”). The nodal block results in prolonged atrial asystole (0.3 s). Supraventricular

tachycardia or atrial fibrillation may occur, alternating with sinus bradycardia (bradycardia-tachycardia syndrome).

Tachyarrhythmias alone are less likely to produce syncope. Certainly intermittent ventricular fibrillation can cause fainting, and supraventricular tachycardias with rapid ventricular responses (usually over 180 beats per minute) cause syncope when sustained, predominantly in patients who are upright at the time. *The long QT syndrome* is a rare familial condition in which syncope and ventricular arrhythmias are prone to occur. Mutations in at least six different genes encoding cardiac sodium and potassium channels cause this syndrome. Another inherited syndrome with right bundle branch block and ST-segment elevation in the right precordial leads is known to cause syncope and even sudden death (Brugada syndrome). Some patients with mitral valve prolapse seem disposed to syncope and presyncope and an inordinate number are also said to have panic attacks.

Aortic stenosis or *subaortic stenosis* from cardiomyopathy often sets the stage for exertional syncope, because cardiac output cannot keep pace with the demands of exercise. Primary pulmonary hypertension and obstruction of right ventricular outflow (pulmonic valvular or infundibular stenosis) or intracardiac tumors may also be associated with exertional syncope. Syncope may also be a manifestation of pulmonary embolism. Vagal overactivity may be a factor contributing to the syncope in these conditions as well as in the syncope that may accompany pulmonary embolus and acute aortic outflow obstruction. *Tetralogy of Fallot* is the congenital cardiac malformation that most often leads to syncope. Other cardiac causes are listed in the classification given at the opening of this chapter.

Syncope Associated with Cerebrovascular Disease

It should be stated at the outset that syncope is an uncommon manifestation of cerebrovascular disease; cases that do occur are usually associated with multiple occlusions of the large arteries in the neck. The best examples are found in patients with the aortic-arch syndrome (Takayasu pulseless disease, page 732), in which the brachiocephalic, common carotid, and vertebral arteries have become narrowed. Physical activity may then critically reduce blood flow to the upper part of the brainstem, causing abrupt loss of consciousness. Stenosis or occlusion of vertebral arteries and the "subclavian steal syndrome" are other examples (page 678). Fainting is said also to occur occasionally in patients with congenital anomalies of the upper cervical spine (Klippel-Feil syndrome) or cervical spondylosis, in which the vertebral circulation is compromised. Head turning may then cause vertigo, nausea and vomiting, visual scotomas, and finally unconsciousness. Syncope does not occur with ischemic attacks that are confined to the territory of the internal carotid artery. Nor, in the authors' experience, do pure syncopal attacks occur with vertebrobasilar ischemia (see further on).

Cerebral Hemorrhage and Syncope The onset of a subarachnoid hemorrhage may be signaled by a syncopal episode, often with transient apnea. Because the bleeding is arterial, there is a momentary cessation of cerebral circulation as intracranial pressure and blood pressure approach one another. Unless there has been vomiting, a complaint of headache immediately preceding the syncope, or the discovery of hypertension or stiff neck when the patient awakens, the diagnosis may not be suspected until a CT scan or lumbar puncture is performed.

An associated problem, with which we have had numerous unsatisfactory encounters, is posed by the patient who falls suddenly forward without apparent cause, awakens with headache, and is found to have bifrontal hematomas and subarachnoid blood on CT. These cases highlight the difficulty of distinguishing a primary aneurysmal subarachnoid hemorrhage from an accidental fall or syncope with secondary frontal brain contusions; in almost every case, we have felt obliged to perform cerebral angiography to exclude an anterior communicating artery aneurysm, but we have rarely found one.

Fainting in Hysteria

Hysterical fainting is rather frequent and usually occurs under dramatic circumstances (Chap. 56). The evident lack of change in pulse, blood pressure, or color of the skin or any outward display of anxiety distinguishes it from the vasodepressor faint. Irregular jerking movements and generalized spasms without loss of consciousness or change in the EEG are typical features. The diagnosis is based on these negative findings in a person who exhibits the general personality and behavioral characteristics of hysteria. Several interesting instances of mass faintness and syncope of hysterical type have been described—for example, in school marching bands (RJ Levine).

Syncope of Unknown Cause

Finally, after careful evaluation of patients with syncope and the exclusion of the many forms of the condition described above, there remains a significant proportion (one-third to one-half, according to Kapoor and 40 percent in the earlier noted Framingham Heart Study) in which a cause for the syncope cannot be ascertained. The question of whether a single positive tilt-table test signifies that a prior episode of syncope was neurocardiogenic is not resolved; this obviously has a bearing on the proportion of cases that remain without a diagnosis. If the episodes are repetitive and erratically spaced, a cardiac arrhythmia or intraventricular conduction defect should be sought by use of special monitoring devices and conduction studies.

DIFFERENTIAL DIAGNOSIS

Anxiety Attacks and the Hyperventilation Syndrome These are probably the most important diagnostic considerations in unexplained faintness without syncope. The light-headedness of anxiety and hyperventilation are frequently described as a feeling of faintness, but a loss of consciousness does not follow (see Linzer et al.). Such symptoms are not accompanied by facial pallor or relieved by recumbency. The diagnosis is made on the basis of the associated symptoms, the absence of laboratory and tilt-table abnormalities, and the finding that part of the attack can be reproduced by having the patient hyperventilate. The symptoms produced in this way mimic the persistent or episodic dizziness that accompanies anxiety and panic states (Chap. 15). When anxiety attacks are combined with a Valsalva effect or prolonged standing, fainting may occur. The relationship of anxiety-panic to the previously described postural orthostatic tachycardia syndrome is uncertain.

Hypoglycemia In nondiabetics, hypoglycemia may be an obscure cause of episodic weakness and very rarely of syncope. With progressive lowering of blood glucose, the clinical picture is one of hunger, trembling, flushed facies, sweating, confusion, and finally,

after many minutes, seizures and coma. The diagnosis depends largely on the history, the documentation of reduced blood glucose during an attack, and reproduction of the patient's spontaneous attacks by an injection of insulin or hypoglycemia-inducing drugs (or ingestion of a high-carbohydrate meal in the case of reactive hypoglycemia).

Acute Blood Loss Acute hemorrhage, usually within the gastrointestinal tract, is a cause of weakness, faintness, or even unconsciousness when the patient stands suddenly. The cause (gastric or duodenal ulcer is the most common) may remain obscure until the passage of black stools.

Transient Cerebral Ischemic Attacks The many symptoms comprised by these attacks in the carotid system are fully described in Chap. 34, but syncope is not one of the clinical presentations. In the case of attacks in the vertebrobasilar territory, an impairment of consciousness is a rare manifestation, but almost always in the context of additional signs of upper brainstem dysfunction. The above described syncope of aortic arch occlusive (Takayasu) disease is, however, usually associated with TIAs, some elicited by effort or exercise.

Drop Attacks This term is generally applied to falling spells that occur without warning and *without* loss of consciousness or postictal symptoms. The patient, usually elderly and more often female, suddenly falls down while walking or standing, rarely while stooping. The knees inexplicably buckle. There is no dizziness or impairment of consciousness, and the fall is usually forward, with scuffing of the knees and sometimes the nose. The patient, unless obese, is able to right herself and to rise immediately and go her way, quite embarrassed. There may be several attacks during a period of a few weeks and none thereafter. The interval EEGs and ECGs are normal. One potential mechanism is a lapse of tone in leg muscles during the silent phase of an unnoticed myoclonic jerk. Drop attacks also occur in hydrocephalics, and these patients, though conscious, may not be able to arise for several hours. Drop attacks as defined above are usually without an identifiable mechanism, requiring no treatment if cardiologic studies are normal. On uncertain grounds, they are often attributed to brainstem ischemia. In only about one-quarter of such cases, according to Meissner and coworkers, can an association be made with cardiovascular or cerebrovascular disease, to which treatment should be directed. Rare instances of Ménière disease, in which the patient is suddenly thrown to the ground ("otolithic catastrophe of Tumarkin," page 260) may be mistaken for a syncopal or drop attack, but only briefly, until vertigo becomes prominent.

Seizures and Syncope In the final analysis, the loss of consciousness in the different types of syncope must be caused by impaired function of the neural elements in those parts of the brain subserving consciousness, i.e., in the high brainstem and thalamic reticular activating system. In this respect syncope and primary generalized (so-called centrencephalic) epilepsy have a common ground; yet there is, of course, a fundamental difference. In epilepsy, whether major or minor, the arrest in consciousness is almost instantaneous, and, as revealed by the EEG, is accompanied by a paroxysm of electrical activity occurring simultaneously in all of the cerebral cortex and thalamus. The EEG changes (mainly by way of diffuse slowing—delta waves) in syncope appear later in the course of the attack. The difference relates to the essential pathophysiology—the rapid spread of an electrical discharge in epilepsy and a more gradual failure of cerebral circulation in syncope.

There are also a number of important clinical distinctions between epileptic and syncopal attacks. The epileptic attack may occur

day or night, regardless of the position of the patient; syncope rarely appears when the patient is recumbent, the only common exception being the Stokes-Adams attack. The patient's color usually does not change at the onset of an epileptic attack; pallor is an early and almost invariable finding in all types of syncope except those due to chronic orthostatic hypotension or hysteria, and it precedes unconsciousness. An epileptic attack, as indicated above, is more sudden in onset; if an aura is present, it rarely lasts longer than a few seconds before consciousness is abolished. The onset of syncope is usually more gradual, and the prodromal symptoms are quite distinctive and different from those of seizures. In general, injury from falling is more frequent in epilepsy than in syncope, because protective reflexes are instantaneously abolished in the former. (Nevertheless, cardiogenic syncope is an important cause of hurtful falls, especially in the elderly.) Tonic spasm of muscles with upturning of the eyes is a prominent and often initial feature of epilepsy, but this occurs only rarely and late in the course of a faint; however, twitching and a few clonic contractions of the limbs may occur several seconds after the patient has fainted (see above). Urinary incontinence is a frequent occurrence in epilepsy, but it need not occur during an epileptic attack and may occasionally occur with syncope, so that it cannot be used as a means of excluding entirely the latter disorder. The return of consciousness is slow in epilepsy, prompt in syncope; mental confusion, headache, and drowsiness are common sequelae of seizures, and physical weakness with clear sensorium of syncope (a brief period of grogginess may follow vasodepressor syncope). Repeated spells of unconsciousness in a young person at a rate of several per day or month are much more suggestive of epilepsy than of syncope.

The EEG may be helpful in differentiating syncope from epilepsy. In the interval between epileptic seizures, the EEG, particularly if repeated once or twice, shows some degree of abnormality in 50 to 75 percent of cases, whereas it should be normal between syncopal attacks. Sometimes one must resort to continuous EEG monitoring by tape recording or telemetry to clarify the situation (this can be combined with continuous ECG recording.) Another useful laboratory marker of a seizure, especially if unwitnessed, is an elevation of the serum creatine kinase (CK) concentration; such a finding occurs only infrequently in the rare case of syncope associated with extensive muscle trauma. Elevated prolactin levels have not proved discriminating enough for routine use in separating seizure from syncope but remain useful in distinguishing both of these from other causes of loss of consciousness, particularly hysteria, in which such elevations do not occur.

No single one of these criteria will absolutely differentiate epilepsy from syncope, but taken as a group and supplemented by the EEG, they usually enable one to distinguish the two conditions.

SPECIAL METHODS OF EXAMINATION

In patients who complain of recurrent faintness or syncope but do not have a spontaneous attack while under observation of the physician, an attempt to reproduce attacks may prove to be of great assistance in diagnosis. Here it is important to recall that normal persons can faint if made to squat and overbreathe and then to stand erect and hold their breath (Valsalva maneuver). Prolonged standing at attention in the heat often causes even well-conditioned soldiers to faint, as does compression of the chest and abdomen while holding one's breath, as in the parlor trick of adolescents ("fainting lark").

When an anxiety state is accompanied by faintness, the pattern of symptoms can often be reproduced by having the subject hyperventilate—that is, breathe rapidly and deeply for 2 to 3 min. This test may also be of therapeutic value, because the underlying anxiety tends to be lessened when the patient learns that the symptoms can be produced and alleviated at will simply by controlling breathing.

Most patients with tussive syncope cannot reproduce an attack by the Valsalva maneuver but can sometimes do so by voluntary coughing if severe enough. Another useful procedure is to have the patient perform the Valsalva maneuver for more than 10 s (thus trapping blood behind closed valves in the veins) while the pulse and blood pressure are measured (see “Tests for Abnormalities of the Autonomic Nervous System,” Chap. 26).

In each of the aforementioned instances, the crucial point is not whether symptoms are produced but whether they reproduce the exact pattern of symptoms that occurs in the spontaneous attacks.

Other conditions in which the diagnosis is clarified by reproducing the attacks are carotid sinus hypersensitivity (massage of one or the other carotid sinus) and orthostatic hypotension (observations of pulse rate, blood pressure, and symptoms in the recumbent and standing positions or, even better, with the patient on a tilt table).

The tilt table test is now a regularly used procedure when the diagnosis of syncope is not evident from physical examination and routine studies such as electrocardiography (ECG), blood count, and bedside sphygmomanometry. There is a distinct difference in the cardiovascular challenge imposed by a tilt table and that created by the simple act of standing up from a sitting or recumbent position, as discussed below. It should be re-emphasized that, from the perspective of detecting an underlying autonomic failure, having the patient stand abruptly from a lying position and then recording the blood pressure every 30 to 60 s for up to 3 min is more informative than interposing a period of sitting between the lying and standing positions. Patients with sympathetic failure of central or peripheral type, and those with hypovolemia will show a drop in blood pressure within 30 s; those with a propensity to reflex fainting may take much longer, or show no drop at all.

The measurement of beat-to-beat variation in heart rate is a simple but sensitive means of detecting vagal dysfunction, as described in Chap. 26.

Careful, continuous monitoring of the ECG in the hospital or by using a portable recorder may determine whether an arrhythmia is responsible for the syncopal episode. A continuous cardiac loop ECG recorder (which continually records and erases cardiac rhythm) permits prolonged (a month or longer) ambulatory monitoring at reasonable cost. The diagnostic yield from loop recording is much greater than that from Holter monitoring (Linzer et al). The signal-averaged ECG is reportedly a useful means of identifying individuals at risk for ventricular tachycardia as a cause of syncope (Manolis).

Tilt-Table Testing There are two types of abnormal response to upright tilting: early hypotension (occurring within moments of tilting), which signifies inadequate sympathetic tone and baroreceptor function; and a delayed (several minutes) hypotension and syncope, which indicates a neurocardiogenic mechanism. The normal response to an 60- to 80-degree head-up tilt for 10 min is a transient drop in systolic blood pressure (5 to 15 mmHg), a rise in diastolic pressure (5 to 10 mmHg), and a rise in heart rate (10 to 15 beats per minute). Abrupt and persistent declines in blood pres-

sure of greater than 20 to 30 mmHg systolic and 10 mmHg diastolic and a drop (or failure to rise) of the heart rate are considered abnormal; often these findings are associated with faintness and sometimes with syncope. Although controversial, in some circumstances the infusion of the catecholamine isoproterenol (1 to 5 mg/min for 30 min during head-up tilt) may be a more effective means of producing hypotension (and syncope) than the standard tilt test alone (Almquist et al; Waxman et al).

It should be repeated that the presence of a delayed faint with tilting only demonstrates a proclivity to neurocardiogenic fainting, since it occurs in a proportion of individuals who have never fainted; it is not to be taken as incontrovertible evidence that a recent spell is explained by this mechanism.

TREATMENT

Patients seen during the preliminary stages of fainting or after they have lost consciousness should be placed in a position that permits maximal cerebral blood flow, i.e., with head lowered between the knees if sitting or preferably in the supine position with legs elevated. All tight clothing and other constrictions should be loosened and the head and body positioned so that the tongue does not fall back into the throat and the possible aspiration of vomitus is avoided. Nothing should be given by mouth until the patient has regained consciousness. The patient should not be permitted to rise until the sense of physical weakness has passed and he should be watched carefully for a few minutes after arising.

As a rule, the physician sees the patient after recovery from the faint and is asked to explain why it happened and how it can be prevented in the future. One should think first of those causes of fainting that constitute a therapeutic emergency. Among them are massive internal hemorrhage and myocardial infarction, which may be painless, and cardiac arrhythmias. In an elderly person, a sudden faint without obvious cause must always arouse the suspicion of a complete heart block or other cardiac arrhythmia.

The prevention of fainting depends on the mechanisms involved. In the usual vasodepressor faint of adolescents—which tends to occur in circumstances favoring vasodilatation (warm environment, hunger, fatigue, alcohol intoxication) and periods of emotional excitement—it is enough to advise the patient to avoid such circumstances. In postural hypotension, patients should be cautioned against arising suddenly from bed. Instead, they should first exercise the legs for a few seconds, then sit on the edge of the bed and make sure they are not light-headed or dizzy before starting to walk. Standing for prolonged periods can sometimes be tolerated without fainting by crossing the legs forcefully. Alternatives should be found for medications that are conceivable causes of orthostasis. Beta-adrenergic blocking agents, diuretics, antidepressants, and sympatholytic antihypertensive drugs are the common culprits.

In the syndrome of chronic orthostatic hypotension, special corticosteroid preparations—such as fludrocortisone acetate (Florinef) 0.05 to 0.4 mg/day in divided doses—and increased salt intake to expand blood volume are helpful. Recently the alpha₁ agonist midodrine, beginning with 2.5 mg every 4 h and slowly increasing the dose to 5 mg every 4 to 6 h, has been used successfully in small studies, but this medication has the potential to worsen the situation and must be used with care. Sleeping with the headposts of the bed elevated on wooden blocks 8 to 12 in. high and wearing a snug elastic abdominal binder and elastic stockings are measures that often prove helpful. Tyramine and monoamine oxidase inhibitors have given limited relief in some cases of Shy-

Drager syndrome, and beta blockers (propranolol or pindolol) and indomethacin (25 to 50 mg tid) in others. These and other approaches that have proved useful in treating orthostatic hypotension are reviewed by Mathias and Kimber.

Neurally mediated syncope (neurocardiogenic or vasodepressor syncope), identified largely by the clinical circumstances and by upright tilt-table testing, may be prevented by the use of beta-adrenergic blocking agents. Our colleagues in cardiology have favored, and we endorse from experience, acebutolol 400 mg daily, in part because of its partial alpha-adrenergic activity, which raises baseline blood pressure, but atenolol 50 mg may be as effective. The anticholinergic agent disopyramide has also been used (Milstein et al). Several other drugs (e.g., ephedrine, metoclopramide, dihydroergotamine) have been variably successful in individual patients, but their utility as standard medications remains to be established; the beta-blocking agents are generally preferred.

The treatment of carotid sinus syncope involves, first of all, instructing the patient in measures that minimize the hazards of a fall (see below). A loose collar should be worn, and the patient should learn to turn his whole body, rather than the head alone, when looking to one side. Atropine or one of the sympathomimetic group of drugs should be used, respectively, in patients with pronounced bradycardia or hypotension during attacks. If atropine is

not successful and the syncopal attacks are incapacitating, the insertion of a dual-chamber pacemaker should be considered. Radiation or surgical denervation of the carotid sinus has apparently yielded favorable results in some patients, but it is rarely necessary. Vagovagal attacks usually respond well to an anticholinergic agent (propantheline, 15 mg tid).

Treatment of the hyperventilation syndrome and of hysteria are considered in Chap. 56. For a discussion of the treatment of hypoglycemia and the various cardiac arrhythmias that may induce syncope, the reader is referred to *Harrison's Principles of Internal Medicine*.

In the elderly person, a faint carries the additional hazard of a fracture or other trauma due to the fall. Therefore the patient subject to recurrent syncope should cover the bathroom floor and bathtub with mats and have as much of his home carpeted as is feasible. Especially important is the floor space between the bed and the bathroom, because this is the route along which faints in elderly persons most commonly occur. Outdoor walking should be on soft ground rather than hard surfaces, and the patient should avoid standing still for prolonged periods, which is more likely than walking to induce an attack. Padded hip protectors, now available as a commercial product, should be considered in elderly patients at risk of recurrent falls of any kind.

CHAPTER 19

SLEEP AND ITS ABNORMALITIES

Sleep, that familiar yet inexplicable condition of repose in which consciousness is in abeyance, is obviously not abnormal, yet it is most appropriately considered in connection with abnormal phenomena because there are a number of interesting and common irregularities of sleep, some of which approach serious extremes. Everyone has had a great deal of personal experience with sleep, or lack of it, and has observed people in sleep, so it requires no special knowledge to understand something about this condition or to appreciate its importance to health and well-being. The psychologic and physiologic benefits of sleep have seldom been so eloquently expressed as in the words of Tristram Shandy:

Tis the refuge of the unfortunate—the enfranchisement of the prisoner, the downy lap of the hopeless, the weary, the broken-hearted; of all the soft delicious functions of nature this is the chiefest; what a happiness it is to man, when the anxieties and passions of the day are over.

Physicians are often consulted by patients who suffer some derangement of sleep. Most often the problem is one of sleeplessness, but sometimes it concerns excessive sleep or some peculiar phenomenon occurring in connection with sleep. Certain points concerning normal sleep and the sleep-wake mechanisms are worth reviewing, since familiarity with them is necessary for an understanding of disorders of sleep. A great deal of information about sleep and sleep abnormalities is now available as a result of the development, in relatively recent years, of the subspecialty of sleep medicine and the creation of a large number of centers for the diagnosis and treatment of sleep disorders.

Most disorders of sleep can be readily recognized and managed if one attends closely to the patient's description of his sleep disturbance. Only complex or odd cases or those requiring the documentation of apneic episodes or seizures and other motor disorders during sleep need study in special sleep laboratories.

Physiology of Sleep and Sleep-Wake Mechanisms

Sleep, as everyone knows, is an elemental phenomenon of life and an indispensable phase of human existence. It represents one of the basic 24-h (circadian) rhythms, traceable through all mammalian, avian, and reptilian species. The neural control of circadian rhythms is thought to reside in the ventral-anterior region of the hypothalamus—more specifically, in the suprachiasmatic nuclei. Lesions in these nuclei result in a disorganization of the sleep-wake cycles as well as of the rest-activity, temperature, and feeding rhythms. The ancillary role of melatonin and the pineal body in modulating this cyclic activity is described in Chap. 27.

Effects of Age Observations of the human sleep-wake cycle show it to be age-linked. The newborn baby sleeps from 16 to 20 h a day and the child, 10 to 12 h. Total sleep time drops to 9 to 10 h at age 10 and to about 7 to 7.5 h during adolescence. A gradual

decline to about 6.5 h develops in late adult life. However, there are wide individual differences in the length and depth of sleep, due apparently to genetic factors, early-life conditioning, the amount of physical activity, and particular psychologic states.

The pattern of sleeping, which in terrestrial life is adjusted to the 24-h day, also varies in the different epochs of life. The circadian rhythm, with predominance of daytime wakefulness and nighttime sleep, begins to appear only after the first few weeks of postnatal life of the full-term infant; as the child matures, the morning nap is omitted, then the afternoon nap; by the fourth or fifth year, sleep becomes consolidated into a single long nocturnal period. (Actually, a large part of the world's population continue to have an afternoon nap, or siesta, as a lifelong sleep-wake pattern.) This alternating pattern of sleeping and waking persists throughout the adolescent and adult years unless it is altered by emotional or physical disease; fragmentation of the sleep pattern begins in late adult life. Over ensuing years, night awakenings tend to increase in frequency and the daytime waking period tends to be interrupted by episodic sleep lasting seconds to minutes (microsleep) as well as by longer naps. From about 35 years of age onward, women tend to sleep slightly more than men.

Stages of Sleep Seminal contributions to our understanding of the physiology of sleep were made by Loomis and associates and by Aserinsky, Dement, and Kleitman through EEG and polygraphic analysis. As a result of their studies, five stages of sleep, representative of two alternating physiologic mechanisms, were defined. In each stage, the electrical activity of the brain occurs in organized and recurring cycles, referred to as the *architecture of sleep*. These findings put to rest the antiquated ideas that sleep is a purely passive state and simply reflects fatigue and reduction in environmental stimuli, and that sleep and coma have fundamentally the same anatomic-physiologic basis. As the electrophysiologic stages of sleep progress, sleep becomes deeper, meaning that arousal requires a more intense stimulus.

Relaxed wakefulness with the eyes closed is accompanied in the electroencephalogram (EEG) by posterior sinusoidal alpha waves of 9 to 11 Hz (cycles per second) and low-voltage fast activity of mixed frequency. Except for the facial muscles, the electromyogram (EMG) is silent when the patient is sitting or lying quietly. With drowsiness, as the first stage of sleep sets in, the eyelids begin to droop, the eyes may rove slowly from side to side, and the pupils become smaller. As the early stage of sleep evolves, the muscles relax and the EEG pattern changes to one of progressively lower voltage and mixed frequency with a loss of alpha waves; this is associated with slow, rolling eye movements and is called *stage 1 sleep*. As this changes into *stage 2 sleep*, 1/2- to 2-s bursts of biparietal 12- to 14-Hz waves (sleep spindles) and intermittent high-amplitude, central-parietal sharp slow-wave complexes appear (vertex waves) (Fig. 19-1). The deep sleep of *stages 3 and 4*, also called *slow-wave sleep*, is composed of an increasing proportion of high-amplitude (.75-mV), delta (1- to 2-Hz) waves in the EEG. If the eyelids are raised gently, the globes are usually

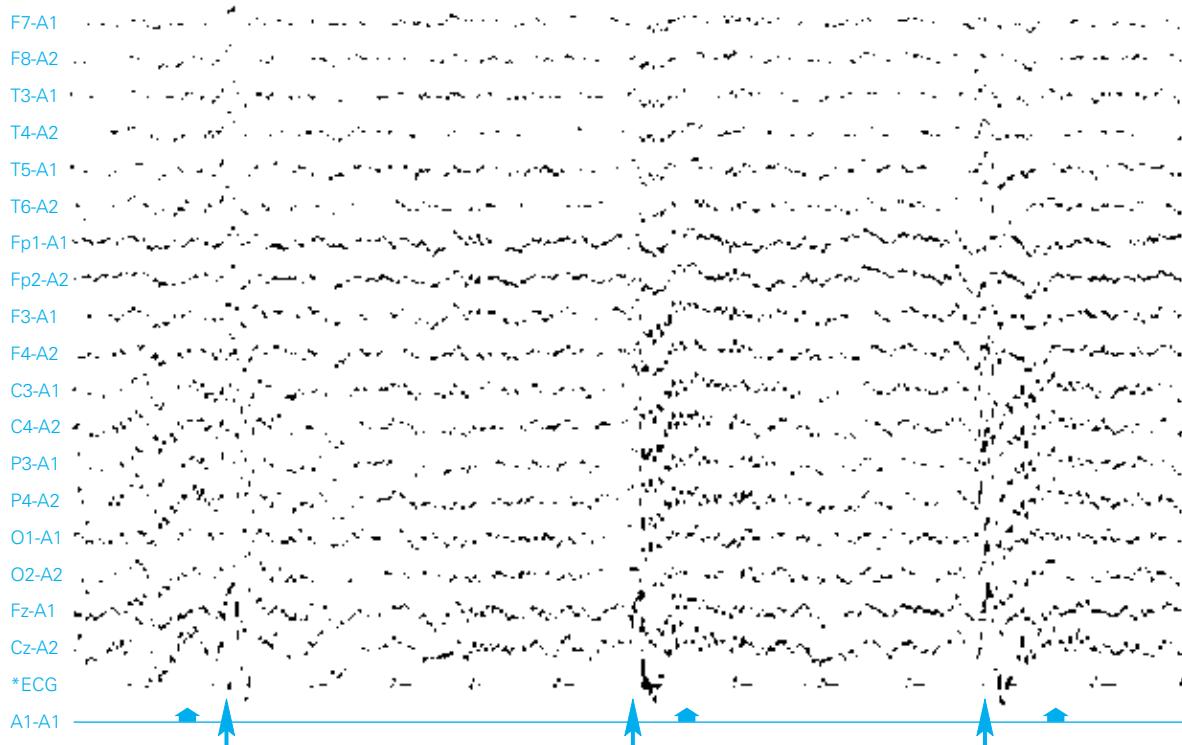

Figure 19-1. Conventional EEG (30 mm/s) of a young healthy woman in stage 2 sleep showing vertex waves (large arrows) and sleep spindles (small arrows), best seen in the central regions.

seen to be exotropic and the pupils are even smaller than before, but with retained responses to light. The last stage of the sleep cycle, which follows the others intermittently throughout the night, is associated with further reduction in muscle tone except in the extraocular muscles and with bursts of rapid eye movements (REM; thus the term *REM sleep* designates this stage) behind the closed lids. The EEG becomes desynchronized, i.e., it has a low-voltage, high-frequency discharge pattern. The first four stages of sleep are called *non-rapid eye movement (NREM) sleep or quiet or synchronized sleep*; the last stage is variously designated as *rapid-eye-movement (REM), fast-wave, nonsynchronized, or desynchronized sleep*. These features are illustrated in Fig. 19-2.

In the first portion of a typical night's sleep, the normal young and middle-aged adult passes successively through stages 1, 2, 3, and 4 of NREM sleep. After about 70 to 100 min, a large proportion of which consists of stages 3 and 4 sleep, the first REM period occurs, usually heralded by a transient increase in body movements and a shift in the EEG pattern from that of stage 4 to stage 2. This NREM-REM cycle is repeated at about the same interval four to six times during the night, depending on the total duration of sleep. The first REM period may be brief; the later cycles have less stage 4 sleep or none at all. In the latter portion of a night's sleep, the cycles consist essentially of two alternating stages—REM sleep and stage 2 (spindle-K-complex) sleep.

Newborn full-term infants spend about 50 percent of their sleep in the REM stage (although their EEG and eye movement characteristics differ from those of adults). The newborn sleep cycle lasts about 60 min (50 percent REM, 50 percent NREM, generally alternating through a 3- to 4-h interfeeding period); with age, the sleep cycle lengthens to 90 to 100 min. About 20 to 25 percent of total sleep time in young adults is spent in REM sleep, 3 to 5

percent in stage 1, 50 to 60 percent in stage 2, and 10 to 20 percent in stages 3 and 4 combined. The amount of sleep in stages 3 and 4 decreases with age, and persons more than 70 years of age have virtually no stage 4 sleep and only small amounts of stage 3 sleep (Fig. 19-3). The 90- to 100-min cycle is fairly stable in any one person and is believed to continue to operate to a less perceptible degree during wakefulness in relation to cyclic gastric motility, hunger, degrees of alertness, and capacity for cognitive activity.

Physiologic Changes and Dreaming in NREM and REM Sleep

A comparison of the physiologic changes in NREM and REM sleep is instructive. The change in the EEG pattern has already been indicated. Cortical neurons tend to discharge in synchronized bursts during NREM sleep and in nonsynchronized bursts in the wakeful states; in REM sleep, the EEG pattern is generally asynchronous as well. Most complex visual dreaming has been found to occur in the REM period, with the qualifications noted below, and is recalled most consistently if the subject is awakened at this time. It is important to point out that similar mental activity may be reported by subjects awakened from NREM sleep, though less consistently. Since the time spent in NREM is so much greater than that in REM, a substantial portion of the total time spent dreaming occurs outside of REM periods. Subjects are easily aroused from REM sleep, but arousing a person during stage 3 or stage 4 of NREM sleep is more difficult; full arousal may take 5 min or more, during which time the subject may be disoriented and confused (physicians called at night should, if possible, avoid making complex medical decisions during this brief period).

As mentioned above, tonic muscle activity is minimal during REM sleep, although small twitches in facial and digital muscles (hand and foot) can still be detected. Eye movements of REM sleep

are conjugate and occur in all directions (horizontal more than vertical). Gross body movements occur every 15 min or so in all stages of sleep but are maximal in the transition between REM and NREM sleep, at which time the sleeping person changes position, usually from side to side (most people sleep on their sides). On closer study, REM sleep has been found to have phasic and tonic components. In addition to the rapid eye movements, phasic phenomena include alternate dilatation and constriction of the pupils and an increase in the blood pressure as well as fluctuation of the blood pressure, pulse, and respiration. The phasic activities are related to bursts of neuronal activity in the pontine, vestibular, and median raphe nuclei and are conducted through the corticobulbar and corticospinal tracts. In the nonphasic periods of REM sleep, alpha and gamma spinal neurons are inhibited, the H responses diminish, and the tendon (phasic myotatic) and postural and flexor reflexes diminish or are abolished. This flaccidity or atonia—which is prominent in the abdominal, upper airway, and intercostal muscles—may compromise breathing during REM sleep and pose a threat in infants with excessive respiratory difficulty and in patients who are obese as well as in those with kyphoscoliosis, muscular dystrophy, and other neuromuscular paralyses (Guilleminault and Dement).

It has long been known that body temperature falls slightly during sleep; however, if sleep does not occur, there is still a drop in body temperature as part of the circadian (24-h) temperature curve. This drop in temperature is also independent of the 24-h recumbency-ambulatory cycle. During sleep, the decline in temperature occurs mainly during the NREM period, and the same is true of the heartbeat and respiration, both of which become slow and more regular in this period. Cerebral blood flow and oxygen consumption in muscle diminish during NREM sleep and increase during REM sleep. Also, cerebral blood flow and metabolism are markedly reduced across the entire brain during deep NREM sleep; however, during REM sleep, metabolism and blood flow are restored to the levels of the waking state (Madsen and Vorstrup). Presumably as a result of increased blood flow, intracranial pressure rises during REM sleep. Braun and colleagues, who used positron emission tomography (PET) to study REM sleep, observed selective activation of the extrastriate visual cortices and limbic-paralimbic regions, with concomitant attenuation of activity in the primary visual cortex and frontal association areas. These authors have speculated that dreaming activates the visual association areas and their paralimbic connections and that these regions op-

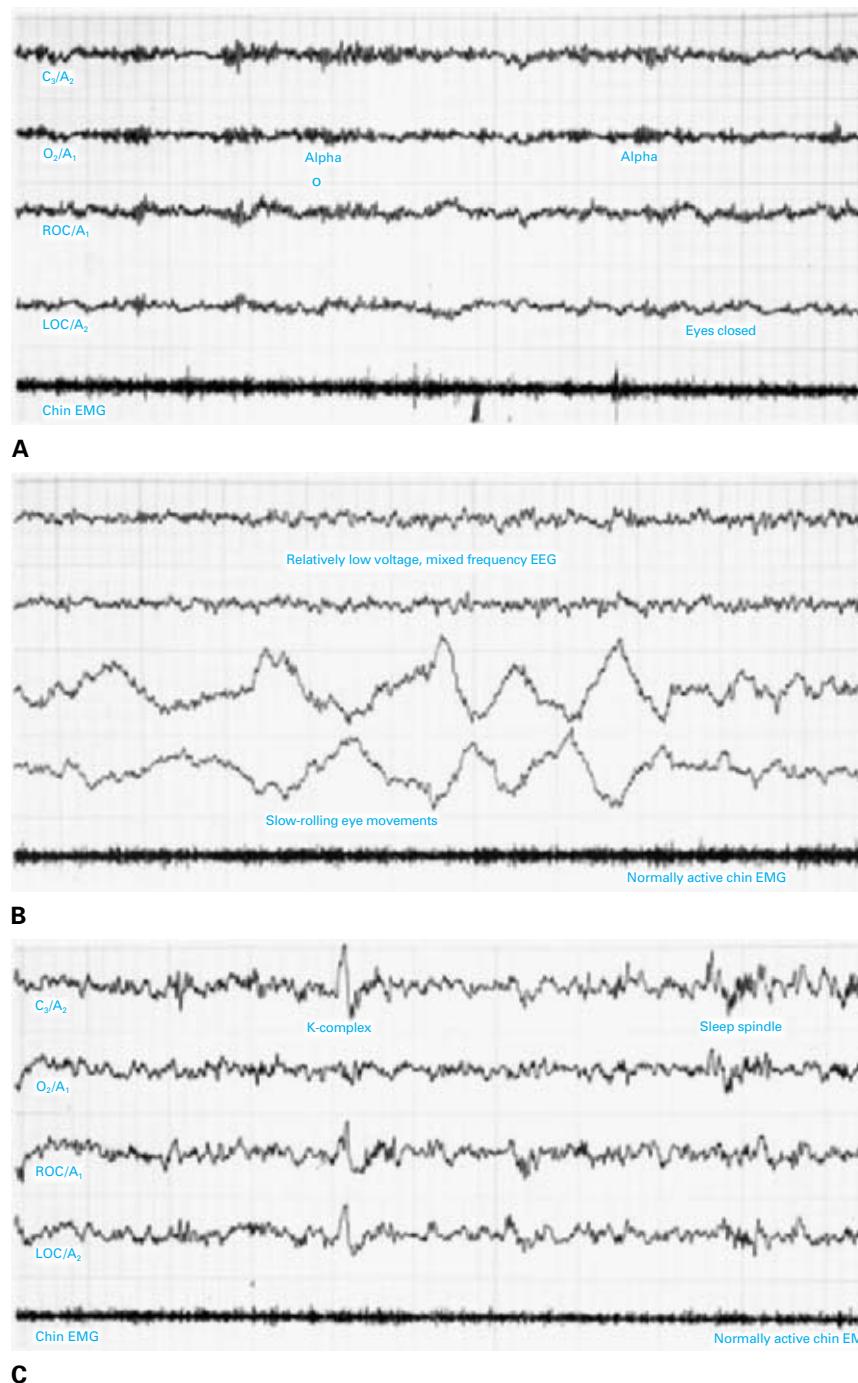

Figure 19-2. Representative polysomnographic recordings from adults in the awake state and various stages of sleep. Recordings are made at conventional sleep-laboratory speed of 10 mm/s (i.e., at the paper speed of one-third standard clinical EEG recordings). **A.** Upper tracings: Awake state (with eyes closed). Alpha rhythms are prominent in EEG. Normally active chin EMG. **B.** Middle tracings: Stage 1 sleep. Onset of sleep is defined by the diminished amplitude of alpha waves in the occipital EEG channel ("flat" appearance). **C.** Lower tracings: Stage 2 sleep, characterized by appearance of high-amplitude single-complex (K) waves and bursts of 13- to 16-Hz waves (sleep spindles) on a background of low frequency.

erate independently of frontal lobe modulation, perhaps explaining the uncritical acceptance of the bizarre content and the disordered temporal relationships and heightened emotionality that characterize dreams.

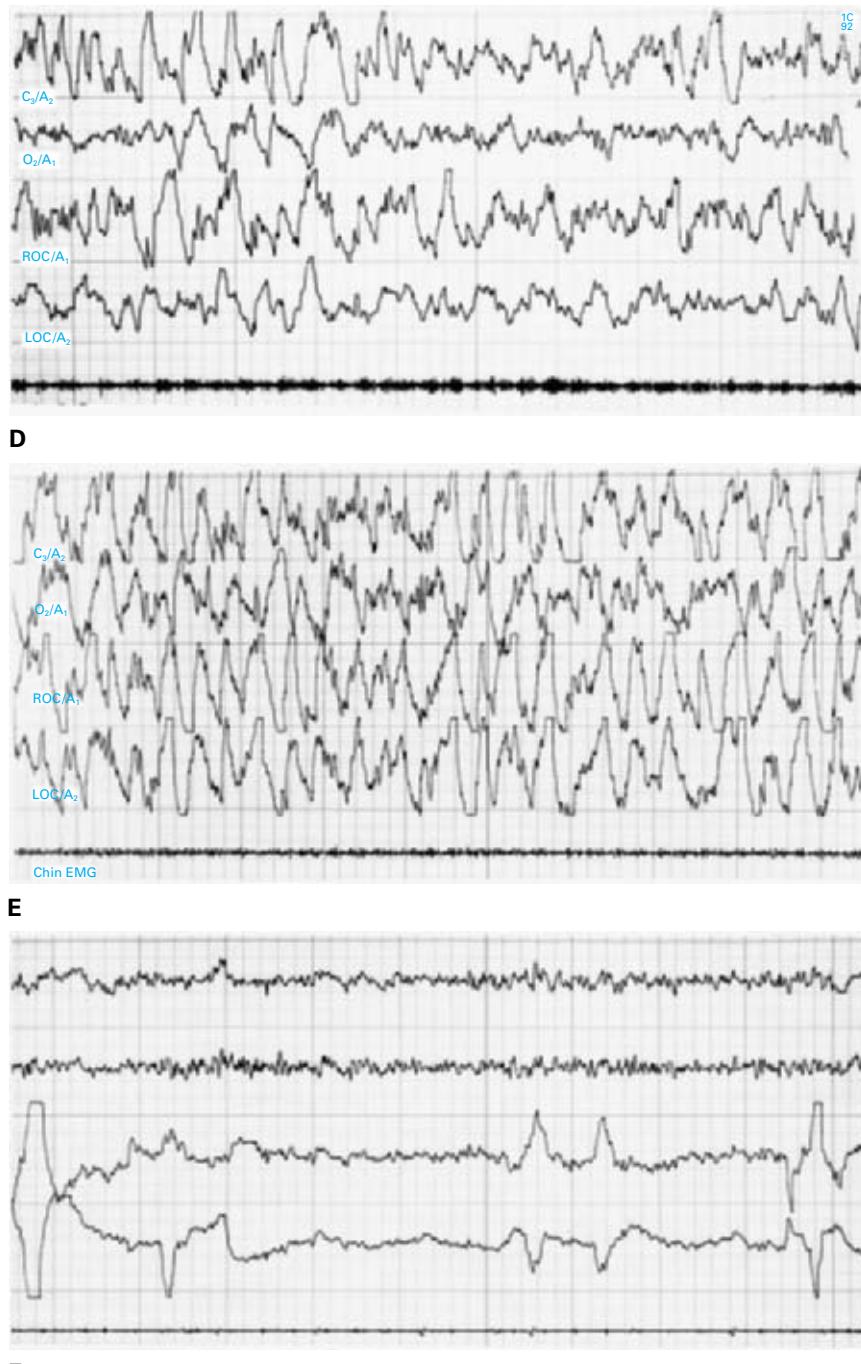

Figure 19-2 (Continued). *D.* Upper tracings: Stage 3 sleep. Appearance of high-voltage slow (delta) waves. *E.* Middle tracings: Stage 4—deepest stage of sleep, with predominant delta wave activity occupying 50 percent of a 30-s tracing. *F.* Lower tracings: REM sleep, characterized by episodes of rapid eye movement and occasional muscle twitches in an otherwise flat chin EMG.

Technical Note: Four sites from the same montage are illustrated in each recording: C₃/A₂, left central to right mastoid; O₂/A₁, right occipital to left mastoid; ROC/A₁, right outer canthus to left mastoid; LOC/A₂, left outer canthus to right mastoid. A chin EMG tracing is added to each recording. (Adapted with permission from Butkov N. Atlas of Clinical Polysomnography. Vol 1. Synapse Media, 1996.)

Urine excretion decreases during sleep, and the absolute quantity of sodium and potassium that is eliminated also decreases; however, urine specific gravity and osmolality increase, presumably because of increased antidiuretic hormone excretion and reab-
