These terms refer to a distinctive cerebral disease in which a rapidly progressive and profound dementia is associated with diffuse myoclonic jerks, and a variety of other neurologic abnormalities, mainly visual or cerebellar. The major neuropathologic changes are in the cerebral and cerebellar cortices; the outstanding features are widespread neuronal loss and gliosis accompanied by a striking vacuolation or spongy state of the affected regions—hence the designation *subacute spongiform encephalopathy* (SSE). Less severe changes in a patchy distribution are found in cases with a briefer clinical course.

These changes, both clinical and pathologic, occur with such uniformity from case to case that they doubtless form a nosologic entity. It is generally referred to as Creutzfeldt-Jakob disease, an inappropriate eponym, since it is most unlikely that the patient described by Creutzfeldt and at least 3 of the 5 patients described by Jakob had the same disease that we now recognize as subacute

spongiform encephalopathy (SSE). It would be desirable to keep them distinct from one another, or at least, whenever one speaks of Creutzfeldt-Jakob disease, to specify what is meant—either SSE or the slower progressive dementia with signs of pyramidal and extrapyramidal affection originally described by Creutzfeldt and Jakob (the latter condition is discussed on page 913). However, decades of use makes the term *Creutzfeldt-Jakob disease* and its acronym, *CJD*, virtually impossible to displace. Precision in definition of these states is of greater importance than before, since it was shown by Gibbs and Gajdusek that brain tissue from patients with SSE, injected into chimpanzees, can transmit the disease after an incubation period of a year or longer.

Epidemiology and Pathogenesis The disease appears in all parts of the world and in all seasons, with an annual incidence of 1 to 2 cases per million of population. The incidence is higher in Israelis of Libyan origin, in immigrants to France from North Africa, and in Slovakia. Although the reported incidence of SSE is somewhat higher in urban than in rural areas, temporospatial clustering of cases has not been observed, at least in the United States. A small proportion of all series of cases is familial—varying from 5 percent reported by Cathala and associates to 15 percent of 1435 cases analyzed by Masters and coworkers. The occurrence of familial cases, not in the same household, suggests a genetic susceptibility to infection, although the possibility of common early exposure to the transmissible agent cannot be dismissed. A small number of conjugal cases have also been reported. The only clearly demonstrated mechanism of spread of SSE is iatrogenic, having occurred in a few cases after transplantation of corneas or dural grafts from infected individuals, after implantation of infected electroencephalographic depth electrodes, and after the injection of human growth hormone or gonadotropins that had been prepared from pooled cadaveric sources of these hormones. At least one neurosurgeon is known to have acquired the disease. Individuals exposed to scrapie-infected sheep and to patients with SSE are not disproportionately affected.

Recently, a great deal of attention has been drawn to an epidemic of prion disease among cows in the British Isles (“mad cow disease”). The epidemic began in 1985, with putative transmission of the disease to some two dozen humans. These patients have been younger (average age of onset, 27 years) than those with typical SSE (65 years) and manifested curious psychiatric and sensory symptoms as the first sign of illness; they did not exhibit the usual EEG findings even as the illness advanced to its later stages (Will et al). This has been called “new variant Creutzfeldt-Jakob disease.” It has recently been shown that the prion strain in these patients is identical to the one from affected cattle. The mode of transmission, presumed to be the ingestion of infected meat, is reminiscent of the propagation of kuru in New Guinea by ceremonial ingestion of brain tissue from infected individuals.

Spongiform encephalopathy has now been fairly firmly associated with the conversion of a normal cellular protein, PrP^c to an abnormal isoform, PrP^{Sc}. The transformation involves a change in the physical conformation of the protein in which its helical proportion diminishes and the proportion of the β pleated sheet increases (see reviews by Prusiner). Current theory holds that the “infectivity” of prions and their propagation in brain tissue may result from the susceptibility of the native prion protein to alter shape as a result of physical exposure to the abnormal protein, a so-called conformational disease. Conformationally altered prions have a tendency to aggregate, and this may be the mode of cellular

destruction that leads to disease. In contrast, familial cases of prion disease are thought to be the result of one of several gene aberrations residing in the region that codes for PrP^c.

Of some interest is the finding by Zanusso and colleagues of the infectious prion protein in the nasal mucosa of all nine patients studied with the sporadic disease. This suggests a route for entry into the nervous system of the aberrant prion and also a potential diagnostic test.

Clinical Features Transmissible SSE is in most cases a disease of late middle age, although it can occur in young adults. The sexes are affected equally. In the large series of pathologically verified cases reported by Brown and coworkers, prodromal symptoms—consisting of fatigue, depression, weight loss, and disorders of sleep and appetite lasting for several weeks—were observed in about one-third of the patients.

The early stages of the disease are characterized by a great variety of clinical manifestations, but the most frequent are changes in behavior, emotional response, and intellectual function, often followed by ataxia and abnormalities of vision, such as distortions of the shape and alignment of objects or actual impairment of visual acuity. Typically, the early phase of the disease is dominated by symptoms of confusion, with hallucinations, delusions, and agitation. In other instances, cerebellar ataxia (Brownell-Oppenheimer variant) or visual disturbances (Heidenhain variant) precede the mental changes and may be the most prominent features for several months. Headache, vertigo, and sensory symptoms are complaints in some patients but become quickly obscured by dementia and muteness.

As a rule, the disease progresses rapidly, so that obvious deterioration is seen from week to week and even day to day. Sooner or later, in almost all cases, myoclonic contractions of various muscle groups appear, perhaps unilaterally at first but later becoming generalized. Or, infrequently, the myoclonus may not appear for weeks or even months after the initial mental changes. The myoclonus is associated with a striking startle response, mainly to a loud noise. In a few patients, a startle response, which is elicitable for a brief period of time, is the only manifestation of myoclonus. In general, the myoclonic jerks are evocable by sudden sensory stimuli of all sorts (noise, bright light, touch), but they occur spontaneously as well. Twitches of individual fingers are typical but it should be emphasized that well-formed seizures are not a component of the illness. These changes gradually give way to a mute state, stupor, and coma, but the myoclonic contractions may continue to the end. Signs of degeneration of the pyramidal tracts or anterior horn cells, palsies of convergence and upgaze, and extra-pyramidal signs occur in a small number of patients as the disease advances.

The clinical diagnosis during life rests mostly on the recognition of one of the clusters of typical clinical features, particularly the unique syndrome of dementia—which progresses much more quickly than that of common degenerative diseases—coupled with stimulus-sensitive myoclonus and the characteristic EEG changes that occur in most patients (see below).

The disease is invariably fatal, usually in less than a year from the onset. In about 10 percent of patients, the illness begins with almost stroke-like suddenness and runs its course rapidly, in a matter of a few weeks. At the other extreme, a small number of patients have reportedly survived for 2 to 10 years, but these cases should be accepted with caution; in some of them, SSE appears to have been superimposed on Alzheimer or Parkinson disease or some other chronic condition that predated the prion illness.

Laboratory Diagnosis The routine CSF and other laboratory tests are normal—useful findings in that they exclude a number of chronic inflammatory causes of dementia. In most patients, the EEG pattern is distinctive, changing over the course of the disease from one of diffuse and nonspecific slowing to one of stereotyped high-voltage slow- (1- to 2-Hz) and sharp-wave complexes on an increasingly slow and low-voltage background (see Fig. 2-3G, page 27). The high-voltage sharp waves, which give the appearance of periodicity (pseudoperiodic), are synchronous with the myoclonus but may persist in its absence. Imaging studies of the brain had been thought until recently to be of little value, but up to 80 percent of cases show a subtle hyperintensity of the lenticular nuclei on T2-weighted images when the disease is fully established (Fig. 33-5). Even more striking in some cases are the changes in diffusion-weighted imaging sequences (DWI). Long segments of the cortex as well as various parts of the basal ganglia show these alterations in a pattern that, in our experience, is characteristic and mistakeable only perhaps for the appearance of diffuse cerebral anoxia (Fig. 33-5B). According to Shiga and colleagues, these changes occur in 90 percent of cases (cortex more often than caudate or lenticular nuclei and sometimes both), making them potentially the most sensitive test for the disease.

There are now helpful confirmatory diagnostic tests but they are often unnecessary. Hsich and colleagues have described a sensitive test of CSF—the finding by immunoassay of a particular peptide fragments of normal brain proteins, termed “14-3-3.” This test is particularly useful in separating SSE from other chronic non-inflammatory dementing diseases, but it has been disappointing on our wards, giving both false-positive and false-negative results. A number of other tests are emerging from specialized laboratories that detect the abnormal PrPSc isoform of the prion protein in the spinal fluid. Prusiner’s laboratory can detect eight prion strains by fluorescence immunoassay. Also, enolase and neopterin concentrations in CSF are elevated in most cases, but the release of these substances may also be found with other types of brain lesions, particularly infarction.

Tonsillar material from patients with new variant Creutzfeldt-Jakob disease (“mad cow disease”) stains with antibodies against abnormal prion protein, but this technique does not appear to be applicable to the early diagnosis of the sporadic disease (Hill). Whether the above mentioned finding of infectious prion material in the nasal mucosa will prove to have practical value in diagnosis is yet to be determined.

The National Prion Disease Pathology Surveillance Center which has been established at Case Western Reserve University is available to assist clinicians by performing, free of charge, a variety of diagnostic tests (<http://www.cjdsurveillance.com>).

Pathology The disease affects principally the cerebral and cerebellar cortices, generally in a diffuse fashion, although in some cases the occipitoparietal regions are almost exclusively involved, as in those described by Heidenhain. In others, such as the cases of Brownell and Oppenheimer, the cerebellum has been most extensively affected, with early and prominent ataxia. The degeneration and disappearance of nerve cells is associated with extensive astroglial proliferation; ultrastructural studies have shown that the microscopic vacuoles, which give the tissue its typically spongy appearance, are located within the cytoplasmic processes of glial cells and dendrites of nerve cells. The loss in particular of certain inhibitory neurons in the thalamic reticular nuclei corresponds to the presence of myoclonus and positive sharp waves in the EEG, according to Tschampa and colleagues. Despite the fact that the disease is due to a transmissible agent, the lesions show no evidence of an inflammatory reaction and no viral particles are seen.

Differential Diagnosis The diagnosis of most cases of SSE presents no difficulty. Not infrequently, however, we have been surprised by a “typical” case that proves to be some other disease. Lithium intoxication, Hashimoto encephalopathy (as emphasized by Seipelt who found a number of cases in an epidemiologic survey of SSE (page 978), Whipple disease (page 603), intravascular lymphoma, carcinomatous meningitis—all of them characterized by myoclonus and dementia—may mimic SSE in the early weeks of illness. Contrariwise, the early mental changes of SSE may be

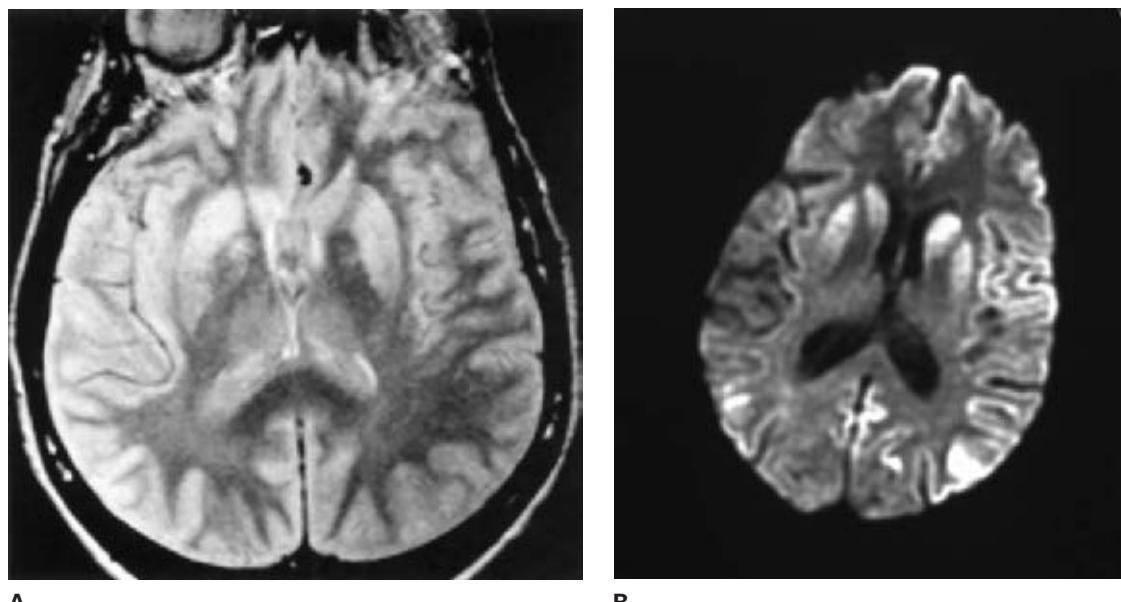

Figure 33-5. A. MRI showing T2 signal changes in the lenticular nuclei in a patient with Creutzfeldt-Jakob disease of 1 month's duration. B. Diffusion-weighted imaging sequence of cortical signal change in an early case.

misinterpreted as an atypical or unusually intense emotional reaction, as one of the major psychoses, as an unusual form of Alzheimer disease with myoclonus, or as Lewy body disease. Despite the designation of SSE as a progressive dementia, the similarities to even rapidly developing Alzheimer disease are superficial. Also, diagnosis may be difficult in patients who present with dizziness, gait disturbance, diplopia, or visual disturbances until the rapidly evolving clinical picture clarifies the issue. Subacute sclerosing panencephalitis (see above), in its fully developed form, may resemble SSE, but the former is chiefly a disease of children or young adults, and the CSF shows elevation of gamma globulin (IgG), whereas the latter is essentially a disease of middle age and the presenile period, and the CSF is normal. Limbic-brainstem-cerebellar encephalitis in patients with an occult tumor and AIDS dementia (discussed earlier) also figure in the differential diagnosis. Cerebral lipidosis in children or young adults can result in a similar combination of myoclonus and dementia, but the clinical course in such cases is extremely chronic and there are retinal changes that do not occur in SSE. Well-formed convulsions should direct attention to a diagnosis other than SSE.

Management No specific treatment is known. Antiviral agents have been ineffective. In view of the transmissibility of the disease from humans to primates and iatrogenically from person to person with infected materials, certain precautions should be taken in the medical care of and handling of materials from patients with SSE. Special isolation rooms are not necessary, and the families of affected patients and nursing staff can be reassured that casual contact poses no risk. Needle punctures and cuts are not thought to pose a risk but some uncertainty remains. The transmissible agent is resistant to boiling, treatment with formalin and alcohol, and ultraviolet radiation but can be inactivated by autoclaving at 132°C at 15 lb/in.² for 1 h or by immersion for 1 h in 5% sodium hypochlorite (household bleach). Workers exposed to infected materials (butchers, abattoir workers, health care workers) should wash thoroughly with ordinary soap. Needles, glassware, needle electrodes, and other instruments should be handled with great care and immersed in appropriate disinfectants and autoclaved or incinerated. The performance of a brain biopsy or autopsy requires that a set of special precautions be followed, as outlined by Brown (see References). Obviously such patients or any others known to have been demented should not be donors of organs for transplantation or blood for transfusion.

Gerstmann-Sträussler-Scheinker Syndrome This is a rare, strongly familial disease inherited as an autosomal dominant trait. It begins insidiously in midlife and runs a chronic course (mean duration, 5 years). The main characteristics are a progressive cerebellar ataxia, corticospinal tract signs, dysarthria, and nystagmus.

Dementia is often associated but is relatively mild. There are characteristic spongiform changes, as in SSE.

Brain tissue from patients with this disease, when inoculated into chimpanzees, has produced a spongiform encephalopathy (Masters et al). Molecular genetic studies of affected members demonstrate a mutation of the prion protein gene. This syndrome should be considered as a small familial subset of SSE, of slowly progressive type.

Fatal Familial Insomnia This is another very rare familial disease; it is characterized by intractable insomnia, sympathetic overactivity, and dementia, leading to death in 7 to 15 months (see also page 340). The pathologic changes, consisting of neuronal loss and gliosis, are found mainly in the medial thalamic nuclei. Studies of a few families have shown a mutation of the prion protein gene, and brain material was found to contain a protease-resistant form of the gene. Transmission of the disease by inoculation of infected brain material has not been accomplished (Medori et al).

Kuru This disease, which occurs exclusively among the Fore linguistic group of natives of the New Guinea highlands, was the first slow infection due to a nonconventional transmissible agent to be documented in human beings. Clinically the disease takes the form of an afebrile, progressive cerebellar ataxia, with abnormalities of extraocular movements, weakness progressing to immobility, incontinence in the late stages, and death within 3 to 6 months of onset. In some ways it is similar to the ataxic (Brownell-Oppenheimer) variant of Creutzfeldt-Jakob disease. The remarkable epidemiologic and pathologic similarities between kuru and scrapie were pointed out by Hadlow (1959), who suggested that it might be possible to transmit kuru to subhuman primates. This was accomplished in 1966 by Gajdusek and coworkers; inoculation of chimpanzees with brain material from affected humans produced a kuru-like syndrome in chimpanzees after a latency of 18 to 36 months. Since then the disease has been transmitted from one chimpanzee to another and to other primates by using both neural and nonneural tissues. The pioneering work in this field led to the awarding of a Nobel Prize. Histologically there is a noninflammatory loss of neurons and spongiform change throughout the brain, but predominantly in the cerebellar cortex, with astroglial proliferation and PAS-positive stellate plaques of amyloid-like material ("kuru plaques"). The transmissible agent has not been visualized, however.

Kuru has gradually disappeared, apparently because of the cessation of ritual cannibalism by which the disease had been transmitted. In this ritual, infected brain tissue was ingested and rubbed over the body of the victim's kin (women and young children of either sex), permitting absorption of the infective agent through conjunctivae, mucous membranes, and abrasions in the skin.

CHAPTER 34

CEREBROVASCULAR DISEASES

Among all the neurologic diseases of adult life, the cerebrovascular ones clearly rank first in frequency and importance. At least 50 percent of the neurologic disorders in a general hospital are of this type. At some time or other, every physician will be required to examine patients with cerebrovascular disease and should at least know something of the common types—particularly those in which there is a reasonable prospect of successful medical or surgical intervention or the prevention of recurrence. There is another advantage to be gained from the study of this group of diseases—namely, that they have traditionally provided one of the most instructive approaches to neurology. As our colleague C. M. Fisher has aptly remarked, house officers and students learn neurology literally “stroke by stroke.” Moreover, the focal ischemic lesion has divulged some of our most important ideas about the function of the human brain.

It must also be noted that, in the last two decades, new and extraordinary types of imaging technology have been introduced that allow the physician to make physiologic distinctions between normal, ischemic, and infarcted brain tissue. This biopathologic approach to stroke will likely guide the next generation of treatments and has already had a pronounced impact on the direction of research in the field. Salvageable brain tissue to be protected in the acute phase of stroke can be delineated by these methods. To identify this ischemic but not yet infarcted tissue virtually defines the goal of modern stroke treatment. Which of the sophisticated imaging techniques will contribute to improved clinical outcome is still to be determined, but certain ones, such as diffusion-weighted imaging, have already proved invaluable in stroke work.

Despite these valuable advances in stroke neurology, three points should be made. First, all physicians have a role to play in the prevention of stroke by encouraging the reduction in risk factors such as hypertension and the identification of signs of potential stroke, such as transient ischemic attacks, atrial fibrillation, and carotid artery stenosis. Second, careful bedside clinical evaluation integrated with the newer testing methods mentioned above still provide the most promising approach to this category of disease. Finally, the last decade or two have witnessed a departure from the methodical clinicopathologic studies that have been the foundation of our understanding of cerebrovascular disease. Increasingly, randomized studies involving several hundred and even thousands of patients and conducted simultaneously in dozens of institutions have come to dominate investigative activity in this field. These multicenter trials have yielded highly valuable information about the natural history of a variety of cerebrovascular disorders, both symptomatic and asymptomatic. However, this approach suffers from a number of inherent weaknesses, the most important of which is that the homogenized data derived from an aggregate of patients may not be applicable to a specific case at hand. Moreover, many large studies show only marginal differences between treated and control groups. Each of these multicenter studies will therefore be critically appraised at appropriate points in the ensuing discussion.

Incidence of Cerebrovascular Diseases

Stroke, after heart disease and cancer, is the third most common cause of death in the United States. Every year there are in this

country approximately 700,000 cases of stroke—roughly 600,000 ischemic lesions and 100,000 hemorrhages, intracerebral or subarachnoid—with 175,000 fatalities from these causes. Since 1950, coincident with the introduction of effective treatment for hypertension, there has been a substantial reduction in the frequency of stroke. This was most apparent three decades ago, as treatment for high blood pressure became a public health focus. Among the residents of Rochester, Minnesota, Broderick and colleagues documented a reduction of 46 percent in cerebral infarction and hemorrhage when the period 1975–1979 was compared with 1950–1954; Nicholls and Johansen reported a 20 percent decline in the United States between 1968 and 1976. Both sexes shared in the reduced incidence. During this period, the incidence of coronary artery disease and malignant hypertension also fell significantly. By contrast, there has been no change in the frequency of aneurysmal rupture. Interestingly, despite the continued improvement in the treatment of hypertension, the incidence rate of stroke for the period 1980–1984 was 17 percent higher than that for 1975–1979, a feature attributed by Broderick and coworkers to the widespread use of computed tomography (CT), which increased the detection of less severe strokes. In the last decade, according to the American Heart Association, the mortality rate from stroke has declined by 12 percent, but the total number of strokes may again be rising.

Definition of Terms

As discussed below, the term *stroke* is applied to a sudden focal neurologic syndrome, specifically the type due to cerebrovascular disease. The term *cerebrovascular disease* designates any abnormality of the brain resulting from a pathologic process of the blood vessels. *Pathologic process* is given an inclusive meaning—namely, occlusion of the lumen by embolus or thrombus, rupture of a vessel, an altered permeability of the vessel wall, or increased viscosity or other change in the quality of the blood flowing through the cerebral vessels. The vascular pathologic process may be considered not only in its grosser aspects—embolism, thrombosis, dissection, or rupture of a vessel—but also in terms of the more basic or primary disorder, i.e., atherosclerosis, hypertensive arteriosclerotic change, arteritis, aneurysmal dilation, and developmental malformation. Equal importance attaches to the secondary parenchymal changes in the brain resulting from the vascular lesion. These are of two main types—ischemia, with or without infarction, and hemorrhage—and unless one or the other occurs, the vascular lesion usually remains silent. The only exceptions to this statement are the local pressure effects of an aneurysm, vascular headache (migraine, hypertension, temporal arteritis), multiple small vessel disease with progressive encephalopathy (as in malignant hypertension or cerebral arteritis), and increased intracranial pressure (as occurs in hypertensive encephalopathy and venous sinus thrombosis). Also, persistent acute hypotension may cause ischemic necrosis in regions of brain between the vascular territories of cortical vessels, even without vascular occlusion. The many types of cerebrovascular diseases are listed in Table 34-1, and the predominant types during each period of life, in Table 34-2.

Table 34-1

Causes of cerebral abnormalities from alterations of arteries and veins

1. Atherosclerotic thrombosis
2. Transient ischemic attacks
3. Embolism
4. Hypertensive hemorrhage
5. Ruptured or unruptured saccular aneurysm or AVM
6. Arteritis
 - a. Meningovascular syphilis, arteritis secondary to pyogenic and tuberculous meningitis, rare infective types (typhus, schistosomiasis, malaria, mucormycosis, etc.)
 - b. Connective tissue diseases (polyarteritis nodosa, lupus erythematosus), necrotizing arteritis. Wegener arteritis, temporal arteritis, Takayasu disease, granulomatous or giant-cell arteritis of the aorta, and giant-cell granulomatous angiitis of cerebral arteries
7. Cerebral thrombophlebitis: secondary to infection of ear, paranasal sinus, face, etc.; with meningitis and subdural empyema; debilitating states, postpartum, postoperative, cardiac failure, hematologic disease (polycythemia, sickle cell disease), and of undetermined cause
8. Hematologic disorders: anticoagulants and thrombolytics, clotting factor disorders, polycythemia, sickle cell disease, thrombotic thrombocytopenic purpura, thrombocytosis, intravascular lymphoma, etc.
9. Trauma and dissection of carotid and basilar arteries
10. Amyloid angiopathy
11. Dissecting aortic aneurysm
12. Complications of arteriography
13. Neurologic migraine with persistent deficit
14. With tentorial, foramen magnum, and subfalcial herniations
15. Miscellaneous types: fibromuscular dysplasia, with local dissection of carotid, middle cerebral, or vertebrobasilar artery, x-irradiation, unexplained middle cerebral infarction in closed head injury, pressure of unruptured saccular aneurysm, complication of oral contraceptives
16. Undetermined cause in children and young adults: moyamoya disease and others

More than any other organ, the brain depends from moment to moment on an adequate supply of oxygenated blood. Constancy of the cerebral circulation is assured by a series of baroreceptors and vasomotor reflexes under the control of centers in the lower brainstem. In Stokes-Adams attacks, for example, unconsciousness occurs within 10 s of the beginning of asystole. In animal experiments and probably in humans, the complete stoppage of blood flow for longer than 5 min produces irreversible damage. Brain tissue deprived of blood undergoes *ischemic necrosis* or *infarction* (also referred to as a zone of *softening* or *encephalomalacia*). Obstruction of an artery by thrombus or embolus is the usual cause of focal ischemic damage, but failure of the circulation and hypotension from cardiac decompensation or shock, if severe and prolonged enough, can produce focal as well as diffuse ischemic changes.

Cerebral infarcts vary greatly in the amount of congestion and hemorrhage found within the softened tissue. Some infarcts are devoid of blood and therefore pallid (*pale infarction*); others show mild congestion (dilatation of blood vessels and escape of red blood cells), especially at their margins; still others show an extensive

Table 34-2

Cerebrovascular diseases characteristic of each age period

1. Prenatal circulatory diseases leading to
 - a. Porencephaly
 - b. Hydranencephaly
 - c. Hypoxic-ischemic damage
 - d. Unilateral cerebral infarction
2. Perinatal and postnatal circulatory disorders resulting in
 - a. Cardiorespiratory failure and generalized ischemia—*état marbre*
 - b. Periventricular infarcts
 - c. Matrix hemorrhages and ischemic foci in premature infants
 - d. Hemorrhagic disease of the newborn
3. Infancy and childhood: vascular diseases associated with
 - a. Ischemic infarction
 - b. Congenital heart disease and paradoxical embolism
 - c. Moyamoya
 - d. Bacterial endocarditis, rheumatic fever, lupus erythematosus
 - e. Sickle cell anemia
 - f. Mitochondrial disorders (MELAS^a)
 - g. Homocystinuria and Fabry's angiokeratosis
4. Adolescence and early adult life: vascular occlusion or hemorrhage with
 - a. Pregnancy and puerperium
 - b. Estrogen-related stroke
 - c. Migraine
 - d. Vascular malformations
 - e. Premature atherosclerosis
 - f. Arteritis
 - g. Valvular heart disease
 - h. Sickle cell anemia
 - i. Antiphospholipid arteriopathy, plasma C-protein deficiency and other coagulopathies
 - j. Moyamoya, Takayasu disease
 - k. Arterial dissections
 - l. Amyloid angiopathy
5. Middle age
 - a. Atherosclerotic thrombosis and embolism
 - b. Cardiogenic embolism
 - c. Primary (hypertensive) cerebral hemorrhage
 - d. Ruptured saccular aneurysm
 - e. Dissecting aneurysm
 - f. Fibromuscular dysplasia
6. Late adult life
 - a. Atherosclerotic thrombotic occlusive disease
 - b. Embolic occlusive disease
 - c. Lacunar state
 - d. Brain hemorrhage (multiple causes)
 - e. Multi-infarct dementia
 - f. Binswanger disease

^a Mitochondrial encephalomyopathy, lactic acidosis, and stroke.

SOURCE: Reproduced by permission from Salam-Adams and Adams.

extravasation of blood from many small vessels all through the infarcted tissue (red or *hemorrhagic infarction*). Some infarcts are all of one type, either pale or hemorrhagic; many are mixed. The reason for the occurrence of hemorrhagic infarction—almost always, occurring in cases of cerebral embolism—is not fully un-

derstood. The explanation most consistent with our observations is that embolic material, after occluding an artery and causing ischemic necrosis of brain tissue, then fragments and migrates distally from its original site. This allows partial restoration of the circulation to the infarcted zone, and blood seeps through the damaged small vessels (Fisher and Adams). In such cases, one often cannot find the embolus by arteriography or postmortem examination, or one finds only a few fragments proximal to the pale ischemic zones.

Cerebral hemorrhage is one of two types. In the intracerebral variety, blood leaks from the vessel (usually a small artery) directly into the brain, forming a hematoma in the brain substance and sometimes spreading into the ventricles and then to the subarachnoid space. Once the leakage is arrested, the blood slowly disintegrates and is absorbed over a period of weeks and months. The mass of clotted blood causes physical disruption of the tissue and pressure on the surrounding brain. The second type of bleeding originates from an aneurysmal dilation at branching points of the large arteries of the circle of Willis; the bleeding is almost exclusively contained within the subarachnoid spaces and therefore, causes little immediate focal effect on the brain. In this way, subarachnoid hemorrhage differs from other stroke syndromes. However, blood within the subarachnoid space, if large in quantity, may cause a delayed cerebral ischemia through a mechanism of constriction of the vessels of the circle of Willis and their primary branches (vasospasm). In addition to these two main types of hemorrhage, a bland infarction in many instances has areas of leakage of blood into the brain, so-called hemorrhagic infarction.

THE STROKE SYNDROME

So distinctive is the clinical presentation of cerebrovascular disease that the diagnosis is seldom in doubt. The common mode of expression is the *stroke*, defined as the sudden occurrence of a non-convulsive, focal neurologic deficit. In its most severe form the patient becomes hemiplegic or even comatose—an event so dramatic that it had been given its own designations, namely *apoplexy*, *cerebrovascular accident (CVA)*, or shock (colloquial). However, *stroke* is the currently preferred term. In its mildest form it may consist of a trivial neurologic disorder insufficient for the patient even to seek medical attention. There are all gradations of severity between these two extremes, but in all forms of stroke the denotative feature is the *temporal profile* of neurologic events. It is the abruptness with which the neurologic deficit develops—a matter of seconds or minutes—that stamps the disorder as vascular. Embolic strokes characteristically occur suddenly, and the deficit reaches its peak almost at once. Thrombotic strokes may have a similarly abrupt onset, but they evolve somewhat more slowly over a period of several minutes or hours and occasionally days; in the latter case, the stroke usually progresses in a saltatory fashion, i.e., in a series of steps rather than smoothly. In hypertensive cerebral hemorrhage, also abrupt in onset, the deficit may be virtually static or steadily progressive over a period of minutes or hours, while subarachnoid hemorrhage is almost instantaneous.

The other important aspect of the temporal profile is the arrest and then regression of the neurologic deficit in almost all except the fatal strokes. At one extreme of rapid regression is a focal syndrome that reverses itself entirely and dramatically over a period of minutes or up to an hour; this defines the “transient ischemic attack” (TIA). Not infrequently, an extensive deficit from embolism reverses itself within a few hours or days. More often, and this is the case in most thrombotic strokes, improvement occurs gradually

over weeks and months, and the residual disability is considerable. A gradual downhill course over a period of several days or weeks will usually be traced to a nonvascular disease. The only exceptions are the additive effects of multiple vascular occlusions (platelet thrombosis, lupus erythematosus, and other arteritides; see Table 34-1) and the progressive brain edema surrounding large infarctions and cerebral hemorrhages.

The neurologic deficit reflects both the location and the size of the infarct or hemorrhage. Hemiplegia stands as the classic sign of all cerebrovascular diseases, whether in the cerebral hemisphere or brainstem, but there are many other manifestations, occurring in large but highly recognizable combinations. These include mental confusion, numbness and sensory deficits of many types, aphasia, visual field defects, diplopia, dizziness, dysarthria, and so forth. The neurovascular syndromes that they form enable the physician to localize the lesion—sometimes so precisely that even the affected arterial branch can be specified—and to indicate whether the lesion is an infarct or a hemorrhage. These neurovascular syndromes are described in the section that follows.

It would be incorrect to assume that every cerebrovascular illness expresses itself as a clearly delineated stroke. Some lesions are clinically silent or cause disorders of function so mild as to concern the patient little if at all. Neither the patient nor the family can then date the onset of the illness. Other small incidents may become sources of complaint only when their cumulative effects become manifest. Sometimes, stenosis of the common or internal carotid results in a chronic marginally low blood flow, which, by fluctuating during physical activity, may diminish vision or induce a defect in sensory or motor function or an abnormality of movement. Another problem is that certain dominant hemispheric lesions cause aphasic disturbances, which hamper history taking, and nondominant ones cause anosognosia, in which the patient is unaware of his deficits or denies them—hence his descriptions are close to useless.

Imaging techniques, as already alluded to, continue to enhance the clinical study of stroke patients; they allow the demonstration of both the cerebral lesion and the affected blood vessel. CT scanning demonstrates and accurately localizes even small hemorrhages, hemorrhagic infarcts, subarachnoid blood, clots in and around aneurysms, regions of infarct necrosis and arteriovenous malformations. Magnetic resonance imaging (MRI) also demonstrates these lesions and, in addition, reveals flow voids in vessels, hemosiderin and iron pigment, and the alterations resulting from ischemic necrosis and gliosis. Of the two procedures, MRI is particularly advantageous in demonstrating small lacunar lesions deep in the hemispheres and abnormalities in the brainstem (a region obscured by adjacent bone in CT scans). One of the diagnostic advances in the last decade has been the introduction of the diffusion-weighted technique, which allows the early detection of an infarctive lesion within minutes of the stroke, i.e., considerably earlier than CT and MRI scan (Fig. 34-1). The various MRI imaging sequences used in the diagnosis and dating of stroke are discussed below and in Chap. 2.

Other ancillary procedures for the investigation of cerebrovascular disease include Doppler ultrasound flow studies, which demonstrate atherosomatous plaques and stenoses of large vessels, particularly of the carotid but also the vertebrobasilar arteries. The transcranial Doppler technique has reached a degree of precision whereby occlusion or spasm of the main vessels of the circle of Willis can be seen. Arteriography, now enhanced by digital processing of images, most accurately demonstrates stenoses and oc-

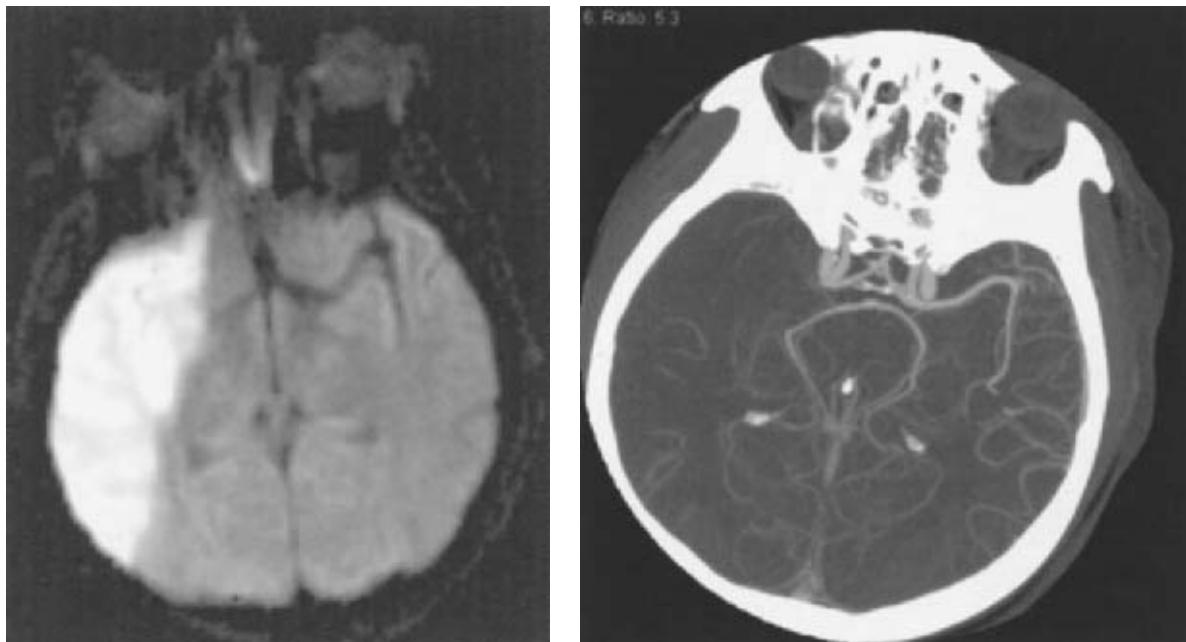

Figure 34-1. Diffusion-weighted image (DWI) showing a large right middle cerebral artery infarction (*left*) and the corresponding magentic resonance angiogram (*right*) demonstrating that the vessel is occluded at its proximal portion. The DWI bright signal changes are evident well before alterations are seen in the CT or MRI.

clusions of the larger vessels as well as aneurysms, vascular malformations, and other blood vessel diseases such as arteritis. To a large degree, conventional dye-injection angiography has been supplanted by magnetic resonance angiography (MRA; Fig. 34-1) and venography (MRV) for the visualization of large intracranial arteries and veins; these have the advantage of safety but do not yet give refined images of the smaller vessels and are not as accurate as angiography in measuring the severity of stenosis of a vessel. New CT techniques called *spiral CT angiography* now offer images of better resolution, comparable to conventional arteriograms. They have the additional advantage of demonstrating soft tissues and bone adjacent to these vessels, thus providing the surgeon with important anatomic information (see Chap. 2). Lumbar puncture indicates whether blood has entered the subarachnoid space (from aneurysm, vascular malformation, hypertensive hemorrhage, and some instances of hemorrhagic infarction). The cerebrospinal fluid (CSF) is clear in cases of “pale” infarction from thrombosis and embolism. In most stroke cases, the CT scan or MRI, neither of which entails any risk to the patient, precludes the need for lumbar puncture and conventional angiography.

The electroencephalogram (EEG) has lost favor in stroke diagnosis but is probably underutilized as a readily available means of detecting cortical infarction in the wake of ischemia of a region of one hemisphere. It allows a distinction to be made between occlusion of a small and a large vessel, because focal EEG abnormalities are sparse or absent with a deep lacunar stroke. The EEG is most useful soon after the stroke, when the only available alternative is the CT scan, which often does not visualize the infarct until several days have passed.

Risk Factors for Stroke

Several factors are known to increase the liability to stroke, and it has been here that large-scale public health measures have had a

substantial influence. The most important of these are hypertension, heart disease, atrial fibrillation, diabetes mellitus, cigarette smoking, and hyperlipidemia. Others, such as systemic diseases associated with a hypercoagulable state and the use of birth control pills, also contribute, but only in special circumstances. Hypertension is the most readily recognized factor in the genesis of primary intracerebral hemorrhage. It appears that the stroke-producing potential of hypertension is as much the product of heightened systolic pressure as of diastolic pressure (Fisher; Rabkin et al). The cooperative studies of the Veterans Administration (see Freis et al) and the report by Collins and associates (collating 14 randomized trials of antihypertensive drugs) have convincingly demonstrated that the long-term control of hypertension decreases the incidence of both atherothrombotic infarction and intracerebral hemorrhage. And simple measures such as the use of hydrochlorthiazide for blood pressure control may be overall the most effective. The presence of congestive heart failure and coronary atherosclerosis also greatly increases the probability of stroke. As for embolic strokes, the most important risk factors are structural cardiac disease and arrhythmias, particularly atrial fibrillation, which increases the incidence of stroke about six-fold, and by eighteen-fold if there is also rheumatic valvular disease. Bacterial and nonbacterial (marantic) endocarditis and right-to-left shunts between the cardiac chambers or in the lung also predispose to embolic stroke. Diabetes hastens the atherosclerotic process in both large and small arteries; Weinberger and colleagues and Roehmholdt and coworkers have found diabetic patients to be twice as liable to stroke as age-matched nondiabetic groups. Also, Homer and Ingall and their colleagues have documented the importance of long-duration cigarette smoking in the development of carotid atherosclerosis. The interactions between diabetes and hypertension on the one hand and intracerebral hemorrhage and atherothrombotic infarction on the other—as well as the association of cardiac disease and cerebral embolism—are considered further on in this chapter, in relation to

each of these categories of cerebrovascular disease. Subsidiary factors, such as low potassium intake and reduced serum levels of potassium, have been associated with an increased stroke rate in several studies, including one that we conducted, but the mechanism of this effect is obscure (Green et al); a detrimental effect on blood pressure is possible. Numerous clinical trials have also shown a marked reduction in stroke incidence with the use of cholesterol-lowering drugs. Public health measures designed to detect and reduce the aforementioned risk factors offer the most intelligent long-range approach to the prevention of cerebrovascular disease.

Ischemic Stroke

Focal cerebral ischemia differs fundamentally from global ischemia. In the latter state, if absolute, there is no cerebral blood flow of the entire brain and irreversible destruction of neurons occurs within 4 to 8 min at normal body temperature. In focal ischemia, there is nearly always some degree of circulation (via collateral vessels), permitting to a varying extent the delivery of oxygenated blood and glucose.

The effects of a focal arterial occlusion on brain tissue also vary depending on the location of the occlusion in relation to available collateral and anastomotic channels. If the obstruction lies proximal to the circle of Willis (toward the heart), the anterior and posterior communicating arteries of the circle are often adequate to prevent infarction. In occlusion of the internal carotid artery in the neck, there may be anastomotic flow from the external carotid artery through the ophthalmic artery or via other smaller external-internal connections (Fig. 34-2). With blockage of the vertebral artery, the anastomotic flow may be via the deep cervical, thyrocervical, or occipital arteries or retrograde from the other vertebral artery. If the occlusion is in the stem portion of one of the cerebral arteries, i.e., distal to the circle of Willis, a series of meningeal interarterial anastomoses may carry sufficient blood into the compromised territory to lessen (rarely to prevent) ischemic damage (see Figs. 34-2 and 34-3). There is also a capillary anastomotic system between adjacent arterial branches, and although it may reduce the size of the ischemic field, particularly of the penetrating arteries, it is usually not significant in preventing infarction. Thus, in the event of occlusion of a major arterial trunk, the extent of infarction ranges from none at all to the entire vascular territory of that vessel. Between these two extremes are all degrees of variation in the extent of infarction and its degree of completeness.

Additional *ischemia-modifying factors* determine the extent of necrosis. The speed of occlusion assumes importance; gradual narrowing of a vessel allows time for collateral channels to open. The level of blood pressure may influence the result; hypotension at a critical moment may render anastomotic channels ineffective. Hypoxia and hypercapnia are presumed to have deleterious effects. Altered viscosity and osmolality of the blood and hyperglycemia are potentially important factors but difficult to evaluate. Finally, anomalies of vascular arrangement (of neck vessels, circle of Willis, and surface arteries) and the existence of previous vascular occlusions must influence the outcome.

The specific neurologic deficit obviously relates to the location and size of the infarct or focus of ischemia. The territory of any artery, large or small, deep or superficial, may be involved. When an infarct lies in the territory of a carotid artery, as would be expected, unilateral signs predominate: hemiplegia, hemianesthesia, hemianopia, aphasia, and agnosias are the usual consequences. In the territory of the basilar artery, the signs of infarction

are frequently bilateral and occur in conjunction with cranial nerve palsies and other segmental brainstem and cerebellar signs; quadriplegia, hemiparesis, and/or unilateral or bilateral sensory impairment are typical, coupled with diplopia, dysarthria, and vertigo in various combinations.

Pathophysiology of Cerebral Ischemia and Ischemic Infarction

Cerebral infarction basically comprises two pathophysiologic processes—one, a loss in the supply of oxygen and glucose secondary to vascular occlusion, and the other, an array of changes in cellular metabolism consequent to the collapse of energy-producing processes, ultimately with disintegration of cell membranes. Of potential therapeutic importance are the observations that some of the cellular processes leading to neuronal death are not irrevocable and may be reversed by early intervention, either through restoration of blood flow, by prevention of the influx of calcium into cells, or by interdicting intermediary processes involved in cell death.

Vascular Factors At the center of an ischemic stroke is a zone of infarction. The necrotic tissue swells rapidly, mainly because of excessive intracellular and intercellular water content. Since anoxia also causes necrosis and swelling of cerebral tissue (although in a different distribution), oxygen lack must be a factor common to both infarction and anoxic encephalopathy. The effects of ischemia, whether functional and reversible or structural and irreversible, depend on its degree and duration. The margins of the infarct are hyperemic, being nourished by meningeal collaterals, and here there is only minimal or no parenchymal damage.

If the brain is observed at the time of arterial occlusion, the venous blood is first seen to darken, owing to an increase in reduced hemoglobin. The viscosity of the blood and resistance to flow both increase, and there is sludging of formed elements within vessels. The tissue becomes pale. Arteries and arterioles become narrowed, especially in the pale areas. Upon re-establishing flow in the occluded artery, the sequence is reversed and there may be a slight hyperemia. If the ischemia is prolonged, sludging and endothelial damage prevent normal reflow (the “no-reflow” phenomenon described below).

These flow factors have been studied in experimental animals by Heiss and by Siesjo and others and are reviewed in detail by Hossman. These investigators have determined the critical threshold of cerebral blood flow (CBF), measured by xenon clearance, below which functional impairment occurs. In several animal species, including macaque monkeys and gerbils, the critical level was 23 mL/100 g/min (normal is 55 mL); if, after short periods of time, CBF is restored to higher levels the impairment of function can be reversed. Reduction of CBF below 10 to 12 mL/100 g/min causes infarction, almost regardless of its duration. The critical level of hypoperfusion that abolishes function and leads to tissue damage is therefore a CBF between 12 and 23 mL/100 g/min. At these levels of blood flow the EEG is slowed, and below this level it becomes isoelectric. In the region of marginal perfusion (“ischemic penumbra”), the K level increases (efflux from injured depolarized cells) and ATP and creatine phosphate are depleted. These biochemical abnormalities are reversible if the circulation is restored to normal. Disturbance of calcium ion homeostasis and accumulation of free fatty acids interfere with full recovery. A CBF of 6 to 8 mL/100 g/min causes marked ATP depletion, increase in extracellular K, increase in intracellular Ca, and cellular acidosis,

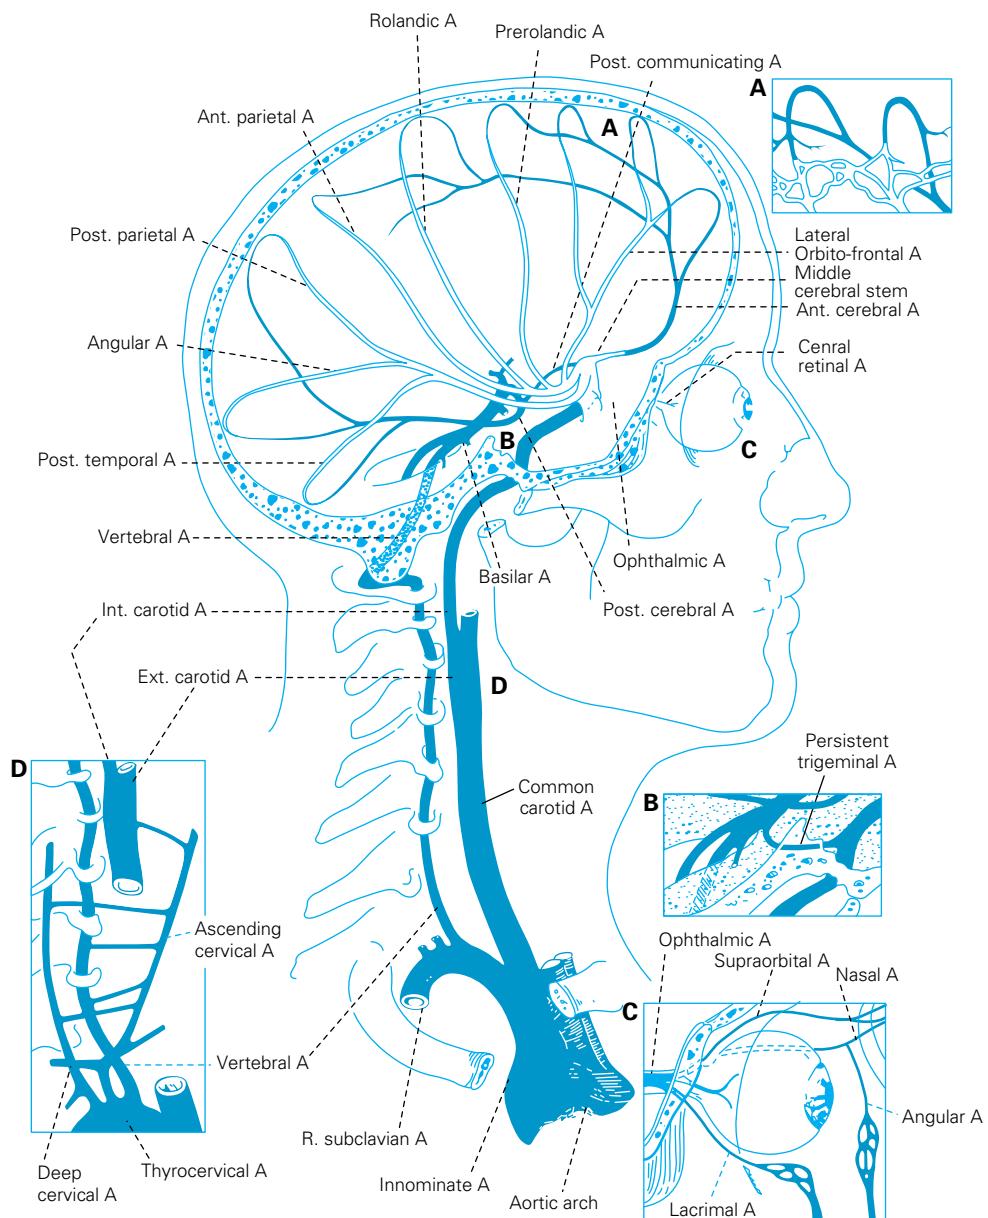

Figure 34-2. Arrangement of the major arteries on the right side carrying blood from the heart to the brain. Also shown are collateral vessels that may modify the effects of cerebral ischemia. For example, the posterior communicating artery connects the internal carotid and the posterior cerebral arteries and may provide anastomosis between the carotid and basilar systems. Over the convexity, the subarachnoid interarterial anastomoses linking the middle, anterior, and posterior cerebral arteries are shown, with insert A illustrating that these anastomoses are a continuous network of tiny arteries forming a border zone between the major cerebral arterial territories. Occasionally a persistent trigeminal artery connects the internal carotid and basilar arteries proximal to the circle of Willis, as shown in insert B. Anastomoses between the internal and external carotid arteries via the orbit are illustrated in insert C. Wholly extracranial anastomoses from muscular branches of the cervical arteries to vertebral and external carotid arteries are indicated in insert D.

leading invariably to histologic signs of necrosis. These changes do not become apparent for several hours. Free fatty acids (appearing as phospholipases) are activated and destroy the phospholipids of neuronal membranes. Prostaglandins, leukotrienes, and free radicals accumulate, and intracellular proteins and enzymes are denatured. Cells then swell, a process called *cellular*, or *cystotoxic, edema* (see page 550). Similar abnormalities affect mitochondria, even before other cellular changes are evident.

Implicit in all discussions of ischemic stroke and its treatment is the existence of a “penumbra” zone that is marginally perfused and contains viable neurons. Presumably this zone exists at the margins of an infarction, which at its core has irrevocably damaged tissue that is destined to become necrotic. Using various methods, such a penumbra can be demonstrated in association with some infarctions but not all, and the degree of reversible tissue damage is difficult to determine. The neurons in the penumbra are consid-

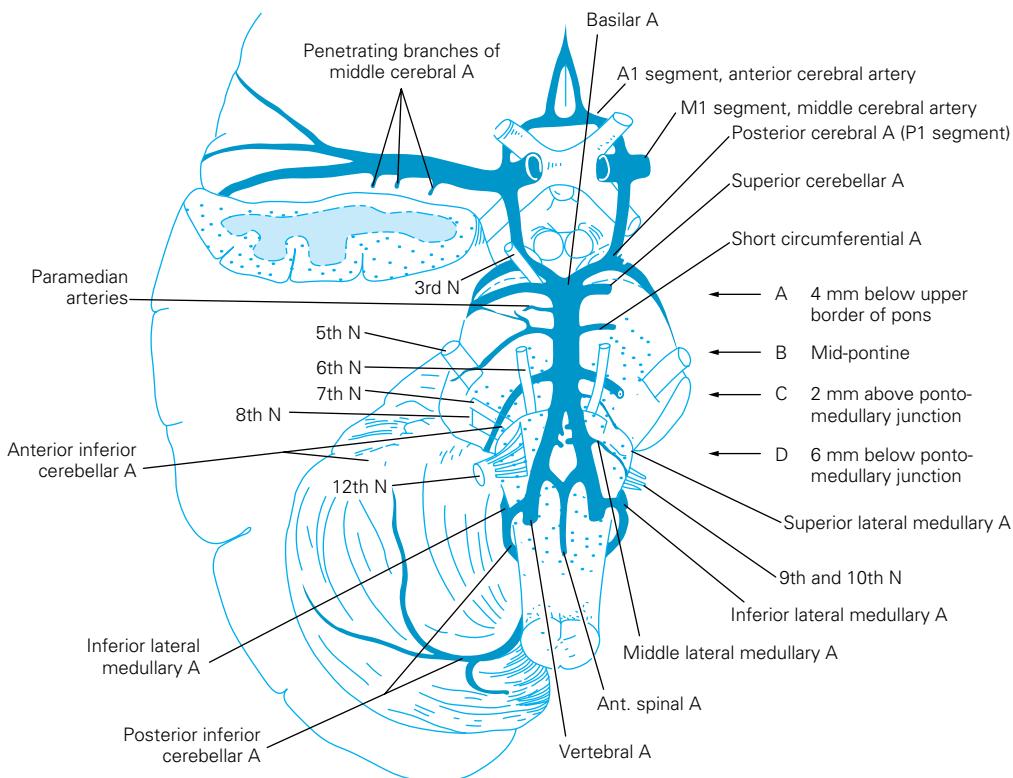

Figure 34-3. Diagram of the brainstem showing the principal vessels of the vertebrobasilar system (the circle of Willis and its main branches). The term M1 is used to refer to the initial (stem) segment of the middle cerebral artery; A1 to the initial segment of the anterior cerebral artery proximal to the anterior communicating artery; A2 to the post-communal segment of the anterior cerebral artery; and P1 and P2 to the corresponding pre- and postcommunal segments of the posterior cerebral artery.

The letters and arrows on the right indicate the levels of the four cross sections following: A = Fig. 34-16; B = Fig. 34-15; C = Fig. 34-14; D = Fig. 34-13.

Although vascular syndromes of the pons and medulla have been designated by sharply outlined shaded areas, one must appreciate that since satisfactory clinicopathologic studies are scarce, the diagrams do not always represent established fact. The frequency with which infarcts fail to produce a well-recognized syndrome and the special tendency for syndromes to merge with one another must be emphasized.

ered to be “stunned” by moderate ischemia and subject to salvage if blood flow is restored in a certain period of time. As with all infarction, the duration of ischemia plays a role. Olsen and colleagues have been able to demonstrate hypoperfused penumbral zones but, interestingly, found that regions just adjacent to them are hyperperfused. Furthermore, these investigators and others have shown that elevating the systemic blood pressure or improving the rheologic flow properties of blood in small vessels by hemodilution improves flow in the penumbra; however, attempts to use these techniques in clinical work have met with mixed success.

The phenomenon of cerebrovascular *autoregulation* is appropriately introduced here. Over a range of mean blood pressures of approximately 50 to 150 mm Hg, the small pial vessels are able to dilate and to constrict in order to maintain CBF in a relatively narrow range. This accommodation eventually fails at the extremes of blood pressure, after which CBF follows systemic pressure passively, either falling precipitously or rising to levels that damage small vessel walls. The conditions in which the limits of autoregulation are exceeded are at the extremes of hypertensive encephalopathy at one end and circulatory failure at the other, both of which are discussed in later sections of the chapter.

Metabolic Factors Interest has focused on the role of excitatory neurotransmitters, particularly glutamate and aspartate, which are formed from glycolytic intermediates of the Krebs cycle. It has been found that these neurotransmitters, released by ischemic cells, excite neurons and produce an intracellular influx of Na and Ca. These changes are said to be responsible for irreversible cell injury. This is presently a subject of active biochemical and clinical research. Some current attempts at therapy, for example, are directed at limiting the extent of infarction by blocking the glutamate receptor, particularly the NMDA (*N*-methyl-D-aspartate) channel—one of several calcium channels that open under conditions of ischemia and set in motion a cascade of cellular events, eventuating in neuronal death. However, even complete blockade of the NMDA channels has so far not prevented cellular death, presumably because dysfunction of several other types of calcium channels continues. Novel strategies have been suggested to prevent calcium influx, but the drugs that block the various calcium channels seem to work only if given before the stroke, making this approach impractical in most situations. Additional biochemical events must be induced by ischemia, including the production of free radicals, which leads to peroxidation and disruption of the outer cell membrane. Clearly, the cascade of intracellular events that lead to neu-

ronal death is likely to be more complex than is currently envisioned.

However, the extent of neural tissue dysfunction is not dictated solely by the activation of these mechanisms in neurons. It is now clear that highly toxic influences are exerted on oligodendroglial cells in white matter during ischemia. Moreover, the injury to both neurons and oligodendroglial cells is augmented in brain tissues by an inflammatory response to the initial injury, activating endothelial cells to express cell adhesion molecules that can attract additional inflammatory cells and upregulating levels of inflammatory proteases (e.g., metalloproteases) and cytokines (e.g. interleukins and chemokines). These events are summarized in the review by Lo and coworkers.

It is evident that these events are highly complex, invoking multiple parallel molecular phenomena. The salient feature of these molecular pathways is that they provide points for potential therapeutic interventions. As one example, it is clear that as ATP production fails and energy gradients are depleted, there is significant accumulation of lactic acid in cerebral tissue, and all the biochemical changes consequent to the cellular acidosis occur. These may also be of importance in determining the extent of cell damage (see reviews of Raichle and of Plum). Myers and Yamaguchi showed that monkeys infused with glucose before the induction of cardiac arrest suffered more brain damage than did either fasted or saline-infused animals. They suggested that the high cerebral glucose level under anaerobic conditions led to increased glycolysis during the ischemic episode and that the accumulated lactate was neurotoxic. On the basis of such observations, Plum has suggested that scrupulous control of the blood glucose might reduce the risk of cerebral infarction in diabetic and other stroke-prone patients and during conditions of potential hyperglycemia. Clinical implementation of this idea is difficult and its advantages remain to be established.

Regarding anoxic damage of the brain, Ames and Nesbett have studied the rabbit retina in an immersion chamber in which O₂ and various substrates could be altered directly rather than through the vasculature. They found that cells could withstand complete absence of O₂ for 20 min. After 30 min of anoxia, there was irreversible damage, reflected by an inability of the tissue to utilize glucose and to synthesize protein. Hypoglycemia further reduced the tolerance to hypoxia, whereas the tolerance could be prolonged by reducing the energy requirements of cells (increasing magnesium in the medium). Ames postulated that the long period of tolerance of retinal neurons to complete anoxia *in vitro*, in comparison to that *in vivo*, is related to what he called the no-reflow phenomenon (swelling of capillary endothelial cells, which prevents the restoration of circulation), as mentioned earlier. Body temperature is yet another important factor in determining the extent of infarction. A reduction of even 2 to 3°C (3.6 to 5.4°F) reduces the metabolic requirements of neurons and increases their tolerance to hypoxia by 25 to 30 percent.

These biochemical, cellular, and CBF findings enable one to conceptualize maneuvers for restoring blood flow within the marginally hypoperfused zone and salvaging brain tissue, particularly since under conditions of partial ischemia, cerebral tissue may survive for periods of 5 to 6 h or even longer.

NEUROVASCULAR SYNDROMES

The clinical picture that results from an occlusion of any one artery differs in minor ways from one patient to another, but there is

sufficient uniformity to justify the assignment of a typical syndrome to each of the major arteries and their branches. The following descriptions apply particularly to the clinical effects of ischemia and infarction due to embolism and thrombosis. The identification by careful examination of highly specific neurovascular syndromes is one of cardinal skills of the clinical neurologist. Although hemorrhage within a specific vascular territory may give rise to many of the same effects, the total clinical picture is different because it usually involves regions supplied by more than one artery and, by its deep extension and pressure effects, causes secondary features of headache, vomiting, and hypertension as well as a series of falsely localizing signs, as described in Chaps. 17 and 31.

The Carotid Artery

The carotid system consists of three major arteries—the common carotid, internal carotid, and external carotid. As indicated in Fig. 34-2, the right common carotid artery arises at the level of the sternoclavicular notch from the innominate (brachiocephalic) artery, and the left common carotid comes directly from the aortic arch. The common carotids ascend in the neck to the C4 level, just below the angle of the jaw, where each divides into external and internal branches (sometimes the bifurcation is slightly above or below this point).

Common carotid occlusion accounts for less than 1 percent of cases of carotid artery syndrome—the remainder being due to disease of the internal carotid artery itself. Nevertheless, the common carotid can be occluded by an atheromatous plaque at its origin, more often on the left side. Atherosclerotic stenosis or occlusion of the midportion of the common carotid may also occur years after radiation therapy for laryngeal or other head and neck cancer. If the bifurcation is patent, few if any symptoms may result, in some cases because retrograde flow from the external carotid maintains internal carotid flow and perfusion of the brain.

Because the syndromes caused by common carotid occlusion are identical to those of its internal branch, the remainder of this discussion is concerned with disease of the *internal carotid artery*. The territory supplied by this vessel and its main branches is shown in Figs. 34-4, 34-5, and 34-6. The clinical manifestations of atherosclerotic thrombotic disease of this artery are among the most variable of any cerebrovascular syndrome. Unlike other cerebral vessels, the internal carotid artery is not an end vessel. In most individuals it is in continuity with the vessels of the circle of Willis and those of the orbit, and no part of the brain is completely dependent on it. Therefore occlusion, which occurs most frequently in the first part of the internal carotid artery (immediately beyond the carotid bifurcation), is often silent (30 to 40 percent of cases).

There are two mechanisms by which strokes arise from atherosclerosis and superimposed thrombotic occlusion of the internal carotid artery. (We use the terms *atherothrombotic* and *atherothrombosis* here and in subsequent sections of the chapter to indicate this common mechanism of local stenosis, which leads to occlusion of the proximal parts of cerebral vessels or at their origins in the thorax and neck; see page 686). First, occlusion of the carotid may give rise to an embolus that passes distally in the territory of its tributary vessels, downstream from the internal carotid artery (middle and anterior cerebral arteries and their branches, as described further on). This has been termed *artery-to-artery embolism*. Second, and less often, occlusion of the carotid artery may lead to ischemia in the distal field (watershed or border zone) in the region of lowest perfusion between its major branch vessels.

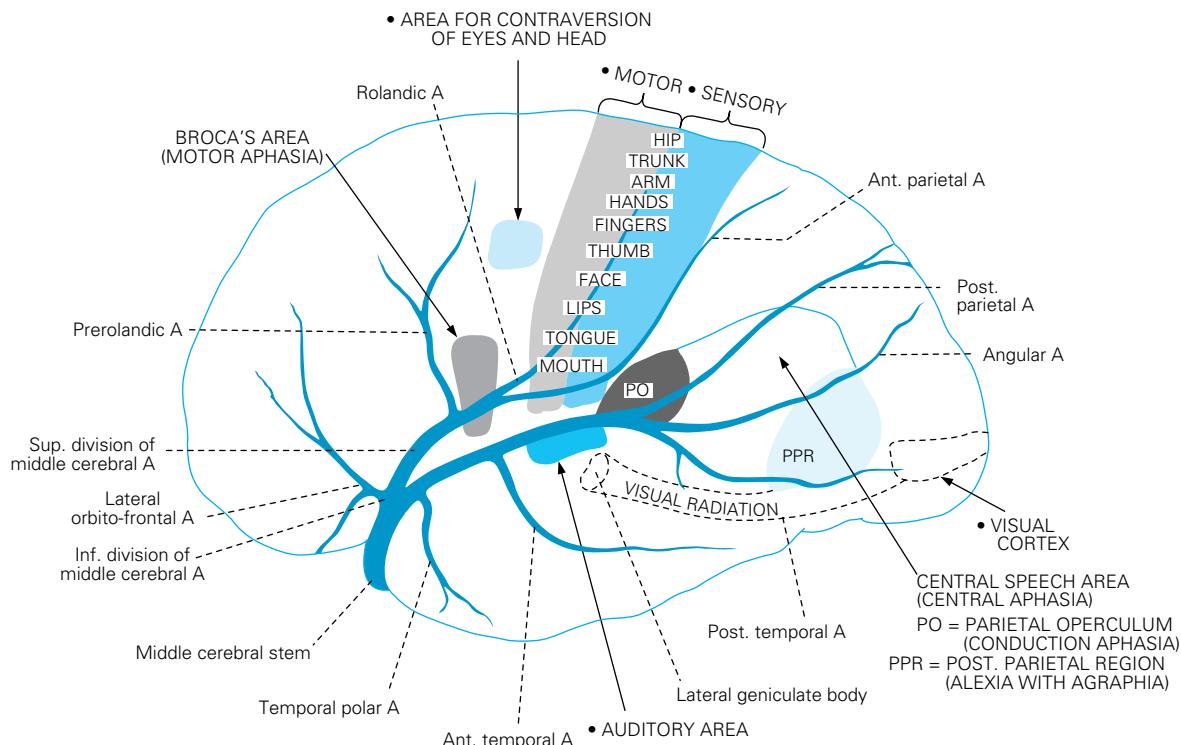

Figure 34-4. Diagram of a cerebral hemisphere, lateral aspect, showing the branches and distribution of the **middle cerebral artery** and the principal regions of cerebral localization. Below is a list of the clinical manifestations of infarction in the territory of this artery and the corresponding regions of cerebral damage.

Signs and symptoms	Structures involved
Paralysis of the contralateral face, arm, and leg	Somatic motor area for face and arm and the fibers descending from the leg area to enter the corona radiata
Sensory impairment over the contralateral face, arm, and leg (pin-prick, cotton touch, vibration, position, two-point discrimination, stereognosis, tactile localization, baragnosia, cutaneographia)	Somatosensory area for face and arm and thalamoparietal projections
Motor speech disorder	Broca and adjacent motor area of the <i>dominant hemisphere</i>
“Central” aphasia, word deafness, anomia, jargon speech, alexia, agraphia, acalculia, finger agnosia, right-left confusion (the last four comprise the Gerstmann syndrome)	Central language area and parieto-occipital cortex of the <i>dominant hemisphere</i>
Apractagnosia (amorphosynthesis), anosognosia, hemiasomatognosia, unilateral neglect, agnosia for the left half of external space, “dressing apraxia,” “constructional apraxia,” distortion of visual coordinates, inaccurate localization in the half field, impaired ability to judge distance, upside-down reading, visual illusions	Usually <i>nondominant</i> parietal lobe. Loss of topographic memory is usually due to a <i>nondominant</i> lesion, occasionally to a dominant one
Homonymous hemianopia (often superior homonymous quadrantanopia)	Optic radiation deep to second temporal convolution
Paralysis of conjugate gaze to the opposite side	Frontal contraversive field or fibers projecting therefrom
Avoidance reaction of opposite limbs	Parietal lobe
Miscellaneous:	
Ataxia of contralateral limb(s)	Parietal lobe
So-called Bruns ataxia or apraxia of gait	Frontal lobes (bilateral)
Loss or impairment of optokinetic nystagmus	Supramarginal gyrus or inferior parietal lobe
Limb-kinetic apraxia	Premotor or parietal cortical damage
Mirror movements	Precise location of responsible lesions not known
Cheyne-Stokes respiration, contralateral hyperhidrosis, mydriasis (occasionally)	Precise location of responsible lesions not known
Pure motor hemiplegia	Upper portion of the posterior limb of the internal capsule and the adjacent corona radiata

Failure of distal perfusion may involve all or part of the middle cerebral territory; when the anterior communicating artery is very small, the ipsilateral anterior cerebral territory is affected as well. In extreme instances where the circle of Willis provides no communication to the side of an occluded carotid artery, thus isolating the hemisphere from other blood flow, massive infarction involving the anterior two-thirds or all of the cerebral hemisphere, including the basal ganglia, may result. If the two anterior cerebral arteries arise from a common stem on one side, infarction may occur in the territories of both vessels. The territory supplied by the posterior cerebral artery will also be included when this vessel is supplied by the internal carotid rather than the basilar artery (an occasional configuration that is a residual fetal configuration of the origin of the posterior cerebral artery).

If one internal carotid artery was occluded at an earlier time, occlusion of the other may cause bilateral cerebral infarction. The clinical effects in such cases may include coma with quadriplegia and continuous horizontal "metronomic" conjugate eye movements. Occlusion of the intracranial portion of the internal carotid artery—for example by an embolus to its distal part—produces a clinical picture like that of middle cerebral artery occlusion: contralateral hemiplegia, hemihypesthesia, and aphasia (with involvement of the dominant hemisphere). When the anterior cerebral territory is included, some or all of the clinical features of the latter will be added (see further on). Patients with such large infarctions are usually immediately drowsy or stuporous because of an ill-defined effect on the reticular activating system.

Headache—located as a rule, above the eyebrow—may occur with thrombosis or embolism of the carotid artery, but cranial pain is not invariable. The headache sometimes associated with occlusion of the middle cerebral artery tends to be more lateral, at the temple; that of posterior cerebral occlusion is in or behind the eye.

When the circulation of one carotid artery has been incompletely compromised, reducing blood flow in both the middle and anterior cerebral territories, the zone of maximal ischemia lies between the two vascular territories ("cortical watershed") or, alternatively, in the deep portions of the hemisphere, between the territories of the lenticulostriate branches and the penetrating vessels from the convexity ("internal or deep watershed"). The infarction in the first instance occupies a region in the high parietal and frontal cortex and subcortical white matter. Its size depends upon the adequacy of collateral vessels. The weakness that results tends to involve the shoulder and hip more than the hand and face. With long-standing carotid stenosis, the cortical watershed zone tends to shift downward toward the perisylvian portions of the middle ce-

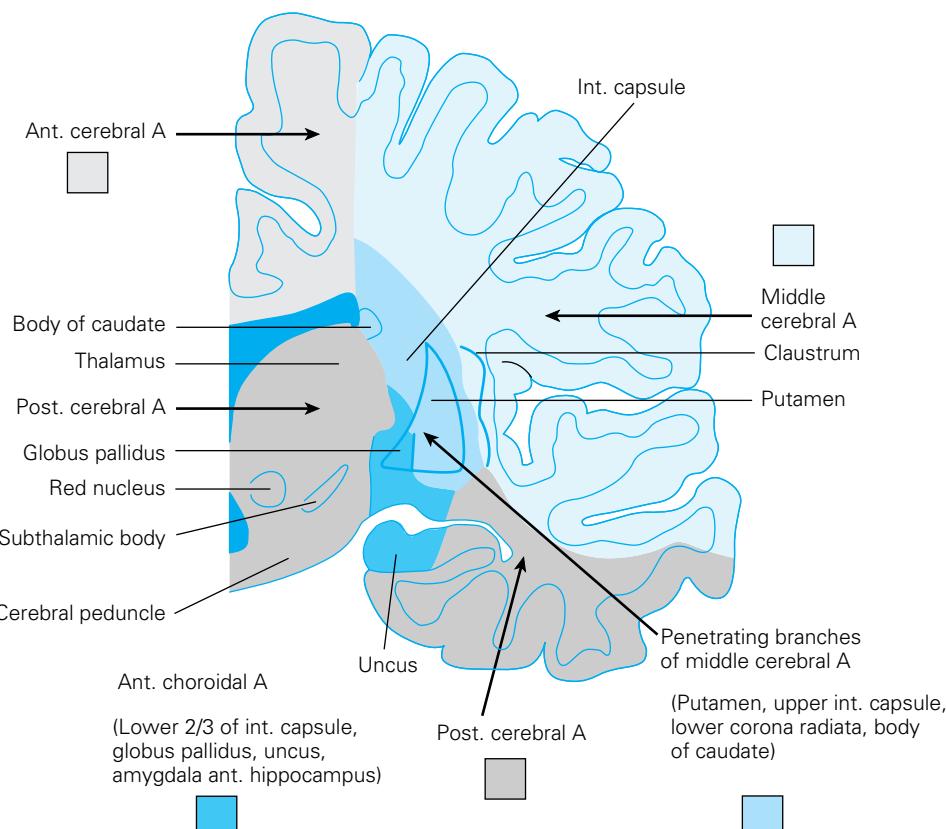

Figure 34-5. Diagram of a cerebral hemisphere, coronal section, showing the territories of the major cerebral vessels.

rebral artery territory, even to the extent of affecting facial movement or causing a motor aphasia. The frequent sparing of the posterior part of the hemisphere is reflected in the low incidence of Wernicke types of aphasia and of homonymous hemianopia. With impaired perfusion of the so-called internal watershed, infarctions of varying size are situated in the subfrontal and subparietal portions of the centrum semiovale.

The situation is somewhat different in cases of circulatory collapse, usually from cardiac arrest, in which perfusion fails not only in the watershed areas between the middle and anterior cerebral arteries but also between the middle and posterior cerebral arteries. The infarction is then situated within a zone that extends as a sickle-shaped strip of variable width from the cortical convexity of the frontal lobe, through the high parietal lobe, to the occipitoparietal junction. Deeper infarctions also occur, but they more often take the form of contiguous extensions of the cortical infarction into the subjacent white matter. Also there may appear to be two or more separate infarctions after hypoperfusion states, but these turn out to be radiographically visible portions of a larger border-zone lesion.

The internal carotid artery nourishes the optic nerve and retina as well as the brain. For this reason, *transient monocular blindness* occurs prior to the onset of stroke in 10 to 25 percent of cases of symptomatic carotid occlusion. Yet central retinal artery ischemia is a relatively rare manifestation of carotid artery occlusion, presumably because of efficient collateral supply in the globe.

Whereas most cerebral arteries can be evaluated only indirectly by bedside techniques, more direct clinical means are available for the evaluation of the common and internal carotid arteries

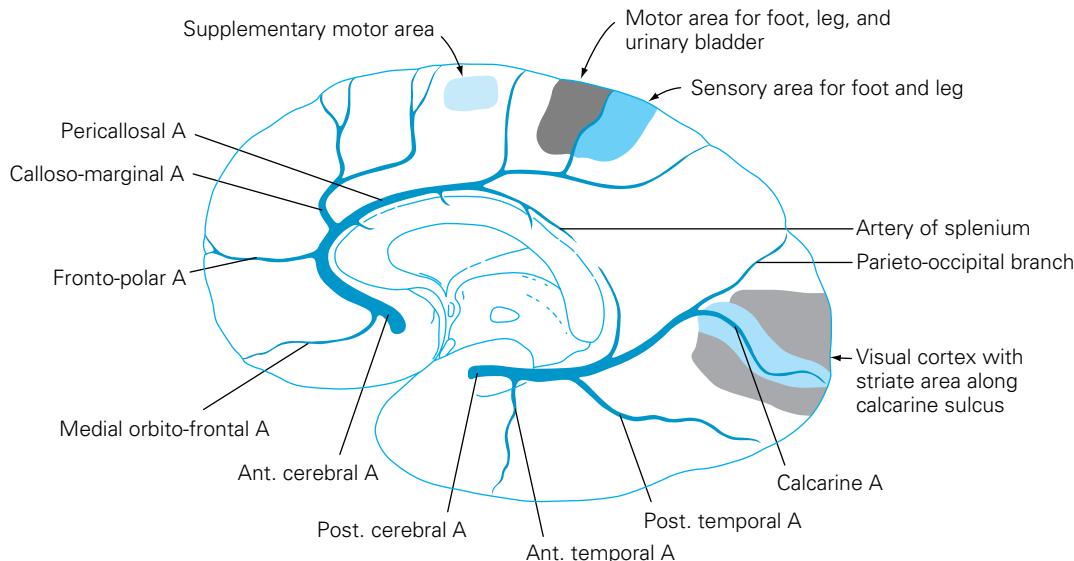

Figure 34-6. Diagram of a cerebral hemisphere, medial aspect, showing the branches and distribution of the **anterior cerebral artery** and the principal regions of cerebral localization. Below is a list of the clinical manifestations of infarction in the territory of this artery and the corresponding regions of cerebral damage. Also shown is the course of the main branch of the **posterior cerebral artery** on the medial side of the hemisphere.

Signs and symptoms	Structures involved
Paralysis of opposite foot and leg	Motor leg area
A lesser degree of paresis of opposite arm	Involvement of arm area of cortex or fibers descending therefrom to corona radiata
Cortical sensory loss over toes, foot, and leg	Sensory area for foot and leg
Urinary incontinence	Posteromedial part of superior frontal gyrus (bilateral)
Contralateral grasp reflex, sucking reflex, gegenhalten (paratonic rigidity), "frontal tremor"	Medial surface of the posterior frontal lobe (?)
Abulia (akinetic mutism), slowness, delay, lack of spontaneity, whispering, motor inaction, reflex distraction to sights and sounds	Uncertain localization—probably superomedial lesion near subcallosum
Impairment of gait and stance (gait "apraxia")	Inferomedial frontal-striatal (?)
Mental impairment (perseveration and amnesia)	Localization unknown
Miscellaneous: dyspraxia of left limbs	Corpus callosum
Tactile aphasia in left limbs	Corpus callosum
Cerebral paraplegia	Motor leg area bilaterally (due to bilateral occlusion of anterior cerebral arteries)

Note: Hemianopia does not occur; transcortical aphasia occurs rarely (page 423).

in the neck. With severe atherosclerotic stenosis at the level of the carotid sinus, with or without a superimposed thrombus, auscultation frequently discloses a *bruit*, best heard with the bell of the stethoscope held against the skin just tightly enough to create a seal (excessive pressure creates a diaphragm of the skin and filters the low-pitched frequencies that are typical of the bruit of carotid stenosis). Occasionally a bruit is due to stenosis at the origin of the external carotid artery or is a radiated murmur from the aortic valve and can then be misleading. If the bruit is loudest at the angle of the jaw, the stenosis usually lies at the proximal internal carotid; if heard lower in the neck, it is in the common carotid or subclavian artery. Rarely, stenosis in vertebral arteries or vascular malforma-

tions at the base of the brain may produce bruits heard posteriorly in the neck.

The duration and quality of the bruit are relevant—bruits that extend into diastole and are high-pitched are almost invariably associated with a tight stenosis (lumen < 1.5 mm). An additional though infrequent sign of carotid occlusion is the presence of a bruit over the opposite carotid artery, heard best by placing the bell of the stethoscope over the eyeball (ocular bruit). As pointed out by Pessin and colleagues (1983), this murmur is often due to augmented circulation through the patent vessel but there are as many instances in our experience when a bruit over the eye instead reflects a stenosis in the intracranial portion of the carotid artery on

that side. Pulsation may be palpably reduced or absent in the common carotid artery in the neck, in the external carotid artery in front of the ear, and in the internal carotid artery in the lateral wall of the pharynx, but these are among the least dependable signs of carotid disease and too vigorous compression risks dislodging plaque material. Also, in the presence of a unilateral internal carotid occlusion, compression of the normal common carotid should be avoided because it may precipitate neurologic symptoms.

Central retinal artery pressure is reduced on the side of a carotid occlusion or severe stenosis; this can be appreciated by gentle pressure on the globe while viewing the vessels emanating from the optic nerve head. A diastolic retinal pressure (determined by ophthalmic dynamometry) of less than 20 mmHg usually means that the common or internal carotid artery is occluded. These and other tests for assessing carotid flow have been largely supplanted by ultrasound insonation and MRI imaging of the carotid artery, but retinal examination remains highly valuable in that it may demonstrate *emboli* within retinal arteries, either shiny white or reddish in appearance; this is another important sign of carotid disease (crystalline cholesterol is sloughed from an atheromatous ulcer).

Additional signs of carotid occlusion include pulseless arms (as in Takayasu disease, see page 732); faintness on arising from the horizontal position or recurrent loss of consciousness when walking; headache and sometimes ocular, retro-orbital, and neck pain; transient blindness, either unilateral or bilateral; unilateral visual loss or dimness of vision with exercise, after exposure to bright light, or on assuming an upright position; retinal atrophy and pigmentation; atrophy of the iris; heterochromia of the iris (differing coloration on the two sides is a sign of carotid occlusion early in life); leukomas (corneal scars); peripapillary arteriovenous anastomoses in the retinae; optic atrophy; and claudication of jaw muscles.

The cardinal clinical sign of stenoses, ulcerations, and dissections of the internal carotid artery near its origin from the common carotid artery are TIAs. It is a subject of debate whether these are the result of fibrin platelet emboli or a reduction in blood flow. TIAs are discussed further on, but here it can be stated that TIAs and severe stenosis of the vessel represents an important risk factor for stroke.

Middle Cerebral Artery (MCA)

This artery has superficial and deep hemispherical branches. Through its *cortical branches*, it supplies the lateral (convexity) part of the cerebral hemisphere (Fig. 34-4). Its cortical territory encompasses (1) cortex and white matter of the lateral and inferior parts of the frontal lobe—including motor areas 4 and 6, contraversive centers for lateral gaze—and motor speech area of Broca (dominant hemisphere); (2) cortex and white matter of the parietal lobe, including the sensory cortex and the angular and supramarginal convolutions; and (3) superior parts of the temporal lobe and insula, including the sensory language areas of Wernicke. The deep *penetrating or lenticulostriate branches* of the middle cerebral artery supply the putamen, part of the head and body of the caudate nucleus, the outer globus pallidus, the posterior limb of the internal capsule, and the corona radiata (Fig. 34-5). The size of both the middle cerebral artery and the territory that it supplies is larger than those of the anterior and posterior cerebral arteries.

MCA Stem (M1) Occlusion The middle cerebral artery may be occluded in its stem (the term *M1* is used by radiologists to denote this portion of the vessel), the portion that is distal to its origin at

the distal internal carotid and proximal to its bifurcation. An occlusion here blocks the flow in the small deep penetrating vessels as well as in superficial cortical branches; alternatively, an occlusion at the distal end of the stem blocks the orifices of the divisions of the artery in the sylvian sulcus but leaves unaffected the more proximal deep penetrating vessels. The picture of *total occlusion of the stem is one of contralateral hemiplegia (face, arm, and leg), hemianesthesia, and homonymous hemianopia* (due to infarction of the lateral geniculate body), with *deviation of the head and eyes toward the side of the lesion*; in addition, there is a variable but usually *global aphasia with left hemispheric lesions and anosognosia and amorphosynthesis with a right-sided ones* (see Chap. 22). In the beginning, the patient may be dull or stuporous because of an ill-defined effect of widespread paralysis of neurologic function. Once fully established, the motor, sensory, and language deficits remain static or improve very little as months and years pass. If the patient is globally aphasic for a prolonged period of time, he seldom ever again communicates effectively (see Chap. 23 on the aphasic disorders). Occlusion of branches of the middle cerebral artery gives rise to only parts of the symptom complex. If there are adequate collateral vessels over the surface of the hemisphere, only those component of the stroke referable to the deep structures are evident (mainly hemiplegia encompassing the contralateral limbs and face, as discussed below, under “Deep MCA Territory Occlusion”), the cortical elements then being absent or mild (aphasia, agnosia, etc.).

Occlusion of the stem of the middle cerebral artery by a thrombus, contrary to conventional teaching, is relatively infrequent (less than 10 percent of middle cerebral artery occlusions in our experience); cerebral embolism is a more common cause. Pathologic studies over the years have shown that most carotid occlusions are thrombotic, whereas most middle cerebral occlusions are embolic (Fisher, 1975; Caplan, 1989). The emboli tend to lodge in the stem or, more often, drift into superficial cortical branches; not more than 1 in 20 will enter deep penetrating branches that originate in the stem. The middle cerebral artery may, however, become stenotic from atherosclerosis. In several series of such cases, the permanent stroke was preceded by TIAs, producing a picture resembling that of carotid stenosis (see Day; Caplan).

MCA Branch (Superior and Inferior Division) Occlusion

Superior Division An embolus entering the middle cerebral artery most often lodges in one of its two main branches, the superior division (supplying the rolandic and prerolandic areas) or the inferior division (supplying the lateral temporal and inferior parietal lobes). Major infarction in the territory of the *superior division* causes a *dense sensorimotor deficit in the contralateral face, arm, and, to a lesser extent, leg as well as ipsilateral deviation of the head and eyes*; i.e., it mimics the syndrome of stem occlusion except that the foot is spared and the leg is less involved than the arm and face (“brachiofacial paralysis”); there is no impairment of alertness. If the occlusion is lasting (not merely transient ischemia with disintegration of the embolus), there will be slow improvement; after a few months, the patient will be able to walk with a spastic leg, while the motor deficits of the arm and face remain. The sensory deficit may be profound, resembling that of a thalamic infarct (pseudothalamic syndrome of Foix), but more often it is less severe than the motor deficit, taking the form of stereoanesthesia, agnosesthesia, impaired position sense, tactile localization, and two-point discrimination as well as variable changes in touch, pain,

and temperature sense. With *left-sided lesions there is initially a global aphasia, which changes gradually to a predominantly motor (Broca) aphasia*, with improvement in comprehension of spoken and written words and the emergence of an effortful, hesitant, grammatically simplified, and dysmelodic speech (Chap. 23); or there is a *Broca aphasia from the outset*.

Embolic occlusion limited to one of the *branches of the superior division*, perhaps the most common stroke seen in clinical practice, produces a more circumscribed infarct that further fractionates the above described syndrome. With occlusion of the ascending frontal branch, the motor deficit is limited to the face and arm with little or no affection of the leg, and the latter, if weakened at all, soon improves; with left-sided lesions, there is dysfluent and agrammatic speech, with normal comprehension (page 418). Embolic occlusion of the rolandic branches results in sensorimotor paresis with severe dysarthria but little evidence of aphasia. A cortical-subcortical branch occlusion may give rise to a brachial monoplegia. Embolic occlusion of ascending parietal and other posterior branches of the superior division may cause no sensorimotor deficit but only a conduction aphasia (page 421) and bilateral ideomotor apraxia. There are many other limited stroke syndromes or combinations of the aforementioned syndromes relating to small regions of damage in the frontal, parietal, or temporal lobes. Most of these are discussed in Chap. 22, on lesions in particular parts of the cerebrum. Improvement can be expected within a few weeks to months but often some remnant of the original problem remains in place. As indicated earlier, the distal territory of the middle cerebral artery may also be rendered ischemic by failure of the systemic circulation, especially if the carotid artery is stenotic; this may simulate embolic branch occlusions.

Inferior Division Occlusion of the *inferior division* of the middle cerebral artery is slightly less frequent than occlusion of the superior one, but again is nearly always due to embolism. The usual result in left-sided lesions is a *Wernicke aphasia*, which generally remains static for days or weeks, or a month or two, after which some improvement can be expected (page 419). In less extensive infarcts from branch occlusions (superior parietal, angular, or posterior temporal), the deficit in comprehension of spoken and written language may be especially severe. Again, after a few months, the deficits usually improve, often to the point where they are evident only in self-generated efforts to read and copy visually presented words or phrases. With either right- or left-hemispheric lesions, there is usually a *superior quadrantanopia* or *homonymous hemianopia* and, with right-sided ones, a *left visual neglect* and other signs of amorphosynthesis; rarely, an agitated confusional state, presumably from temporal lobe damage, may be a prominent feature of dominant hemispherical lesions and sometimes of nondominant ones.

Deep MCA ("MCA Stem," M1) Territory Occlusion (Striatocapsular Infarction) A number of interesting syndromes occur with deep lesions in the territory of the penetrating vessels of the middle cerebral artery (Figs. 34-5 and 34-7). Most are attributable to emboli to the stem of the middle cerebral artery, although imaging studies show a patent vessel in half of the cases; a few are presumably atherothrombotic. There have been few adequate pathologic studies. Although centered in the deep white matter, most of these lesions are fragments of the cortical-subcortical stroke patterns described above. The most common type in our experience has been a *large striatocapsular infarction*, similar to that described by Weller and colleagues. All of their patients had some degree of hemiparesis and one-fifth had aphasia or hemineglect.

Aphasia, when it occurs, tends to be a limited form of the Broca type and, in our experience, has been short-lived. With deep small strokes, we have most often encountered incomplete motor syndromes affecting only the arm and hand, without language disturbance or neglect; these are quite difficult to differentiate from small embolic cortical strokes. The lesions in the corona radiata are larger than typical lacunes (see further on) but probably have a similar pathophysiology.

Foix and Levy, who described the clinical effects of deep capsular-basal ganglionic lesions and of more superficial cortical-subcortical ones, found few important differences in the degree and pattern of the hemiplegia and sensory disorder. Homonymous hemianopia may occur with posterior capsular lesions, but it must be distinguished from visual hemineglect of contralateral space. Bilateral cerebral infarctions involving mainly the insular-perisylvian (anterior opercular) regions manifest themselves by a facio-glossopharyngomasticatory diplegia (anarthria without aphasia; see Mao et al).

Anterior Cerebral Artery

This artery, through its cortical branches, supplies the anterior three-quarters of the medial surface of the frontal lobe, including its medial-orbital surface, the frontal pole, a strip of the lateral surface of the cerebral hemisphere along the superior border, and the anterior four-fifths of the corpus callosum. Deep branches, arising near the circle of Willis (proximal or distal to the anterior communicating artery), supply the anterior limb of the internal capsule, the inferior part of the head of the caudate nucleus, and the anterior part of the globus pallidus (Figs. 34-5, 34-6, and 34-7). The largest of these deep branches is the artery of Heubner.

The clinical picture will depend on the location and size of the infarct, which, in turn, relates to the site of the occlusion, the pattern of the circle of Willis, and the other ischemia-modifying factors mentioned earlier. Well-studied cases of infarction in the territory of the anterior cerebral artery are not numerous; hence the syndromes have not been completely elucidated (see Brust and also Bogousslavsky and Regli for a review of the literature and a description of developmental abnormalities of the artery).

Occlusion of the stem of the anterior cerebral artery, proximal to its connection with the anterior communicating artery (the A1 segment, in neuroradiologic parlance), is usually well tolerated, since adequate collateral flow will come from the artery of the opposite side. Maximal disturbance occurs when both arteries arise from one anterior cerebral stem, in which case occlusion of the stem will cause infarction of the anterior and medial parts of both cerebral hemispheres and result in paraparesis, incontinence, abulia and motor aphasic symptoms, and frontal lobe personality changes (Chap. 22). Occlusion of the anterior cerebral arteries is usually embolic, but atherothrombotic lesions are known and surgical instances have been described (occlusion with operations on anterior communicating aneurysms).

Complete infarction due to *occlusion of one anterior cerebral artery distal to the anterior communicating artery (A2 segment)* results in a *sensorimotor deficit of the opposite foot and leg and, to a lesser degree, of the shoulder and arm, with sparing of the hand and face*. The motor disorder is more pronounced in the foot and leg than in the hip and thigh. Sensory loss, when it occurs, is mainly of the discriminative modalities and is mild or absent in some cases. The head and eyes may deviate to the side of the lesion. Urinary incontinence and a contralateral grasp reflex and paratonic

rigidity (*gegenhalten*) may be evident. With a left-sided occlusion, there may be a sympathetic apraxia of the left arm and leg or involuntary misdirected movements of the left arm (alien arm or hand). Also, transcortical motor aphasia (page 423) may occur with occlusions of Heubner's branch of the left anterior cerebral artery. Alexander and Schmitt cite cases in which a right hemiplegia (predominant in the leg) with grasping and groping responses of the right hand and buccofacial apraxia are accompanied by a diminution or absence of spontaneous speech, agraphia, labored telegraphic speech, and a limited ability to name objects and compose word lists but with a striking preservation of the ability to repeat spoken and written sentences (i.e., transcortical motor aphasia). *Disorders of behavior* that may be overlooked are abulia, presenting as slowness and lack of spontaneity in all reactions, muteness or a tendency to speak in whispers, and distractibility. Branch occlusions of the anterior cerebral artery produce only fragments of the total syndrome, usually a spastic weakness or corticosensory loss in the opposite foot and leg.

With occlusion of *penetrating branches of the anterior cerebral artery* on one or both sides, the anterior limb of the internal capsule and caudate are usually involved. In a series of 18 cases of unilateral caudate region infarcts collected by Caplan and associates, a transient hemiparesis was present in 13. Dysarthria and either abulia or agitation and hyperactivity were also common. Stuttering and language difficulty occurred with two of the left-sided lesions and visuospatial neglect with three of the right-sided ones. To what extent these symptoms were due to a disturbance of neighboring structures is difficult to determine. With bilateral cau-

date infarctions, a syndrome of inattentiveness, abulia, forgetfulness, and sometimes agitation and psychosis was observed. Transitory choreoathetosis and other dyskinesias have also been attributed to ischemia of basal ganglia, occurring sometimes under conditions of prolonged standing and exercise (Caplan and Sergay; Margolin and Marsden).

Anterior Choroidal Artery

This is a long, narrow artery that springs from the internal carotid, just above the origin of the posterior communicating artery. It supplies the internal segment of the globus pallidus and posterior limb of the internal capsule and various contiguous structures, including (in most patients) the optic tract (Fig. 34-5); then it penetrates the temporal horn of the lateral ventricle, where it supplies the choroid plexus and anastomoses with the posterior choroidal artery.

Only a few complete clinicopathologic studies have been made of the syndrome caused by occlusion of this artery. It was found by Foix and colleagues to consist of *contralateral hemiplegia, hemihypesthesia, and homonymous hemianopia* due to involvement of the posterior limb of the internal capsule and white matter posterolateral to it, through which the geniculocalcarine tract passes. *Cognitive and language functions are notably spared* in most cases. This combination of extensive motor, sensory, and visual impairment in an individual with well-preserved language and cognition distinguishes this stroke syndrome from the more common syndromes involving the major cerebral arteries. Decroix and colleagues reported 16 cases (identified by CT) in which the lesion appeared to lie in the vascular territory of this artery. In most of their cases the clinical syndrome fell short of what was expected on anatomic grounds. With right-sided lesions, there may be a left spatial neglect and constructional apraxia; slight disorders of speech and language may accompany left-sided lesions. Hupperts and colleagues have discussed the controversy regarding the effects of occlusion of the anterior choroidal artery and in particular the variability of its supply to the posterior paraventricular area of the corona radiata and adjacent regions. They concluded, also from a survey of CT scans, that there was no uniform syndrome attributable to occlusion of this vessel and that in most cases its territory of supply was overlapped by small surrounding vessels. Of course, in both these studies, the lesions may have extended beyond the territory of this artery, since postmortem confirmation was lacking. It should be remembered that for a time, in order to abolish the tremor and rigidity of unilateral Parkinson disease, the anterior choroidal artery was being surgically ligated without these other effects having been produced.

Vertebrobasilar and Posterior Cerebral Arteries

Posterior Cerebral Artery In about 70 percent of persons, both posterior cerebral arteries are formed by the bifurcation of the basilar artery, and only thin posterior communicating arteries join this system to the internal carotid arteries. In 20 to 25 percent, one posterior cerebral artery arises from the basilar in the usual way, but the other arises from the internal carotid, a so-called persistent fetal circulation; in the remainder, both arise from the corresponding carotids.

The configuration and branches of the *proximal segment of the posterior cerebral artery* (P1 segment) are illustrated in Figs. 34-6, 34-8, and 34-9. The *interpeduncular branches*, which arise

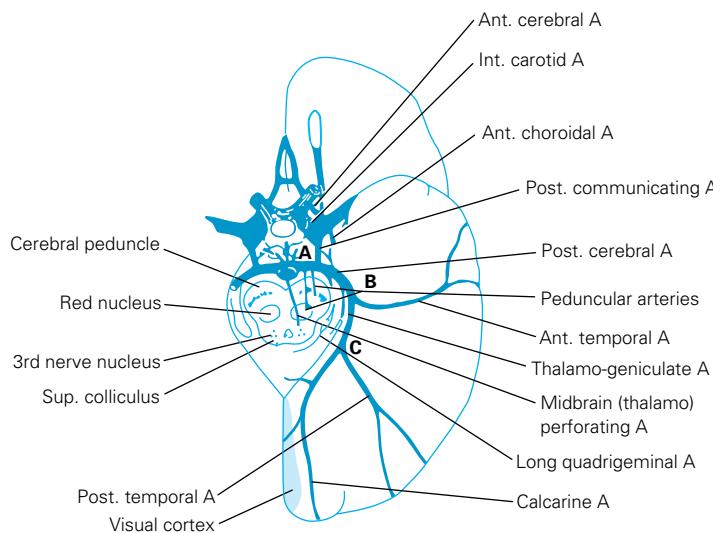

Figure 34-8. Inferior aspect of the brain showing the branches and distribution of the **posterior cerebral artery** and the principal anatomic structures supplied. Listed below are the clinical manifestations produced by infarction in its territory and the corresponding regions of damage.

Signs and symptoms	Structures involved
<i>Central territory</i>	
Thalamic syndrome: sensory loss (all modalities), spontaneous pain and dysesthesias, choreoathetosis, intention tremor, spasms of hand, mild hemiparesis	Ventral posterolateral nucleus of thalamus in territory of thalamo-geniculate artery. Involvement of the adjacent subthalamic nucleus or its pallidal connections results in hemiballismus and choreoathetosis.
Thalamoperforate syndrome: (1) superior, crossed cerebellar ataxia; (2) inferior, crossed cerebellar ataxia with ipsilateral third nerve palsy (Claude syndrome)	Dentatothalamic tract and issuing third nerve
Weber syndrome—third nerve palsy and contralateral hemiplegia	Issuing third nerve and cerebral peduncle
Contralateral hemiplegia	Cerebral peduncle
Paralysis or paresis of vertical eye movement, skew deviation, sluggish pupillary responses to light, slight miosis and ptosis (retraction nystagmus and “tucked-in” eyelids may be associated)	Supranuclear fibers to third nerve, high midbrain tegmentum ventral to superior colliculus (nucleus of Cajal, nucleus of Dark-schevich, rostral interstitial nucleus of the MLF, and posterior commissure)
Contralateral ataxic or postural tremor	Dentatothalamic tract (?) after decussation. Precise site of lesion unknown.
Decerebrate attacks	Damage to motor tracts between red and vestibular nuclei
<i>Peripheral territory</i>	
Homonymous hemianopia	Calcarine cortex or optic radiation; hemiachromatopsia may be present. Macular or central vision is preserved if posterior striate area is spared.
Bilateral homonymous hemianopia, cortical blindness, unawareness or denial of blindness; achromatopsia, failure to see to-and-fro movements, inability to perceive objects not centrally located, apraxia of ocular movements, inability to count or enumerate objects	Bilateral occipital lobe, possibly with involvement of parieto-occipital region
Dyslexia without agraphia, color anomia	Dominant calcarine lesion and posterior part of corpus callosum
Memory defect	Lesion of inferomedial portions of temporal lobe bilaterally; occasionally of the dominant side only
Topographic disorientation and prosopagnosia	Nondominant calcarine and lingual gyri, usually bilateral
Simultagnosia	Dominant visual cortex, sometimes bilateral
Unformed visual hallucinations, metamorphopsia, teleopsia, illusory visual spread, palinopsia, distortion of outlines, photophobia	Calcarine cortex

Note: Tremor in repose has been omitted because of the uncertainty of its occurrence in the posterior cerebral artery syndrome. Peduncular hallucinosis may occur in thalamic-subthalamic ischemic lesions, but the exact location of the lesion is unknown.

just above the basilar bifurcation, supply the red nuclei, the substantia nigra bilaterally, medial parts of the cerebral peduncles, oculomotor and trochlear nuclei and nerves, reticular substance of the upper brainstem, decussation of the brachia conjunctivae (superior cerebellar peduncles), medial longitudinal fasciculi, and medial lemnisci. The portion of the posterior cerebral artery giving rise to the interpeduncular branches (the portion between the bifurcation of the basilar artery and the ostium of the posterior communicating artery) is also referred to as the *mesencephalic artery* or the *basilar communicating artery*.

The *thalamoperforate branches* (also called *paramedian thalamic arteries*) arise slightly more distally, near the junction of the posterior cerebral and posterior communicating arteries (P2 segment of the artery) and supply the inferior, medial, and anterior parts of the thalamus. As pointed out by Percheron (whose name is often applied to the largest of these vessels), the arterial configuration of the thalamoperforate arteries varies considerably: in some cases they arise symmetrically, one from each side; in others, both arteries arise from the same posterior cerebral stem, either separately or by a common trunk, which then bifurcates. In the latter case, one posterior cerebral stem supplies the medial thalamic territories on both sides, and an occlusion of this artery or one common paramedian trunk produces a bilateral butterfly-shaped lesion in the medial parts of the diencephalon. The *thalamogeniculate branches* arise still more distally, opposite the lateral geniculate body, and supply the geniculate body and the central and posterior parts of the thalamus. Medial branches from the posterior cerebral, as it encircles the midbrain, supply the lateral part of the cerebral peduncle, lateral tegmentum and corpora quadrigemina, and pineal gland. Posterior choroidal branches run to the postero-superior thalamus, choroid plexus, posterior parts of the hippocampus, and psalterium (decussation of fornices).

The terminal or *cortical branches* of the posterior cerebral artery supply the inferomedial part of the temporal lobe and the medial occipital lobe, including the lingula, cuneus, precuneus, and visual Brodmann's areas 17, 18, and 19 (see Figs. 34-6, 34-8, and 34-9).

Occlusion of the posterior cerebral artery produces a greater variety of clinical effects than occlusion of any other artery because both the upper brainstem, which is crowded with important structures, and the inferomedial parts of the temporal and occipital lobes lie within its domain. Obviously, the site of the occlusion and the arrangement of the circle of Willis will in large measure determine the location and extent of the resulting infarct. For example, occlusion proximal to the posterior communicating artery may be asymptomatic or have only transitory effects if the collateral flow is adequate from the opposite posterior cerebral vessel (Fig. 34-8; see also Fig. 34-9). Even distal to the posterior communicating artery, an occlusion may cause relatively little damage if the collateral flow through border-zone collaterals from anterior and middle cerebral arteries is sufficient.

In the series of posterior cerebral artery strokes studied by Milandre and coworkers, the causes were in general similar to those of strokes in other vascular territories except that there was a surprisingly high incidence of atherosclerotic occlusion (35 patients) in contrast to cardioembolic types (15 patients). Two of their stroke cases were attributed to migraine. Our experience has differed in that the proportion of presumed embolic occlusions has been far greater than that of other causes.

For convenience of exposition, it is helpful to divide the posterior cerebral artery syndromes into three groups: (1) anterior and

proximal (involving interpeduncular, thalamic perforant, and thalamogeniculate branches), (2) cortical (inferior temporal and medial occipital), and (3) bilateral.

Anterior and Proximal Syndromes (See Figs. 34-9 and 34-10.) The *thalamic syndrome of Déjerine and Roussy* (page 141) follows infarction of the sensory relay nuclei in the thalamus, the result of occlusion of thalamogeniculate branches. There is both a deep and cutaneous sensory loss, usually severe in degree, of the opposite side of the body, including the trunk and face, sometimes accompanied by a transitory hemiparesis. A homonymous hemianopia may be conjoined. In some instances there is a dissociated sensory loss—pain and thermal sensation being more affected than touch, vibration, and position—or only one part of the body may be anesthetic. But again, the characteristic feature is sensory loss that includes the entire hemibody up to the midline. After an interval, sensation begins to return, and the patient may then develop pain, paresthesia, and hyperesthesia in the affected parts. The painful paresthetic syndrome may persist for years. There may also be distortion of taste, athetotic posturing of the hand, and alteration of mood. Mania and depression have occasionally been observed with infarction of the diencephalon and adjacent structures, but the data are usually incomplete.

Central midbrain and subthalamic syndromes are due to occlusion of the interpeduncular branches of the posterior cerebral artery. The clinical syndromes include palsies of vertical gaze, stupor, or coma. Syndromes of the *paramedian arteries*, including the proximal posterior cerebral artery, have as their main feature a third nerve palsy combined with contralateral hemiplegia (*Weber syndrome*), contralateral ataxic tremor (*Benedikt syndrome*), or ataxia and hemiparesis (*Claude syndrome*) as summarized in Table 34-3, page 681.

Anteromedial-inferior thalamic syndromes follow occlusion of the thalamoperforant branches. Here the most common effect is an extrapyramidal movement disorder (hemiballismus or hemichorea-horeathetosis or less often, asterixis). Deep sensory loss, hemiataxia, or tremor may be added in various combinations. Hemiballismus is usually due to occlusion of a small branch to the subthalamic nucleus (of Luys) or its connections with the pallidum. Occlusion of the paramedian thalamic branch(es) to the mediodorsal thalamic nuclei or to the dominant (left) mediodorsal nucleus is a recognized

(Reproduced by permission from Krayenbühl and Yasargil.)

substrate of the vascular amnesia (Korsakoff) syndrome; this simulates infarction of the hippocampi from occlusion of the medial temporal branch of the posterior cerebral artery as noted below.

Unilateral Cortical Syndromes Occlusion of branches to the temporal and occipital lobes gives rise to a homonymous hemianopia as a result of involvement of the primary visual receptive areas (calcarine or striate cortex) or of the converging geniculocalcarine fibers. It may be incomplete and then involves the upper quadrants of the visual fields more than the lower ones (see Chap. 13). Macular or central vision may be spared because of collateralization of the occipital pole from distal branches of the middle (or anterior) cerebral arteries. There may be visual hallucinations in the blind parts of the visual fields (Cogan) or metamorphopsia and palinopsia (Brust and Behrens).

Posterior cortical infarcts of the dominant hemisphere cause alexia (with or without agraphia), anomia (amnesic aphasia), a variety of visual agnosias, and rarely some degree of impaired memory. The anomias (dysnomias) are most severe for colors, but the naming of other visually presented material such as pictures, musical notes, mathematical symbols, and manipulable objects may also be impaired. The patient may treat objects as familiar—that is, describe their functions and use them correctly—but be unable to name them. Color dysnomia and amnesic aphasia are more often present in this syndrome than is alexia. The defect in retentive memory is of varying severity and may or may not improve with the passage of time. These syndromes are described in Chaps. 22 and 23.

A complete proximal arterial occlusion leads to a syndrome that combines cortical and anterior-proximal syndromes in part or totally. The vascular lesion may be either an embolus or an atherosclerotic thrombus.

Bilateral Cortical Syndromes These occur as a result of successive infarctions or from a single embolic or thrombotic occlusion of the upper basilar artery, especially if the posterior communicating arteries are unusually small.

Bilateral lesions of the occipital lobes, if extensive, cause total “cortical blindness,” i.e., a bilateral homonymous hemianopia, sometimes accompanied by unformed visual hallucinations. The pupillary reflexes are preserved, and the optic discs appear normal. Sometimes the patient is unaware of being blind and may deny it even when it is pointed out to him (Anton syndrome). More frequently the lesions are incomplete, and a sector of the visual fields, usually on one side, remains intact. When the intact remnant is small, vision may fluctuate from moment to moment as the patient attempts to capture the image in the island of intact vision, in which case hysteria is incorrectly inferred. The Balint syndrome (page 406) is another effect of bilateral occipitoparietal border-zone lesions. In bilateral lesions confined to the occipital poles, there may be a loss of central vision only (homonymous central scotomas). With more anteriorly placed lesions of the occipital pole, there may be homonymous paracentral scotomas, or the occipital poles may be spared, leaving the patient with only central vision. Horizontal or altitudinal field defects are usually due to similar restricted lesions affecting the upper or lower banks of the calcarine sulci.

With bilateral lesions that involve the inferomedial portions of the temporal lobes, the impairment of memory may be severe, causing the Korsakoff amnesia state. In several of our patients, a solely left-sided infarction of the inferomedial temporal lobe impaired retentive memory. These amnesia states and their accompaniments are fully described in Chaps. 21 and 22. Bilateral mesiotemporal-occipital lesions also cause a lack of recognition of

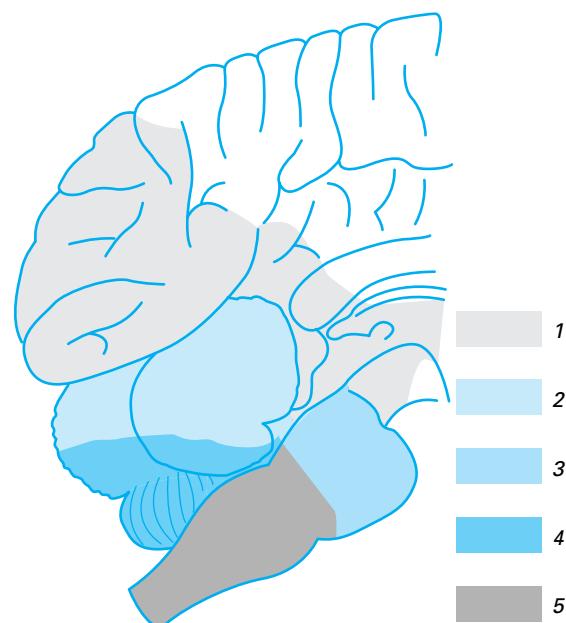

Figure 34-11. Regions of supply by the posterior segment of the circle of Willis, lateral view: (1) posterior cerebral artery; (2) superior cerebellar artery; (3) basilar artery and superior cerebellar artery; (4) posterior inferior cerebellar artery; (5) vertebral artery (posterior inferior cerebellar artery, anterior spinal artery, posterior spinal artery).

faces (prosopagnosia). These and other effects of temporal and occipital lesions are discussed in Chaps. 13 and 22.

Vertebral Artery The vertebral arteries are the chief arteries of the medulla; each supplies the lower three-fourths of the pyramid, the medial lemniscus, all or nearly all of the retro-olivary (lateral medullary) region, the restiform body, and the posteroinferior part of the cerebellar hemisphere (Figs. 34-11 and 34-12). The relative sizes of the vertebral arteries vary considerably, and in approximately 10 percent of cases, one vessel is so small that the other is essentially the only artery of supply to the brainstem. In the latter

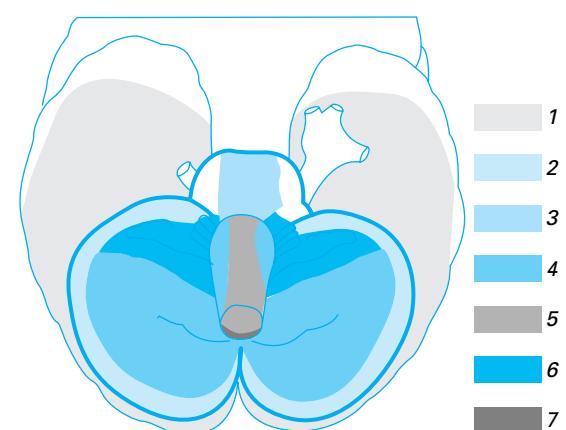

Figure 34-12. Regions supplied by the posterior segment of the circle of Willis, basal view: (1) posterior cerebral artery; (2) superior cerebellar artery; (3) paramedian branches of the basilar artery and spinal artery; (4) posterior inferior cerebellar artery; (5) vertebral artery; (6) anterior inferior cerebellar artery; (7) dorsal spinal artery. (Reproduced by permission from Krayenbühl and Yasargil.)

cases, if there is no collateral flow from the carotid system via the circle of Willis, occlusion of the one functional vertebral artery is equivalent to occlusion of the basilar artery (see below). The posteroinferior cerebellar artery (PICA) is usually a branch of the vertebral artery but can have a common origin with the anteroinferior cerebellar artery (AICA) from the basilar artery. It is necessary to keep these anatomic variations in mind in considering the effects of vertebral artery occlusion.

The vertebral arteries are most often occluded by atherosclerosis in their intracranial portion. Since the vertebral arteries have a long extracranial course and pass through the transverse processes of C6 to C1 vertebrae before entering the cranial cavity, one might expect them to be subject to trauma, spondylotic compression, and a variety of other vertebral diseases. With the exception of arterial dissection, in our experience this happens only infrequently. We have not seen convincing examples of spondylotic occlusion but several have been reported. Extreme extension of the neck, as experienced by women who are having their hair washed in beauty salons, may give rise to transient symptoms in the territory of the vertebral artery.

Dissection of the vertebral artery is well described; it declares itself by cervico-occipital pain and deficits of brainstem function, usually bilateral. It may be precipitated by vigorous and protracted bouts of coughing or by trauma to the neck or head. Dissection of the extracranial vessels is discussed under “Dissection of the Cervical and Intracranial Vessels,” further on. Examples of “posterior circulation” stroke in children have been reported in association with odontoid hypoplasia and other atlantoaxial dislocations, causing the vertebral arteries to be stretched or kinked in their course through the transverse processes of C1-C2 (see Phillips et al).

The results of vertebral artery occlusion are quite variable. When there are two good-sized arteries, occlusion of one PICA may cause no recognizable symptoms and signs. If the occlusion of the vertebral artery is so situated as to block the branch supplying the lateral medulla and inferior cerebellum (PICA), a characteristic syndrome results with vertigo being a prominent symptom (see

“Lateral Medullary Syndrome” below). If the subclavian artery is blocked proximal to the origin of the left vertebral artery, exercise of the arm on that side may draw blood from the right vertebral and basilar arteries, down the left vertebral and into the distal left subclavian artery—sometimes resulting in the symptoms of basilar insufficiency. This phenomenon, described in 1961 by Reivich and colleagues, was referred to by Fisher as the *subclavian steal*. Its most notable features are vertigo and sometimes other brainstem signs coupled with transient weakness on exercise of the left arm. There may also be headache and claudication or pain of the arm.

Less often, occlusion of the vertebral artery or one of its medial branches produces an infarct that involves the medullary pyramid, the medial lemniscus, and the emergent hypoglossal fibers; the resultant syndrome consists of a contralateral paralysis of arm and leg (with sparing of the face), contralateral loss of position and vibration sense, and ipsilateral paralysis and later atrophy of the tongue. This is the *medial medullary syndrome* (Fig. 34-13). A more limited lesion, from occlusion of one spinal artery arising from the vertebral artery, gives rise to a contralateral hemiplegia (rarely a quadriplegia) that spares the face. When the vertebral branch to the anterior spinal artery is blocked, flow from the other (corresponding) branch is usually sufficient to prevent infarction of the cervical cord, but we and others have described pyramidal infarction with hemiplegia that spares the face. Occlusion of a vertebral artery low in the neck is usually compensated by anastomotic flow to the upper part of the artery via the thyrocervical, deep cervical, and occipital arteries or reflux from the circle of Willis. **Lateral Medullary Syndrome** Known also as the *Wallenberg syndrome* (who described a case in 1895), this common stroke is produced by infarction of a wedge of lateral medulla lying posterior to the inferior olive nucleus (Fig. 34-13). The complete syndrome, as outlined by Fisher and colleagues (1961), comprises involvement of the vestibular nuclei (vertigo, nystagmus, oscillopsia, vomiting); spinothalamic tract (contralateral or, less often, ipsilateral impairment of pain and thermal sense over half the body); descending sympathetic tract (ipsilateral Horner syndrome—mio-

Figure 34-13 (Continued).

Signs and symptoms	Structures involved
1. Medial medullary syndrome (occlusion of vertebral artery or branch of vertebral or lower basilar artery)	
a. On side of lesion	Issuing twelfth nerve
(1) Paralysis with later hemiatrophy of the tongue	
b. On side opposite lesion	Pyramidal tract
(1) Paralysis of arm and leg sparing face	Medial lemniscus
(2) Impaired tactile and proprioceptive sense over half the body	
2. Lateral medullary syndrome (occlusion of any of five vessels may be responsible—vertebral, posterior inferior cerebellar, or superior, middle, or inferior lateral medullary arteries)	
a. On side of lesion	Descending tract and nucleus of fifth nerve
(1) Pain, numbness, impaired sensation over half the face	Uncertain—restiform body, cerebellar hemisphere, olivocerebellar fibers, spinocerebellar tract (?)
(2) Ataxia of limbs, falling to side of lesion	Vestibular nuclei and connections
(3) Vertigo, nausea, vomiting	Vestibular nuclei and connections
(4) Nystagmus, diplopia, oscillopsia	Descending sympathetic tract
(5) Horner syndrome (miosis, ptosis, decreased sweating)	Issuing fibers ninth and tenth nerves
(6) Dysphagia, hoarseness, paralysis of vocal cord, diminished gag reflex	
(7) Loss of taste (rare)	Nucleus and tractus solitarius
(8) Numbness of ipsilateral arm, trunk, or leg	Cuneate and gracile nuclei
(9) Hiccup	Uncertain
b. On side opposite lesion	Spinothalamic tract
(1) Impaired pain and thermal sense over half the body, sometimes face	
3. Total unilateral medullary syndrome (occlusion of vertebral artery); combination of medial and lateral syndromes	
4. Lateral pontomedullary syndrome (occlusion of vertebral artery); combination of medial and lateral syndromes	
5. Basilar artery syndrome (the syndrome of the lone vertebral artery is equivalent); a combination of the various brainstem syndromes plus those arising in the posterior cerebral artery distribution. The clinical picture comprises bilateral long-tract signs (sensory and motor) with cerebellar and cranial nerve abnormalities.	
a. Paralysis or weakness of all extremities, plus all bulbar musculature	Corticobulbar and corticospinal tracts bilaterally
b. Diplopia, paralysis of conjugate lateral and/or vertical gaze, internuclear ophthalmoplegia, horizontal and/or vertical nystagmus	Ocular motor nerves, apparatus for conjugate gaze, medial longitudinal fasciculus, vestibular apparatus
c. Blindness, impaired vision, various visual field defects	Visual cortex
d. Bilateral cerebellar ataxia	Cerebellar peduncles and the cerebellar hemispheres
e. Coma	Tegmentum of midbrain, thalamus
f. Sensation may be strikingly intact in the presence of almost total paralysis. Sensory loss may be syringomyelic or the reverse or involve all modalities	Medial lemniscus, spinothalamic tracts or thalamic nuclei

sis, ptosis, decreased sweating); issuing fibers of the ninth and tenth nerves (hoarseness, dysphagia, ipsilateral paralysis of the palate and vocal cord, diminished gag reflex); otolithic nucleus (vertical diplopia and illusion of tilting of vision); olivocerebellar and/or spinocerebellar fibers and restiform body and inferior cerebellum (*ipsilateral* ataxia of limbs, falling or toppling to the *ipsilateral* side, or lateropulsion); descending tract and nucleus of the fifth nerve

(pain, burning, and impaired sensation over *ipsilateral* half of the face); nucleus and tractus solitarius (loss of taste); and rarely cuneate and gracile nuclei (numbness of *ipsilateral* limbs). Fragmentary syndromes are more frequent at the onset of the stroke; the fragmentary syndromes are vertigo and ptosis, toppling and vertical diplopia, hoarseness and disequilibrium, etc. Vertigo alone, however, is not an indication of lateral medullary infarction. The small-

est infarction we have studied gave rise only to symptoms of lateral pulsion and mild ipsilateral limb ataxia.

The eye signs of lateral medullary infarction may be difficult to interpret. Often there is a fragment of an internuclear ophthalmoplegia or a skew deviation (the globe on the affected side usually higher). Direction changing nystagmus (with different head positions) is said to be the most useful feature that distinguishes labyrinthine disease from brainstem forms of nystagmus, but infarction of the vestibular nucleus as part of the lateral medullary syndrome may also show this sign (see also Chap. 15).

The entire lateral medullary syndrome, one of the most striking in neurology, is almost always due to infarction, with only a small number of cases being the result of hemorrhage or tumor. Although it was traditionally attributed to occlusion in the course of the posterior inferior cerebellar artery (PICA), careful studies have shown that in 8 out of 10 cases it is the vertebral artery that is occluded by atherosclerosis; in the remainder, either the posterior inferior cerebellar artery or one of the lateral medullary arteries is occluded. Embolism is a less frequent cause. The inferior cerebellum is usually affected, causing vomiting, vertigo, and ataxia.

In recent years, we have become aware from our own patients that although most of those with lateral medullary infarction do well and have considerable recovery, sudden and unexpected death may occur from respiratory or cardiac arrest, sometimes even in the absence of cerebellar swelling or basilar artery thrombosis. Cases of this nature have been reviewed by Norving and Cronqvist. The related and important issue of cerebellar swelling after vertebral artery or PICA occlusion and the subsequent need for surgery is discussed under "Treatment of Cerebral Edema and Raised Intracranial Pressure," later in the chapter.

Basilar Artery The branches of the basilar artery may be instructively grouped as follows: (1) paramedian, 7 to 10 in number, supplying a wedge of pons on either side of the midline; (2) short circumferential, 5 to 7 in number, supplying the lateral two-thirds of the pons and the middle and superior cerebellar peduncles; (3) long circumferential, 2 on each side (the superior and anterior inferior cerebellar arteries), which run laterally around the pons to reach the cerebellar hemispheres (Figs. 34-11 and 34-12); and (4) several paramedian (interpeduncular) branches at the bifurcation of the basilar artery and origins of the posterior cerebral arteries supplying the high midbrain and medial subthalamic regions. These interpeduncular and other short proximal branches of the posterior cerebral artery have been described above.

The picture of basilar artery occlusion due to thrombosis may arise in several ways: (1) occlusion of the basilar artery itself, usually in the lower or middle third at the site of an atherosclerotic plaque and superimposed thrombosis; (2) occlusion of both vertebral arteries; and (3) occlusion of a single vertebral artery when it is the only one of adequate size. Also, thrombosis may involve a branch of the basilar artery rather than the trunk (*basilar branch occlusion*). When there is embolism, the clot usually lodges at the upper bifurcation of the basilar or in one of the posterior cerebral arteries, since the embolus, if it is small enough to pass through the vertebral artery, easily traverses the length of the basilar artery, which is of greater diameter than either vertebral artery. The syndrome of *basilar artery occlusion*, as delineated by Kubik and Adams, reflects the involvement of a large number of structures: corticospinal and corticobulbar tracts, cerebellum, middle and superior cerebellar peduncles, medial and lateral lemnisci, spinothalamic

tracts, medial longitudinal fasciculi, pontine nuclei, vestibular and cochlear nuclei, descending hypothalamospinal sympathetic fibers, and the third through eighth cranial nerves (the nuclei and their segments within the brainstem).

The *complete basilar syndrome* comprises bilateral long tract signs (sensory and motor) with variable cerebellar, cranial nerve, and other segmental abnormalities of the brainstem. Often the patient is comatose because of ischemia of the high midbrain reticular activating system. Others are mute and quadriplegic but conscious, reflecting interruption of descending motor pathways in the base of the pons but sparing of the reticular activating system ("locked-in" syndrome; see page 305). Midbasilar disease may also cause coma if the posterior communicating arteries are inadequate to perfuse the distal basilar artery territory. In the presence of the full syndrome, it is usually not difficult to make the correct diagnosis. The aim should be, however, to recognize basilar insufficiency long before the stage of total deficit has been reached. The early manifestations (in the form of TIAs) occur in many combinations, described in detail further on (page 692).

Basilar Branch Occlusion Occlusion of branches at the bifurcation (top) of the basilar artery results in a remarkable number of complex syndromes that include, in various combinations, somnolence or coma, memory defects, akinetic mutism, visual hallucinations, ptosis, disorders of ocular movement (convergence spasm, paralysis of vertical gaze, retraction nystagmus, pseudoabducens palsy, retraction of upper eyelids, skew deviation of the eyes), an agitated confusional state, and visual defects. These have been reviewed by Petit and coworkers and Castaigne and associates as paramedian thalamic, subthalamic, and midbrain infarction syndromes and by Caplan as the "top of the basilar" syndrome.

The main signs of occlusion of the *superior cerebellar artery* are ipsilateral cerebellar ataxia of the limbs (middle and/or superior cerebellar peduncles); nausea and vomiting; slurred speech; and loss of pain and thermal sensation over the opposite side of the body (spinothalamic tract). Partial deafness, static tremor of the ipsilateral upper extremity, an ipsilateral Horner syndrome, and palatal myoclonus have also been reported, but we have not seen these.

With occlusion of the *anteroinferior cerebellar artery* (AICA), the extent of the infarct is extremely variable, since the size of this artery and the territory it supplies vary inversely with the size and territory of supply of the posteroinferior cerebellar artery (PICA). The principal findings are vertigo, vomiting, nystagmus, tinnitus and sometimes unilateral deafness; facial weakness; ipsilateral cerebellar ataxia (inferior or middle cerebellar peduncle); an ipsilateral Horner syndrome and paresis of conjugate lateral gaze; and contralateral loss of pain and temperature sense of the arm, trunk, and leg (lateral spinothalamic tract). The tinnitus may be overwhelming, called "screaming" by some of our patients. If the occlusion is close to the origin of the artery, the corticospinal fibers may also be involved, producing a hemiplegia; if distal, there may be cochlear and labyrinthine infarction. Cerebellar swelling has not occurred in our cases or in the 20 collected by Amarenco and Hauw.

The most characteristic manifestation of all these branch or division brainstem infarcts is the "crossed" cranial nerve and long tract sensory or motor deficit. These crossed syndromes, which may involve cranial nerves III through XII, are listed in Table 34-3. Although the finding of bilateral neurologic signs strongly suggests brainstem involvement, it must be emphasized that in many instances of infarction within the basilar territory, the signs are lim-

Table 34-3
Intramedullary (brainstem) syndromes

EPONYM ^a	SITE	CRANIAL NERVES INVOLVED	TRACTS INVOLVED	SIGNS	USUAL CAUSE
Weber syndrome	Base of midbrain	III	Corticospinal tract	Oculomotor palsy with crossed hemiplegia	Vascular occlusion, tumor, aneurysm
Claude syndrome	Tegmentum of midbrain	III	Red nucleus and brachium conjunctivum	Oculomotor palsy with contralateral cerebellar ataxia and tremor	Vascular occlusion, tumor, aneurysm
Benedikt syndrome	Tegmentum of midbrain	III	Red nucleus, corticospinal tract, and brachium conjunctivum	Oculomotor palsy with contralateral cerebellar ataxia, tremor, and corticospinal signs	Infarct, hemorrhage, tuberculoma, tumor
Nothnagel syndrome	Tectum of midbrain	Unilateral or bilateral III	Superior cerebellar peduncles	Ocular palsies, paralysis of gaze, and cerebellar ataxia	Tumor
Parinaud syndrome	Dorsal midbrain		Supranuclear mechanism for upward gaze and other structures in periaqueductal gray matter	Paralysis of upward gaze and accommodation; fixed pupils	Pinealoma, and other lesions of dorsal midbrain, hydrocephalus
Millard-Gubler syndrome and Raymond-Foville syndrome	Base of pons	VII and often VI	Corticospinal tract	Facial and abducens palsy and contralateral hemiplegia; sometimes gaze palsy to side of lesion	Infarct, or tumor
Avellis syndrome	Tegmentum of medulla	X	Spinothalamic tract; sometimes descending pupillary fibers, with Bernard-Horner syndrome	Paralysis of soft palate and vocal cord and contralateral hemianesthesia	Infarct, or tumor
Jackson syndrome	Tegmentum of medulla	X, XII	Corticospinal tract	Avellis syndrome plus ipsilateral tongue paralysis	Infarct, or tumor
Wallenberg syndrome	Lateral tegmentum of medulla	Spinal V, IX, X, XI	Lateral spinothalamic tract Descending pupillodilator fibers Spinocerebellar and olivocerebellar tracts	Ipsilateral V, IX, X, XI palsy, Horner syndrome and cerebellar ataxia; contralateral loss of pain and temperature sense	Occlusion of vertebral or posterior-inferior cerebellar artery

ited to one side of the body, with or without cranial nerve involvement, indicating occlusion of a branch of the main artery, not of the trunk.

Another feature of note is that it is not possible to distinguish a hemiplegia of pontine origin from one of deep cerebral origin on the basis of motor signs alone. In both, the face, arm, hand, leg, and foot are affected. With brainstem lesions as with cerebral ones, a flaccid paralysis gives way to spasticity after a few days or weeks, and there is no satisfactory explanation for the variability in this period of delay or for the occurrence in some cases of spasticity from the onset of the stroke. There may also be a combined hemiparesis and ataxia of the limbs on the same side. Localization of brainstem hemiplegia depends on coexisting neurologic signs. With a hemiplegia of pontine origin, the eyes may deviate to the side of the paralysis, i.e., the opposite of what occurs with supratentorial lesions. The pattern of sensory disturbance may be helpful. A dissociated sensory deficit over the ipsilateral face and contralateral half of the body usually indicates a lesion in the lower brainstem, while a hemisensory loss including the face and involving all modalities indicates a lesion in the upper brainstem, in the thalamus, or deep in the white matter of the parietal lobe. When position sense, two-point discrimination, and tactile localization are affected relatively more than pain or thermal and tactile sense, a cerebral lesion is suggested; the converse indicates a brainstem localization. Bilaterality of both motor and sensory signs is almost certain evidence that the lesion lies in the brainstem. When hemiplegia or hemiparesis and sensory loss are coextensive, the lesion usually lies supratentorially. Additional manifestations that point unequivocally to a brainstem site are rotational dizziness, diplopia, cerebellar ataxia, a Horner syndrome, and deafness. The several brainstem syndromes illustrate the important point that the cerebellar pathways, spinothalamic tract, trigeminal nucleus, and sympathetic fibers can be involved at different levels, and “neighboring” phenomena must be used to identify the exact site.

A myriad of proper names have been applied to the brainstem syndromes, as noted in Tables 34-3 and 47-1 (page 1180). Most of them were originally described in relation to tumors and other nonvascular diseases. The diagnosis of vascular disorders in this region of the brain is not greatly facilitated by a knowledge of these eponymic syndromes; it is much more profitable to memorize the anatomy of the brainstem. The principal syndromes to be recognized are the full basilar, vertebral-PICA, posteroinferior cerebellar, anteroinferior cerebellar, superior cerebellar, pontomedullary, and medial medullary. Figures 34-13 to 34-16, supplied by C. M. Fisher and used in all previous editions of this book, present both medial and lateral syndromes at four levels of the medulla and pons. Other syndromes can usually be identified as fragments or combinations of the major ones.

Lacunar Syndromes

As one might surmise, small penetrating branches of the cerebral arteries may become occluded, and the resulting infarcts may be so small or so situated as to cause no symptoms whatsoever. As the softened tissue is removed, it leaves a small cavity, or lacune. Early in the twentieth century, Pierre Marie confirmed the occurrence of multiple deep small cavities of this type, first described by Durant-Fardel in 1843. Marie referred to the condition as *état lacunaire*. He distinguished these lesions from a fine loosening of tissue around thickened vessels that enter the anterior and posterior perforated spaces, a change to which he gave the name *état criblé*. Pathologists have not always agreed on these distinctions, but we

have adhered to the view of Fisher and Adams that lacunes are always due to occlusion of small arteries, 50 to 200 mm in diameter, and the cribriform state to mere thickening of vessels and fraying of the surrounding tissue—i.e., dilated perivascular spaces that do not correlate with neurologic disease.

In almost all clinical and pathologic material, there has always been a strong relationship between the lacunar state and a combination of hypertension and atherosclerosis and, to a lesser degree, with diabetes. Sacco and colleagues (1991), in a population-based study in Rochester, Minnesota, found hypertension in 81 percent of patients with lacunar infarctions. In our view, the basis of the lacunar state is unusually severe atherosclerosis that has extended into the finest branches of large arteries.

When Fisher examined a series of such lesions in serial sections, from a basal parent artery up to and through the lacuna, he found atheroma and thrombosis at the mouth of the branch vessels and less often embolic occlusion of small vessels to be the basic abnormality in some (usually the larger) lacunae, and a lipohyalin degeneration and occlusion in the initial course of small vessels in the smaller ones. In some, lipohyalinotic changes had resulted in false aneurysm formation, resembling the Charcot-Bouchard aneurysms that underlie brain hemorrhage (see further on). In a series of 1042 consecutive adults whose brains were examined postmortem in past decades, Fisher observed one or more lacunae in 11 percent. He found 4 to 6 and sometimes up to 10 to 15 lacunae in any given brain specimen. In recent years, better treatment of hypertension appears to us to have reduced this number, at least as judged by MRI. Lacunae are situated, in descending order of frequency, in the putamen and caudate nuclei, thalamus, basis pontis, internal capsule, and deep hemispherical white matter. The cavities range from 3 to 15 mm in diameter, and whether they cause symptoms depends entirely on their location.

Fisher has delineated the more frequent symptomatic forms:

1. Pure motor hemiplegia
2. Pure sensory stroke
3. Clumsy hand–dysarthria
4. Ipsilateral hemiparesis–ataxia

If the lacuna lies in the territory of a lenticulostriate artery, i.e., in the internal capsule or adjacent corona radiata, it causes a *pure motor hemiplegia* involving the face, arm, hand, leg, and foot. A lacuna situated in the ventral pons may cause an identical syndrome. Symptoms may be abrupt in onset or evolve over several hours, but in some instances (10 of 34 cases, according to Weisberg) the neurologic deficit evolves stepwise and relatively slowly, over as long a period as 2 to 3 days, thereby simulating a small hemorrhage. CT scanning shows the lesions in about two-thirds of cases if several days have passed, and MRI in almost all cases within hours of the stroke. Sometimes the motor disorder takes the form of a more limited hemiplegia of the face and arm or arm and leg, or a dysarthria with or without hemiplegia. Recovery, which may begin within hours, days, or weeks, is sometimes nearly complete, even in the face of a severe initial stroke. However, many patients are left with some degree of clumsiness or slowness of movement of the affected side.

Similarly, a lacuna of the lateral thalamus or (less often of the parietal white matter) presents as a pure hemisensory defect involving the limbs, face, and trunk extending to the midline, a *pure sensory stroke*. The incidence, course, and outcome are much the same as in a pure hemiplegia.

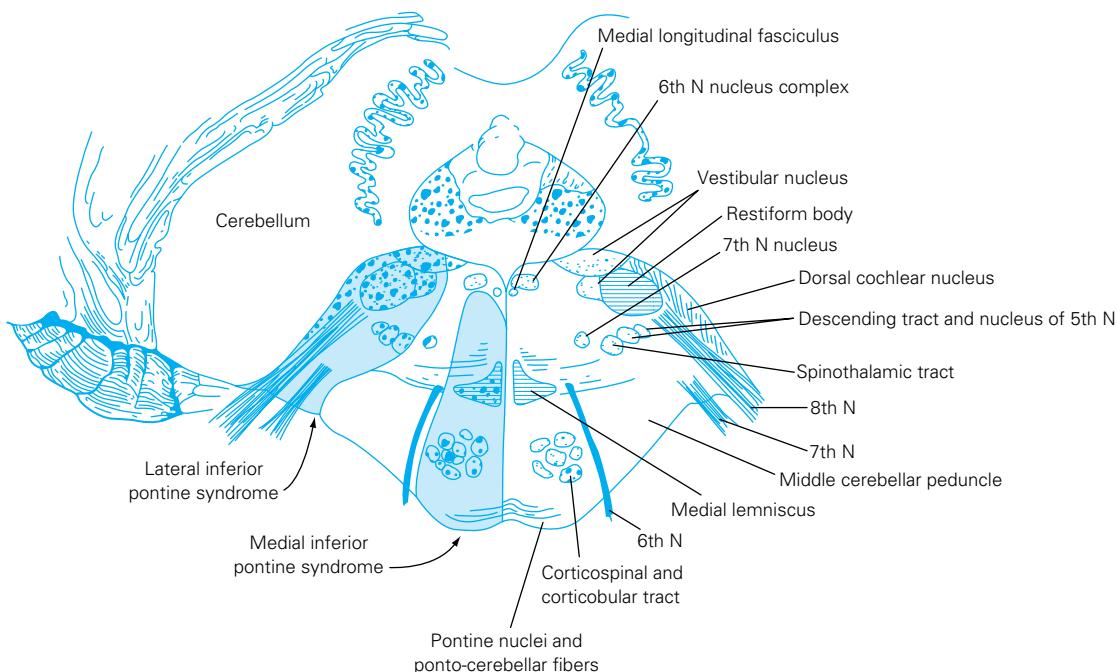

Figure 34-14. Transverse section through the lower pons.

Signs and symptoms	Structures involved
1. Medial inferior pontine syndrome (occlusion of paramedian branch of basilar artery)	
a. On side of lesion	Pontine “center” for lateral gaze—paramedian pontine reticular formation (PPRF)
(1) Paralysis of conjugate gaze to side of lesion (preservation of convergence)	Vestibular nuclei and connections
(2) Nystagmus	Middle cerebellar peduncle
(3) Ataxia of limbs and gait	Abducens nerve or nucleus; PPRF
(4) Diplopia on lateral gaze	Corticobulbar and corticospinal tract in lower pons
b. On side opposite lesion	Medial lemniscus
(1) Paralysis of face, arm, and leg	
(2) Impaired tactile and proprioceptive sense over half of the body	
2. Lateral inferior pontine syndrome (occlusion of anterior inferior cerebellar artery)	
a. On side of lesion	Vestibular nerve or nucleus
(1) Horizontal and vertical nystagmus, vertigo, nausea, vomiting, oscillopsia	
(2) Facial paralysis	Seventh nerve or nucleus
(3) Paralysis of conjugate gaze to side of lesion	Pontine “center” for lateral gaze (PPRF)
(4) Deafness, tinnitus	Auditory nerve or cochlear nuclei
(5) Ataxia	Middle cerebellar peduncle and cerebellar hemisphere
(6) Impaired sensation over face	Main sensory nucleus and descending tract of fifth nerve
b. On side opposite lesion	Spinothalamic tract
(1) Impaired pain and thermal sense over half the body (may include face)	
3. Total unilateral inferior pontine syndrome (occlusion of anterior inferior cerebellar artery); lateral and medial syndromes combined	

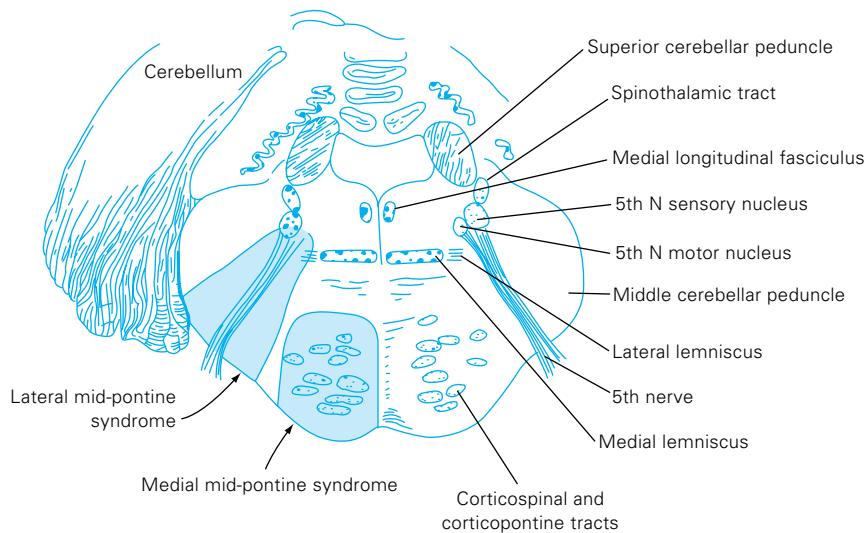

Figure 34-15. Transverse section through the midpons.

Signs and symptoms	Structures involved
1. Medial midpontine syndrome (paramedian branch of midbasilar artery)	
a. On side of lesion	
(1) Ataxia of limbs and gait (more prominent in bilateral involvement)	Middle cerebellar peduncle
b. On side opposite lesion	
(1) Paralysis of face, arm, and leg	Corticobulbar and corticospinal tract
(2) Deviation of eyes	
(3) Variably impaired touch and proprioception when lesion extends posteriorly. Usually the syndrome is purely motor.	Medial lemniscus
2. Lateral midpontine syndrome (short circumferential artery)	
a. On side of lesion	
(1) Ataxia of limbs	Middle cerebellar peduncle
(2) Paralysis of muscles of mastication	Motor fibers or nucleus of fifth nerve
(3) Impaired sensation over side of face	Sensory fibers or nucleus of fifth nerve

As mentioned, in the ventral pons, the lacunar syndrome may be one of pure motor hemiplegia, mimicking that of internal capsular infarction except for relative sparing of the face and the presence of an ipsilateral paresis of conjugate gaze in some cases; or there is a combination of *dysarthria* and *clumsiness* of one hand; in the latter case the lacune is located in the paramedian midpons on the side opposite the clumsy limb. Occasionally a lacunar infarction of the pons, midbrain, internal capsule, or parietal white matter gives rise to a *hemiparesis with ataxia* on the same side as the weakness (Fisher; Sage and Lepore). Some of the brainstem syndromes may blend with basilar branch syndromes. There are many other, less frequent lacunar syndromes, too numerous to tabulate here.

Multiple lacunar infarcts, involving the corticospinal and corticobulbar tracts, are by far the most common cause of pseudobulbar palsy. Undoubtedly, an accumulation of lacunes deep in both hemispheres can give rise to gait disorders and also to mental dulling sometimes referred to as multi-infarct dementia (see further on and pages 373, 691, and 707). The main differential diagnostic considerations are then normal-pressure hydrocephalus (Chap. 31) and degenerative brain conditions that affect the frontal lobes and basal ganglia (Chap. 39).

In all these cases of lacunar infarction, the diagnosis depends essentially on the occurrence of the aforementioned unique stroke syndromes of limited proportions: to recapitulate, pure motor hemiplegia, pure sensory stroke, clumsy-hand with dysarthria, and atactic hemiparesis are the main ones. As mentioned above, MRI is more reliable than CT scanning in demonstrating the lacunes. Initially, lacunes are seen on the MRI as deep oval or linear areas of T2, FLAIR, and especially, diffusion weighted signal abnormality; later they become cavitated. The EEG may be helpful in a negative sense; in the case of lacunes in the pons or the internal capsule, there is a notable discrepancy between the unilateral paralysis or sensory loss and the negligible electrical changes over the affected hemisphere.

THE MAJOR TYPES OF CEREBROVASCULAR DISEASE

In classifying the cerebrovascular diseases, it is most practical, from the clinical viewpoint, to preserve the classic division into thrombosis, embolism, and hemorrhage. The causes of each of the

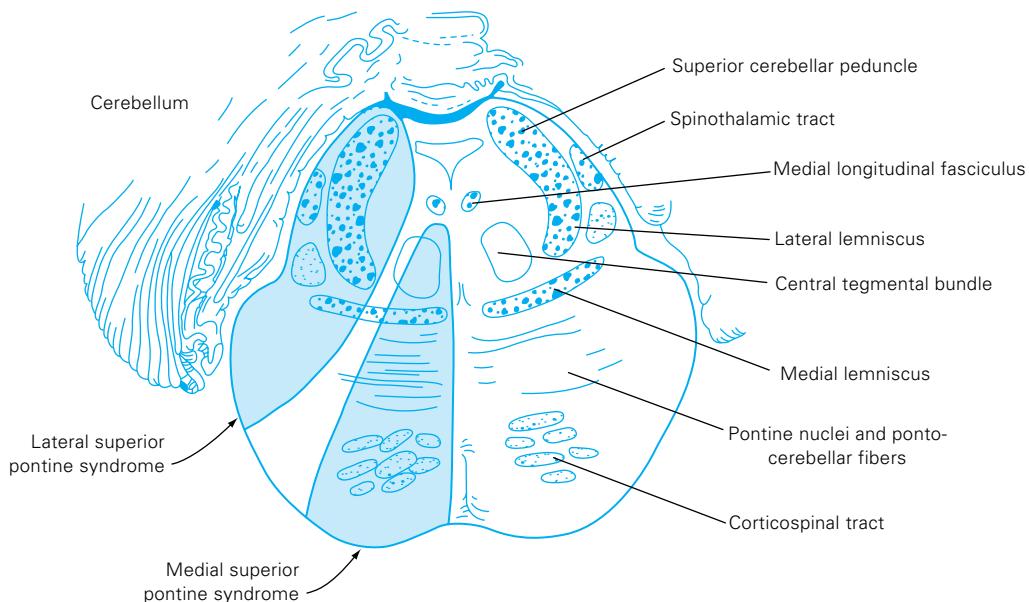

Figure 34-16. Transverse section through the upper pons.

Signs and symptoms	Structures involved
1. Medial superior pontine syndrome (paramedian branches of upper basilar artery)	
a. On side of lesion	
(1) Cerebellar ataxia	Superior and/or middle cerebellar peduncle
(2) Internuclear ophthalmoplegia	Medial longitudinal fasciculus
(3) Rhythmic myoclonus of palate, pharynx, vocal cords, respiratory apparatus, face, oculomotor apparatus, etc.	Central tegmental bundle
b. On side opposite lesion	
(1) Paralysis of face, arm, and leg	Corticobulbar and corticospinal tract
(2) Rarely touch, vibration, and position senses are affected	Medial lemniscus
2. Lateral superior pontine syndrome (syndrome of superior cerebellar artery)	
a. On side of lesion	
(1) Ataxia of limbs and gait, falling to side of lesion	Middle and superior cerebellar peduncles, superior surface of cerebellum, dentate nucleus
(2) Dizziness, nausea, vomiting	Vestibular nuclei Territory of descending branch to middle cerebellar peduncle (occlusion of
(3) Horizontal nystagmus	Vestibular nuclei uncertain
(4) Paresis of conjugate gaze (ipsilateral)	Uncertain
(5) Loss of optokinetic nystagmus	Uncertain
(6) Skew deviation	Uncertain
(7) Miosis, ptosis, decreased sweating over face (Horner syndrome)	Descending sympathetic fibers
b. On side opposite lesion	
(1) Impaired pain and thermal sense on face, limbs, and trunk	Spinothalamic tract
(2) Impaired touch, vibration, and position sense, more in leg than in arm (there is a tendency to incongruity of pain and touch deficits)	Medial lemniscus (lateral portion)

“big three,” along with the criteria for diagnosis and the confirmatory laboratory tests for each, are considered here in separate sections. This classification has the disadvantage of not providing for disorders such as reversible ischemia, hypertensive encephalopathy, and venous thrombosis; these are considered in separate sections later in the chapter.

The frequency of the different types of cerebrovascular disease has been difficult to ascertain. Obviously clinical diagnosis is not always correct, and clinical services are heavily weighted with acute strokes and nonfatal cases of uncertain type. An autopsy series inevitably includes many old vascular lesions, particularly infarcts, whose exact nature cannot always be determined, and there

is a bias also toward large fatal lesions (usually hemorrhages). Table 34-4 summarizes the findings of the Harvard Cooperative Stroke Registry, tabulated in 1978 and comprising 756 successive patients, each of whom was examined by a physician knowledgeable about strokes and subjected when necessary to appropriate ancillary examinations (four-vessel arteriography, CT scan, lumbar puncture, but before the days of MRI). For comparison, we have included an autopsy series of 740 cases, examined during the year 1949 by Fisher and Adams; of these, 179 (nearly 25 percent) had some form of cerebrovascular disease. Interestingly, in both series the ratio of infarcts to hemorrhages was 4:1 and embolism accounted for approximately one-third of all strokes. The above studies correspond reasonably well with more recent data collated in the Stroke Data Bank of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) (Sacco et al, 1989) and other modern series which have had the advantage of MRI.

Atherothrombotic Infarction

Most cerebrovascular disease can be attributed to atherosclerosis and chronic hypertension; until ways are found to prevent or control them, vascular disease of the brain will continue to be a major cause of morbidity. Hypertension and atherosclerosis interact in a variety of ways. Atherosclerosis, by reducing the resilience of large arteries, induces systolic hypertension. In turn, sustained hypertension worsens atherosclerosis, seemingly "driving" it into the walls of small branch arteries (0.5 mm or less). All the coats of the vessel become impregnated with a hyaline-lipid material, a process that Fisher has called *lipohyalinosis*. The segment so affected may also weaken and allow the formation of a small dissecting aneurysm (Charcot-Bouchard aneurysm), which most neuropathologists hold responsible for the hypertensive brain hemorrhage.

The atheromatous process in brain arteries is identical to that in the aorta, coronary, and other large arteries. In general the process in the cerebral arteries runs parallel to but is somewhat less severe than that in the aorta, coronary, and lower limb vessels. There are many exceptions to this rule, however, and not infre-

quently a brain artery becomes occluded when there is no clinical evidence of coronary or peripheral vascular disease. Although atherosclerosis is known to have its onset in childhood and adolescence, only in the middle and late years of life is it likely to have clinical effects. Hypertension, hyperlipidemia, and diabetes greatly aggravate the process. As with coronary and peripheral atherosclerosis, individuals with low blood levels of high-density-lipoprotein (HDL) cholesterol and high levels of low-density-lipoprotein (LDL) cholesterol are particularly disposed to cerebral atherosclerosis (Nubiola et al). Long-duration cigarette smoking, an important factor in the genesis of atherosclerosis, decreases both HDL cholesterol and CBF (Ingall et al). Added to these well-established risk factors is a theorized role of an excess of homocystine and an even more speculative role for chronic inflammation or and intracellular infection of uncertain origin within plaques (*Chlamydia pneumoniae* has been implicated in some studies). Clinical experience indicates that there are families with a predilection for the development of cerebral atherosclerosis, independent of these well-defined risk factors. Obesity is also a risk factor, in part because of its correlation with diabetes.

There is a tendency for atheromatous plaques to form at branchings and curves of the cerebral arteries. *The most frequent sites are in the internal carotid artery, at its origin from the common carotid; in the cervical part of the vertebral arteries and at their junction to form the basilar artery; in the stem or at the main bifurcation of the middle cerebral arteries; in the posterior cerebral arteries as they wind around the midbrain; and in the anterior cerebral arteries as they pass anteriorly and curve over the corpus callosum.* It is rare for the cerebral arteries to develop plaques beyond their first major branching. Also, it is unusual for the cerebellar and ophthalmic arteries to show atheromatous involvement except in conjunction with hypertension. The common carotid and vertebral arteries at their origins from the aorta are frequent sites of atheromatous deposits, but because of abundant collateral arterial pathways, occlusions at these sites are not commonly associated with cerebral ischemia.

The atheromatous lesions develop and grow silently for 20, 30, or more years; only in the event of a thrombotic complication do they become symptomatic. Although atheromatous plaques may narrow the lumen of an artery, causing stenosis, *complete occlusion is nearly always the consequence of superimposed thrombosis ("atherothrombosis")*. In general, the more severe the atherosclerosis, the more likely the thrombotic complication, but the two processes do not always run in parallel. One patient with only scattered atheromatous plaques may thrombose a vessel, whereas another with marked atherosclerosis may have only a few thrombosed vessels or none at all. Atheromatous lesions may regress to some extent under the influence of diet and certain drugs. Hennerici and colleagues followed a series of patients with carotid stenoses for a period of 18 months and observed spontaneous regression in nearly 20 percent of the lesions. In the large majority of cases, however, atherosclerosis is a progressive disease.

Degeneration of the wall of a sclerotic vessel or hemorrhage into the wall (from rupture of the *vasa vasorum*) may damage the endothelium. This is known to occur particularly in the walls of the internal carotid arteries (and the coronary arteries, where it is a main cause of vessel occlusion). The lesion in the atheromatous plaque apparently excites an inflammatory reaction. Platelets and fibrin then adhere to the damaged part of the wall and form delicate, friable clots, or a subintimal atheromatous deposit may slough, spewing crystalline cholesterol emboli into the lumen with result-

Table 34-4
Major types of cerebrovascular diseases and their frequency

ing occlusion of small distal vessels. In contrast to an embolus, a thrombus generally does not occlude the lumen completely from the first moment of its formation; total blockage may occur only after several hours. Once the lumen of the artery has been completely occluded, the thrombus may propagate distally and proximally to the next branching points and block an anastomotic channel.

These several dynamic events in the atherosclerotic-thrombotic process probably account for the prodromal ischemic attacks described below—intermittent blockage of the circulation and variable impairment of function in the vascular territory, before proceeding to permanent ischemia. Not infrequently, several arteries are affected by stenosis and thrombosis over a period of months or years. Then it becomes difficult to decipher the interplay of factors that have led to either transitory or persistent symptoms. Some of the possibilities have been outlined by Adams and colleagues (1961). The evolution of the thrombotic process may be sufficiently prolonged to explain the clinical state known as *stroke in evolution*; when the hemodynamic disturbance stabilizes, the stage of *completed stroke* is reached. These different stages acquire significance in relation to therapy and prognosis.

Pathophysiology of Thrombosis The process of thrombus formation involves an interplay between three components: the endothelium, circulating platelets, and a series of biochemical events that constitute a “coagulative cascade.”

When atherosclerosis is the primary condition, thrombus formation usually begins with a localized injury to the endothelium. As indicated earlier, the endothelium overlying a plaque suffers damage from hemorrhage or necrosis of the vessel wall secondary to an alteration of the vasa vasorum. Thrombus forms from fibrin and platelets that adhere to the endothelial surface and lead to partial or complete occlusion of the lumen. In the process, aggregates of platelets are attracted to the site, partly through the action of prostacyclin (derived from arachidonic acid). Also, a substance called vasomodulin on the surface of the endothelium—which, with protein C, normally inhibits the formation of fibrin through its interaction with thrombin—is reduced at the injured site and induces clotting. Homocystine has a similar effect and is believed thereby to promote thrombosis.

Circulating platelets increase in number locally, enlarge, and become more adherent to one another and to the injured vessel. As they aggregate, they discharge their granules. The latter process is stimulated by thromboxane A₂, which is synthesized in the injured vessel wall. This substance also releases coagulation proteins (including thrombin and Willebrand factor and other elements of the coagulative cascade).

The third component—i.e., of the coagulative cascade—involves the complex interplay of the well known series of factors that results in the formation of thrombin and the conversion of fibrinogen to fibrin. Involved in this process are changes in a number of natural anticoagulative factors such as heparin cofactor 2, antithrombin III, protein C, and protein S. Some of these are extrinsic to the blood vessels and hence may result in thrombosis in one or in multiple sites even without prior vascular injury. Protein C is a vitamin K-dependent protease which, in combination with its cofactors protein S and antithrombin III, inhibits coagulation. A deficiency of any of these factors may predispose to *in situ* thrombosis within either the arterial or venous systems. For example, protein C deficiency (heterozygous in one of every 16,000 individuals) is a cause of thrombosis of both veins and arteries; a resistance

to activated protein C has also been described (causing venous thrombosis almost exclusively). Antiphospholipid antibody is another cause of vascular occlusion that is not incited by damage to the vessel wall (see page 735). The metabolic disturbances in Fabry disease also favor clotting. Persons with certain inflammatory bowel diseases (ulcerative colitis, Crohn disease) are prone to develop thrombotic strokes. Whether inflammation elsewhere in the body also predisposes to cerebral vascular occlusions, as has been suggested, is an open question. Curiously, the hypercoagulable state induced by certain adenocarcinomas, does not produce *in situ* arterial occlusion (although it may precipitate cerebral venous thrombosis). Nevertheless, it does cause platelet-fibrin aggregation on cardiac valves with subsequent cerebral embolism (“marantic endocarditis,” as discussed further on).

These factors should be sought when thrombotic disease in cerebral arteries or veins occurs in children or young adults with unexplained strokes, in families with strokes, in pregnant or parturient women, and in women who are migraineurs or taking birth control pills (see further on). According to Markus and Hambley, whose review of this subject is recommended, screening for lupus anticoagulant, anticardiolipin antibodies, deficiency of proteins C and S, and antithrombin III is probably justified only in these special circumstances. These causes of vascular thrombosis are taken up in later sections.

Clinical Picture of Atherothrombotic Stroke In general, the evolution of clinical phenomena in relation to cerebral thrombosis is more variable than that of embolism and hemorrhage. In more than half of our patients, the main part of the stroke (paralysis or other deficit) is preceded by minor signs or one or more transient attacks of focal neurologic dysfunction, or *TIA*s (Table 34-5). In a sense, these herald the oncoming vascular catastrophe. *A history of such prodromal episodes is of paramount importance in establishing the diagnosis of atherothrombotic stroke.* Only rarely and for unclear reasons are embolism and cerebral hemorrhage preceded by a transient neurologic disorder.

In carotid and middle cerebral artery disease, the transient attacks consist of monocular blindness or of hemiplegia, hemianesthesia, or disturbances of speech and language. In the vertebrobasilar system, the prodromal spells most often take the form of

Table 34-5
Development of the clinical picture in 125 cases of cerebral thrombosis (C. M. Fisher)

CLINICAL DEVELOPMENT	NO. OF CASES	PERCENT
Transient ischemic attacks progressing to a major or minor persistent neurologic deficit	53	42
Stepwise development of a stroke, with or without transient ischemic attacks	23	18
Stroke developing as a single event:		
Abrupt (hours), with or without fluctuations	14	11
Slow, gradual (a few days), with or without minor fluctuations	7	6
Transient ischemic attacks only	17	14
Development of a limited stroke followed by transient ischemic attacks	11	9

episodes of vertigo, diplopia, numbness, impaired vision in one or both visual fields, and dysarthria. These TIA syndromes are described more fully further on. Such attacks last from a few minutes to several hours; in most instances the duration is less than 10 min. Those of several hours' duration have a different connotation, since they are usually due to demonstrable embolism. The final stroke may be preceded by one or two attacks or a hundred or more brief TIAs, and the stroke may follow the onset of the attacks by hours, days, or less frequently by weeks or months. When there are no prodromal ischemic attacks, one must use other criteria to establish the diagnosis of atherosclerotic thrombosis.

The thrombotic stroke, whether or not it is preceded by warning attacks, finally develops in one of several ways. Most often there is a single episode but the whole illness evolves over a few hours or less. More characteristic is a "stuttering" or intermittent progression of neurologic deficits extending over several hours or a day or longer. This is a starkly different profile from the abrupt onset of a complete stroke syndrome that characterizes the embolic mechanism discussed further on. Again, in thrombosis a partial stroke may occur and even recede temporarily for several hours, after which there is rapid progression to the completed stroke—or several fleeting episodes may be followed by a longer one and, hours or a day or two later, by a major stroke. Several parts of the body may be affected at once or only one part, such as a limb or one side of the face, the other parts becoming involved serially in step-like fashion until the stroke is fully developed. Sometimes the deficit is episodic; spells of weakness or involuntary movement of a hand or arm or dimness of vision, lasting 5 to 10 min, occur spontaneously or are brought on by standing or walking. Each of the transient attacks and the abrupt episodes of progression reproduces the profile of the stroke in miniature. The principle of intermittency seems to characterize the thrombotic process from beginning to end.

As frequent as the modes of onset outlined above, and most characteristic of atherothrombotic events, is the occurrence of the stroke during sleep; the patient awakens paralyzed, either during the night or in the morning. Unaware of any difficulty, he may arise and fall helplessly to the floor with the first step. This is the story in fully 60 percent of our patients with thrombotic strokes and in a smaller number with embolic ones as well.

Most deceptive of all are the relatively few patients in whom the neurologic disorder has evolved over several days or even longer, in a slow, gradual fashion ("slow stroke"). One's first impulse is to make a diagnosis of brain tumor, abscess, or subdural hematoma. This error can usually be avoided by a careful analysis of the course of the illness, which will disclose an uneven, saltatory progression; if the clinical data are incomplete, observation for a few days makes the stroke profile more apparent. Actually there are a few cases—and these are usually instances of pure motor hemiplegia—in which the evolution of a thrombotic stroke is evenly progressive over a period of days.

In addition to these several modes of evolution of atherothrombotic stroke, thrombotic stenosis or occlusion of certain large vessels may lead instead to the generation of embolic fragments (*artery-to-artery embolus*), thereby precipitating a new stroke in a region distal to the occlusion. This is most likely to occur during the period of clinical fluctuation and active thrombus formation. The most common occurrence of artery-to-artery embolism is with carotid artery thrombosis, the embolus passing to branches of the ipsilateral middle or anterior cerebral artery. With atherothrombotic blockage of the vertebral or lower basilar artery, the embolus orig-

inates in the occluded vessel but then proceeds to lodge in the posterior cerebral artery or the top of the basilar artery. In most of the cases of this nature that we have observed, there are additional telltale signs of slight pontine strokes (dysarthria, diplopia, see page 702.), presumably from the transient occlusion of the mouths of several small penetrating arteries as the embolus moves upward ("stop-and-go" or "traveling" embolus syndrome).

Arterial thrombosis is not usually accompanied by headache, but lateralized cranial pain occurs in some cases. Usually the pain is located on one side of the head in carotid occlusion, at the back of the head, or simultaneously in forehead and occiput in basilar occlusion, and behind the ipsilateral ear or above the eyebrow in vertebral occlusion. The headache is less severe and more regional than that of intracerebral or subarachnoid hemorrhage, and there is no stiffness of the neck. The mechanism is unclear; presumably it is related to the disease process or distention of the vessel wall, since it may antedate the other manifestations of the stroke by days or even weeks.

As mentioned in the introductory section, hypertension is more often present than not in patients with atherothrombotic infarction. Diabetes mellitus is common also, or the patient is a smoker or hyperlipidemic. Often there is evidence of vascular disease in other parts of the body: a history of coronary occlusion or angina pectoris, an electrocardiographic (ECG) abnormality reflecting a previous myocardial infarction or left ventricular hypertrophy, intermittent claudication, or an absence of one or several pulses in the lower limbs. The retinal arteries may show uniform or focal narrowing, increase and irregularity of the light reflex, and arteriovenous "nicking," but these findings correlate with hypertension rather than atherosclerosis. The patient is more often elderly but may be in the fourth decade of life or even younger.

Laboratory Findings These have been discussed at various points in the preceding pages and need only be recapitulated briefly. In the laboratory investigation of atherothrombotic infarction, one may employ noninvasive techniques. Ultrasonography will reveal with fair accuracy the cervical and intracranial segments of the internal carotid and vertebrobasilar arteries. MRI is more sensitive to ischemic brain damage than is the CT scan. While the latter reveals hemorrhage immediately after it occurs, softened tissue cannot be seen until several days have elapsed. On the other hand, MRI reveals ischemic damage within a few hours, in both white and gray matter, and diffusion-weighted MRI techniques do so even earlier. The various MRI sequences are able to distinguish with reasonable clarity the age of cerebral infarction; the features that signify acute, subacute, and older strokes are summarized in Table 34-6 and discussed in Chap. 2. By MRA, one can see all the major cervical and intracranial arteries and may detect the irregular lumen or occlusion of atherosclerosis and even embolic occlusions in more distal vessels (Fig. 34-17). This method has to a large extent replaced conventional angiography, which is reserved for cases in which the diagnosis is in doubt (e.g., suspected angiitis) or when surgical intervention or long-term anticoagulant therapy is contemplated.

Lumbar puncture is now performed infrequently in patients with stroke. Cerebral thrombosis does not cause blood to enter the CSF. The CSF protein is sometimes slightly elevated (usually 50 to 80 mg/dL); rarely is it in excess of 100 mg/dL. A small number of polymorphonuclear leukocytes (3 to 8/mm³) is not exceptional in the first few days; very rarely, and for unexplained reasons, a brisk, transient pleocytosis (400 to 1000 polymorphonuclear leu-

Table 34-6
MRI sequences in the diagnosis of stroke

SEQUENCE	TE	TR	GOOD FOR	BRIGHT	DARK
T1-weighted	<50	<1000	Subacute blood, contusions, CSF disorders	CSF, bone, edema, deoxyhemoglobin mineralization	
T2-weighted	>80	>2000	Infarcts, inflammation, tumors	CSF, liquids, edema	Solids, calcium
Proton (spin) Density	<50	>2000		"Most pathology"	Fat, water, acute blood
Fluid-attenuated inversion recovery (FLAIR)	>80	>10,000	Edema, inflammation	Edema, inflammation, gliosis	CSF; otherwise like T2
Diffusion-weighted image (DWI)			Acute infarcts		Blood after several days
Susceptibility sequence			Hemorrhages, calcification		
Short tau inversion recovery (STIR)			Spine and orbit studies (eliminates fat signals)		blood

kocytes per cubic millimeter) occurs on about the third day. A persistent pleocytosis, however, suggests a chronic meningitis (syphilis, tuberculosis, cryptococcosis), granulomatous arteritis, septic embolism, thrombophlebitis, or a nonvascular process as the cause of vascular occlusion.

Serum cholesterol, triglycerides, or both are elevated in many cases, but normal values are not helpful. The EEG is of value in distinguishing large strokes from lacunes, as already mentioned. The changes in the EEG overlying a cortical infarct may normalize during the subsequent several months.

Course and Prognosis When the patient is seen early in the course of cerebral thrombosis, it is difficult to give an accurate prognosis. One must ask where the patient stands in the stroke process at the time of the examination. Is worsening to be antici-

pated or not? No rules have yet been formulated that allow one to predict the early course with confidence. A mild paralysis today may become a disastrous hemiplegia tomorrow, or the patient's condition may worsen only temporarily for a day or two. Anticoagulation and thrombolytic therapy may alter the course, as discussed further on. In basilar artery occlusion, dizziness and dysphagia may progress in a few days to total paralysis and deep coma. The course of cerebral thrombosis is so often progressive that a cautious attitude on the part of the physician in what first appears to be a mild stroke is justified.

As indicated above, progression of the stroke is due most often to increasing stenosis and occlusion of the involved artery by mural thrombus. In some instances, extension of the thrombus along the vessel may block side branches and hinder anastomotic flow. In the basilar artery, thrombus may gradually build up along its entire

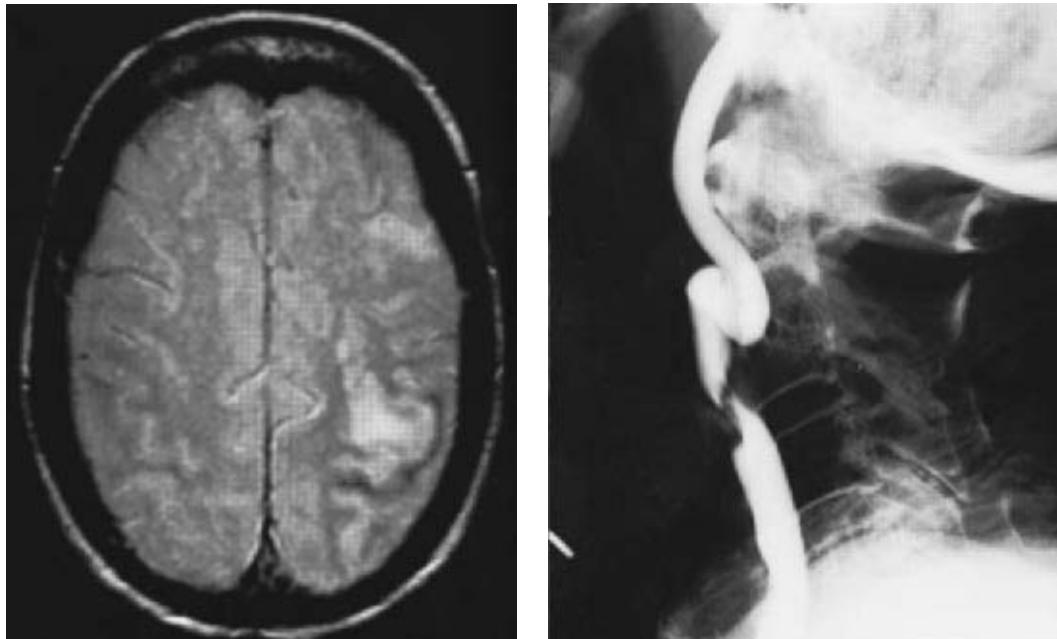

Figure 34-17. Left carotid stenosis with border zone infarction demonstrated by MRI. Conventional angiography (right) show severe stenosis of the left internal carotid artery. The patient was a 72-year-old woman with acute onset of right hemiplegia.

length. In the carotid system, thrombus at times propagates distally from the site of origin in the neck to the supraclinoid portion and possibly into the anterior cerebral artery, preventing collateral flow from the opposite side. In middle cerebral occlusion, retrograde thrombosis may extend to the mouth of the anterior cerebral, perhaps secondarily leading to infarction of the territory of that vessel. And finally, abrupt progression of a stroke may be the result of artery-to-artery embolism, as described above.

Several other circumstances influence the *immediate prognosis* in cerebral thrombosis. In the case of very large infarcts, swelling of the infarcted tissue may occur, followed by displacement of central structures, transtentorial herniation, and death of the patient after several days (Fig. 34-18). This can be anticipated by the sheer volume of the infarct and is usually evident on the CT or MRI scan within a day of the stroke. Smaller infarcts of the inferior surface of the cerebellum may also cause a fatal herniation into the foramen magnum. Milder degrees of swelling and increased intracranial pressure may progress slightly for 2 to 3 days but do not prove fatal. In extensive brainstem infarction associated with deep coma due to basilar artery occlusion, the early mortality rate approaches 40 percent. In any type of stroke, if coma or stupor is present from the beginning, survival is largely determined by success in keeping the airway clear, controlling brain swelling, preventing aspiration pneumonia, and maintaining fluid and electrolyte balance, as described further on under "Treatment of Cerebral Edema and Raised Intracranial Pressure." With smaller thrombotic infarcts, the mortality is 3 to 6 percent, much of it from myocardial infarction and aspiration pneumonia.

As for the *eventual or long-term prognosis* of the neurologic deficit, there are many possibilities. Improvement is the rule if the patient survives. The patient with a lacunar infarct and pure motor hemiparesis usually fares well. With other small infarcts, recovery may start within a day or two, and restoration may be complete or

nearly complete within a week. In cases of severe deficit, there may be no significant recovery; after months of assiduous efforts at rehabilitation, the patient may remain bereft of speech and understanding, with the upper extremity still useless and the lower extremity serving only as an uncertain prop during attempts to walk. Between these two extremes there is every gradation of recovery. In general, and not surprisingly, the longer the delay in onset of recovery, the poorer the prognosis. Measurement of central motor conduction by magnetic stimulation has been predictive of recovery and survival but is not widely used for clinical work. If clinical recovery does not begin in 1 or 2 weeks, the outlook is gloomy for both motor and language functions. Constructional apraxia, uninhibited anger (with left and rarely with right temporal lesions), nonsensical logorrhea and placidity, unawareness of the paralysis and neglect (with nondominant parietal lesions), and confusion and delirium (with nondominant temporal lesions) all tend to diminish and may disappear within a few weeks. A hemianopia that has not cleared in a few weeks will usually be permanent, although reading and color discrimination may continue to improve. In lateral medullary infarction, difficulty in swallowing may be protracted, lasting 4 to 8 weeks or longer; yet relatively normal function is finally restored in nearly every instance. Aphasia, dysarthria, cerebellar ataxia, and walking may improve for a year or longer, but for all practical purposes it may be said that whatever motor and language deficits remain after 5 to 6 months will be permanent.

Characteristically, the paralyzed muscles are flaccid in the first days or weeks following a stroke; the tendon reflexes are usually unchanged but may be slightly increased or decreased. Gradually spasticity develops, and the tendon reflexes become brisker. The arm tends to assume a flexed adducted posture and the leg an extended one. Function is rarely if ever restored after the slow evolution of spasticity (however, the use of botulinum toxin may help considerably in relieving the spasticity). Conversely, the early de-

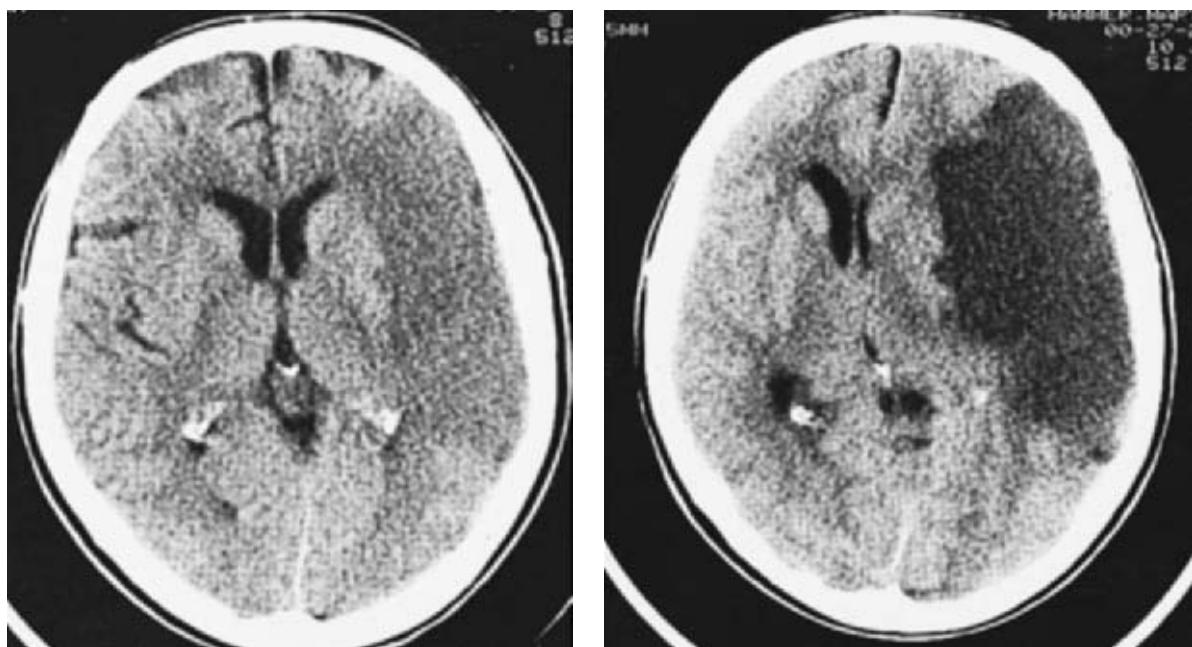

Figure 34-18. Massive ischemic infarct of left cerebral hemisphere mainly in the distribution of the superior division of the middle cerebral artery. CT scans taken 24 h (left) and 72 h (right) following the onset of neurologic symptoms. The second scan demonstrates marked swelling of the infarcted tissue and displacement of central structures.

velopment of spasticity in the arm or the early appearance of a grasp reflex may presage a favorable outcome. In some patients with extensive temporoparietal lesions, the hemiplegia remains flaccid; the arm dangles and the slack leg must be braced to stand. The physiologic explanation of this remains obscure. If the internal capsule is not interrupted completely in a stroke that involves the lenticular nucleus or thalamus, the paralysis may give way to hemichoreoathetosis, hemitremor, or hemiataxia, depending upon the particular anatomy of the lesion. Bowel and bladder control usually returns; sphincteric disorders persist in only a few cases. Often the hemiplegic limbs are at first tender and ache on manipulation. Nevertheless, physiotherapy should be initiated early in order to prevent pseudocontracture of muscles and periarthritis at the shoulder, elbow, wrist, knuckles, knee, and ankle. These are frequent complications and often the source of pain and added disability, particularly of the shoulder. Occasionally, atrophy of bone and pain in the hand may accompany the shoulder pain (shoulder-hand syndrome). An annoying feeling of dizziness and unsteadiness often persists after damage to the vestibular system in brain-stem infarcts.

Convulsive (epileptic) seizures are relatively uncommon sequelae of thrombotic strokes in comparison to embolic cortical infarcts, which are followed by seizures in up to 10 percent of patients. Most often in our experience, the EEG in these cases had never normalized and showed sharp activity over the region of the infarct even many months after the stroke (see further on for advice on the treatment of seizures after stroke).

Many patients complain of fatigability and are depressed, possibly more so after strokes that involve the left frontal lobe (Starkstein et al). The explanation of these symptoms is uncertain; some are certainly expressions of a reactive depression. Only a few patients develop serious behavior problems or are psychotic after a stroke, but paranoid trends, confusion, ill temper, stubbornness, and peevishness may appear, or an apathetic state ensues. Large lesions affect concentration as well as synthetic and executive mental functions in general proportion to their size; these mental changes are independent of any disturbances in language function.

Finally, in regard to prognosis, it must be mentioned that having had one thrombotic stroke, the patient is at increased risk in the ensuing months and years of having a stroke at the same or another site, especially if there is hypertension or diabetes mellitus. When multiple infarcts occur over a period of months or years, special types of dementia may develop, in addition to focal cerebral deficits. In some of these cases, the major lesions involve the white matter, with relative sparing of the cortex and basal ganglia; the lesions may be lacunar or larger in size. This disorder, often referred to as *Binswanger subcortical leukoencephalopathy*, probably represents the accumulation of multiple white matter infarcts and lacunes (pages 707 and 909) (see Mohr and Mast and Babikian and Ropper). The parts of the white matter that are destroyed tend to lie in the border zones between the penetrating cortical and basal ganglionic arteries. The large patches of subcortical myelin loss and gliosis, in combination with small cortical and subcortical infarcts, produce a special radiologic image. This still incompletely understood process and the histologically similar but biologically unique inherited condition of white matter termed *CADASIL* are discussed further on.

During the period 1970–1974 in Rochester, Minnesota, 94 percent of patients with ischemic strokes survived for 5 days and 84 percent for 1 month (Garraway et al). The *survival rate* was 54 percent at 3 years and 40 percent at 7 years. In each of these groups,

survival was significantly greater than it had been during the period 1965–1969. Among long-term survivors, heart disease is a more frequent cause of death than additional strokes. These figures, which were gathered retrospectively, are comparable to more recent ones reported by Bamford and colleagues. The mortality rate following cerebral infarcts in general (no separation being made between thrombotic and embolic types) at the end of 1 month was 19 percent and at the end of 1 year, 23 percent. Of the survivors, 65 percent were capable of an independent existence. Our colleague J. Hinckley has repeatedly pointed out that pneumonia as a result of faulty swallowing is a major determinant of survival; further discussion regarding aspiration problems following stroke are to be found on pages 477 and 699.

Transient Ischemic Attacks

As has already been emphasized, when brief transient ischemic attacks (TIAs) precede a stroke, they almost always stamp the underlying process as atherothrombotic. There is little doubt that they are due to transient focal ischemia, but their precise mechanism is not fully understood (see further on); they might be thought of as temporary strokes that fortunately reverse themselves. They belong, therefore, under the heading of atherosclerotic thrombotic disease but are discussed separately here because of their clinical importance.

Current opinion holds that TIAs are brief, reversible episodes of focal, nonconvulsive ischemic neurologic disturbance. The consensus had been that their duration should be less than 24 h, an idea introduced 30 years ago by a committee assigned to study the problem. It is more useful, however, to separate attacks that last only a few minutes (up to 1 h) and leave no permanent signs, from those of longer duration which are more likely to be due to embolism. *In any clinical analysis of TIAs, it is also important to separate a single transient episode from repeated ones that are all of uniform type.* The latter are more often a warning sign of impending vascular occlusion, particularly of the internal carotid artery, while the former, especially when prolonged are often due to an embolus that leaves no lasting effect. It should also be pointed out that blood diseases that cause excessive viscosity or sludging of blood (polycythemia vera, sickle-cell disease, thrombocytosis, leukemia, and hyperglobulinemic states) may also cause TIAs prior to a stroke.

In a prospective study of 390 patients with focal TIAs caused by atherosclerotic vascular disease, the 5-year cumulative rate of fatal or nonfatal cerebral infarction was 23 percent (Heyman et al). Interestingly, the rate of myocardial infarction in this group of patients, particularly in those with carotid lesions, was almost as high (21 percent) and in other series, it has exceeded the risk of stroke. Thus the occurrence of carotid TIAs is a predictor not only of cerebral infarction but also of myocardial infarction. About two-thirds of all patients with TIAs are men with hypertension, reflecting the higher incidence of atherosclerosis in this group. Occasionally, in younger adults, TIAs may occur as relatively benign phenomena, without recognizable features of atherosclerosis or risk factors for it. Migraine is suspect in such patients (see page 151); other such instances are due to special hematologic disorders such as the antiphospholipid antibody discussed later in the chapter.

Clinical Picture Transient ischemic attacks can reflect the involvement of virtually any cerebral artery: common or internal carotid; middle, posterior, or anterior cerebral; ophthalmic; vertebral,

basilar, or cerebellar; or a penetrating branch to the basal ganglia or brainstem (lacunar TIAs). If the posterior cerebral arteries are considered with the vertebrobasilar system, transient ischemic episodes are slightly more common in this system than in the field of the carotid territory. TIAs may precede, accompany, or infrequently follow the development of a stroke, or they can occur by themselves without leading to a stroke—a fact that makes any form of therapy difficult to evaluate.

As just noted, TIAs that presage stroke may last a few seconds or up to an hour, longer ones almost certainly being due to embolic infarction. Most last 2 to 15 min. There may be only a few attacks or several hundred. Between attacks, the neurologic examination discloses no abnormalities. A stroke may occur after the first or second episode or only after numerous attacks have occurred over a period of weeks or months. Not infrequently the attacks gradually cease and no important paralysis occurs. So far it has not been possible to distinguish those individuals in whom a stroke will develop from those in whom it will not except in a general way. Many attacks which appear over a long period of time tend to be less likely to lead to thrombosis. Prolonged, fluctuating TIAs are the most ominous. About 20 percent of infarcts that follow TIAs occur within a month after the first attack, and about 50 percent within a year (see Whisnant et al, 1973).

Hemispheric Transient Ischemic Attacks (Carotid Artery Territory) The neurologic features of the transient episode indicate the territory or artery involved and are fragments of the stroke that may be approaching. In the carotid system, TIAs indicate involvement of one cerebral hemisphere or eye. The visual disturbance is ipsilateral; the sensorimotor disturbance is contralateral. Individual attacks tend to involve either the eye or the brain; only rarely are the two involved simultaneously. In the hemispheric attacks, ischemia occurs mainly in the distal territory of the middle cerebral artery or in an adjacent border zone, producing weakness or numbness of the opposite hand and arm. However, many different combinations may be seen: face and lips, lips and fingers, fingers alone, hand and foot. Rather than being paralyzed or weak, the arm may shake irregularly, simulating a seizure ("limb-shaking TIA") or rarely display other transient movement disorders (Yanagihara et al). Less common manifestations include confusion, aphasia and difficulty in calculation (when the dominant hemisphere is involved), apractagnosia (nondominant hemisphere), and other temporoparietal disturbances. Headache is not a feature of TIAs.

In ocular attacks, *transient monocular blindness* (also called *amaurosis fugax*) is the usual symptom. Most of these episodes evolve swiftly, over 5 to 30 s, and are described as a horizontal shade falling (or rising) smoothly over the visual field until the eye is completely but painlessly blind. The attack clears slowly and uniformly. Sometimes the attack takes the form of a wedge of visual loss, sudden generalized blurring, or, rarely, a gray or bright light. Transient attacks of monocular blindness are usually more stereotyped than hemispheric attacks. TIAs consisting of a homonymous hemianopia and paresthesias of the hand and arm should suggest a stenosis of the posterior cerebral artery.

The implications of amaurosis fugax have been evaluated by several investigators and found not to be quite as ominous as those of hemispheric TIAs, particularly in younger patients. Poole and Ross Russell observed a group of 110 patients for periods of 6 to 19 years following an episode of amaurosis fugax (exclusive of the type caused by cholesterol emboli). At the end of 6 years, the mor-

tality rate (due mainly to heart disease) had risen to 21 percent and the incidence of stroke to 13 percent (compared to expected figures of 15 and 3 percent, respectively, in an age-matched population). Of the patients who were alive at the end of the observation period, 43 percent had had no further attacks of amaurosis fugax following the initial episode. Noteworthy also was the finding that among patients with normal carotid arteriograms, only 1 of 35 had had a stroke during the follow-up period, whereas stroke had occurred in 8 of 21 patients in whom the internal carotid artery was occluded or stenotic. These figures are in keeping with those of Ackerman; in his series of 139 patients with amaurosis fugax and normal lumens of the common and internal carotid arteries, only 3 had a subsequent hemispheric stroke (personal communication). As pointed out by Benavente and colleagues, the risk of stroke over the 3 years following an attack is as low as 2 percent if there are no other issues such as diabetes, but it may be as high as 24 percent in older patients with risk factors for atherosclerosis. The age of the patient with amaurosis fugax is of particular significance. In the series of Poole and Ross Russell, the youngest patient to have a stroke after amaurosis fugax was 57 years old. Tippin and co-workers reviewed the records of 83 patients with onset of amaurosis fugax before the age of 45 years and found evidence of stroke in none; moreover, 42 of these patients were examined after a mean period of 5.8 years during which no stroke had occurred. It is evident that in this early-onset, good-prognosis group, a mechanism other than atherosclerosis was operative, such as migraine or an antiphospholipid antibody (discussed further on).

Brainstem Transient Ischemic Attacks (Vertebrobasilar Circulation) Recurrent TIAs referable to vertebrobasilar disease tend to be less stereotyped and more prolonged than those related to the carotid circulation. They are also more likely to culminate in a stroke. The clinical picture of TIAs in the vertebrobasilar territory is diverse, since this circulation sustains such a varied sensorimotor traffic. Vertigo, diplopia (vertical or horizontal), dysarthria, bifacial numbness, ataxia, and weakness or numbness of part or all of one or both sides of the body (i.e., a disturbance of the long motor or sensory tracts bilaterally) are the hallmarks of vertebrobasilar involvement. Transient vertigo, diplopia, or headache occurring as solitary symptoms should not be interpreted as a TIA. Also, in some patients, the complaint of dizziness will prove, however infrequently, to be part of a carotid TIA; hence this symptom, in our experience and that of Ueda et al, is not a totally reliable indicator of the vascular territory involved. Other manifestations of vertebrobasilar TIAs, in their approximate order of frequency, include staggering, veering to one side, a feeling of cross-eyedness, dark vision, blurred vision, tunnel vision, partial or complete blindness, pupillary change, ptosis, paralysis of gaze, dysarthria, and dysphagia. Less common symptoms include hemiplegia, noise or pounding in the ear or in the head, pain in the head or face or other peculiar head sensations, vomiting, hiccups, sense of tilting, lapse of memory, confused behavior, drowsiness, transient unconsciousness (rare), impaired hearing, deafness, hemiballismus, hallucination, and forced deviation of the eyes. So-called drop attacks (page 329), according to Ross Russell, have been recorded in 10 to 15 percent of patients with vertebrobasilar insufficiency, but we have never observed such attacks as a recurrent ischemic phenomenon or a manifestation of other forms of cerebrovascular disease.

Vertebrobasilar TIAs may be identical from one episode to another, or they may vary in detail while maintaining the same basic pattern, the latter occurrence being more typical. For exam-

ple, weakness or numbness may involve the fingers and face in some episodes and only the fingers in others; or dizziness and ataxia may occur in some attacks, while in others diplopia is added to the picture. In basilar artery disease, each side of the body may be affected alternately. All the involved parts may be affected simultaneously, or a march or spread from one region to another may occur over a period of 10 s to a minute or a few minutes—much slower than the spread of a seizure. The individual attack may cease abruptly or fade gradually.

Lacunar Transient Ischemic Attacks It has been recognized that strokes due to occlusion of small penetrating vessels of the brain have a proclivity to be intermittent (“stuttering”) at their onset and occasionally to allow virtually complete restitution of function between discrete episodes. Whether this constitutes a lacunar TIA has been debated, but it seems to us that the problem is our inability to distinguish a transitory occlusion of a small vessel from that of a larger vessel. Donnan and colleagues speak of a “capsular warning syndrome,” which we have seen a number of times, consisting of escalating episodes of weakness in the face, arm, and leg and culminating in a capsular lacunar lesion. These “lacunar TIAs” may stutter or remit, and there is no doubt that one or many of them may precede a lacunar stroke.

Mechanism of Transient Ischemic Attacks The question here, so far not satisfactorily answered, is whether low flow or embolic particles are responsible for TIAs. Whatever the exact cause of the attacks, they are in most cases intimately related to vascular stenosis and, usually, to ulceration due to atherosclerosis and to thrombus formation. Embolization of fibrin-platelet material from atherosclerotic sites may indeed be the cause of attacks in some cases, but it is difficult to understand, in attacks of identical pattern, how successive emboli from a distance would enter the same arterial branch each time. Moreover, one would expect the involved cerebral tissue to be at least partially damaged, leaving some residual signs. When a single transient episode has occurred, the factor of recurrence does not enter into the diagnosis, and cerebral embolism must then be strongly considered. In some cases of documented embolism, the neurologic state fluctuates from normal to abnormal repeatedly for as long as 36 h, giving the appearance of TIAs (“accelerated TIAs”); in others, a deficit of several hours’ duration occurs, fulfilling the traditional (now largely discarded) criterion of TIAs. As already noted, the same sequence of events can precede lacunar infarction and seem most likely to be due to locally reduced blood flow. *Again, a single transitory episode, especially if it lasts longer than 1 h, and multiple episodes of different pattern, suggest embolism and must be distinguished from brief (2- to 10-min) recurrent attacks of the same pattern, which suggest atherosclerosis and thrombosis in a large cerebral or feeding vessel.*

Ophthalmoscopic observations of the retinal vessels made during episodes of transient monocular blindness show either an arrest of blood flow in the retinal arteries and breaking up of the venous columns to form a “boxcar” pattern or scattered bits of white material temporarily blocking the retinal arteries. These observations indicate that in some cases of ischemic attacks involving the retinal vessels, a temporary, complete, or relatively complete cessation of blood flow occurs locally and that the cause is sometimes microembolism.

TIAs have in the past been attributed to cerebral vasospasm or to transient episodes of systemic arterial hypotension with resulting compromise of the intracranial circulation, but neither of

these mechanisms is likely in the typical case. Although hypotension may cause focal EEG changes, it has not, in the authors’ experience, reproduced the attacks in either the carotid or basilar territory. In the majority of cases, the attacks bear no strict relation to position or activity, although they are likely to occur when the patient is up and around rather than lying down. Nevertheless, a small proportion of patients with carotid or basilar artery stenosis clearly relate the onset of their attacks to standing up after lying or sitting. Transient symptoms present on awakening from sleep usually indicate that a stroke is impending. Rarely, TIAs are experienced in relation to exercise, outbursts of anger or joy, and bouts of coughing.

On the other hand, exercise and postural TIAs are particularly suggestive of stenosis of aortic branches, as occurs in Takayasu disease (see further on) and dissection of the aortic arch and occasionally in a fixed carotid stenosis. TIAs induced by hyperventilation are said to be characteristic of moyamoya disease, a progressive stenosis of intracranial vessels discussed in a later section.

In states of anemia, polycythemia, thrombocytopenia, extreme hyperlipidemia, hyperviscosity from macroglobulinemia, sickle cell anemia, and hypoglycemia, there may be transient neurologic deficits related to rheologic changes in blood, as already mentioned. In some of these cases, stenosis in a large or small vessel appears to have accounted for a restricted neurologic deficit, but just as often the vasculature is normal. Patients with antiphospholipid antibodies may have TIAs, the mechanism of which is undefined.

In some instances the TIAs begin after the artery has already been occluded by thrombus. As shown by Barnett, emboli may arise from the distal end of the thrombus or enter the upper part of the occluded vessel through a collateral artery. However, almost one-fifth of “carotid TIAs” in the series of Pessin and colleagues and a somewhat larger proportion of cases reported by Ueda and coworkers had neither stenosis nor ulceration of the carotid arteries. In most of the cases with normal carotids, the ischemic attacks exceeded 1 h in duration, suggesting embolism from the heart or great vessels including the aortic arch; but there were also a small number of brief ischemic attacks that were unexplained even after arteriography.

In general, hemodynamic changes in the retinal or cerebral circulation make their appearance when the lumen of the internal carotid artery is reduced to 1.5 mm or less (normal diameter, 7.0 mm; range, 5 to 10 mm, smaller part of this range in women). This corresponds to a reduction in cross-sectional area of more than 95 percent. The exact degree of stenosis that may cause TIAs and the risk of stroke with mild and moderate degrees of stenosis is controversial and is addressed further on.

Differential Diagnosis of Transient Ischemic Attacks Transient focal neurologic symptoms are ubiquitous in neurologic practice. They may be due to seizures, migraine, or unusual conditions such as transient global amnesia (page 379), and they occur occasionally in patients with multiple sclerosis. Almost always the clinical setting in which they occur indicates the nature of the attack. Transient episodes, indistinguishable from TIAs, are also known to occur in patients with meningioma, glioblastoma, metastatic brain tumors situated in or near the cortex, and even with subdural hematoma. Although infrequent, these attacks are important mainly because the use of anticoagulants is relatively contraindicated in some of these circumstances. The episodes that we have seen with meningiomas and subdural hematomas have consisted mainly of transient aphasia or speech arrest lasting from 2

min to several hours, but sensory symptoms with or without spread over the body, arm weakness, and hemiparesis have also been reported. Some remarkable cases of meningioma have involved repeated transient attacks for decades. Seizures are always suspected in these cases but cannot be proved. It has been speculated that a local vascular disturbance of some kind is operative, but the mechanism is not understood.

Treatment of Atherothrombotic Infarction and Transient Ischemic Attacks

The main objective in these forms of cerebrovascular disease is the prevention of stroke. Ideally this should be accomplished by finding patients in the asymptomatic stage of atherosclerosis. However, the medical profession has no efficient means of screening large populations at risk of developing stroke and only limited methods for altering the progression of the atherosclerotic process, even if discovered in its early stages. The widespread use of cholesterol-lowering "statin" medications has been shown to reduce the incidence of stroke and will probably be more widely prescribed to normal older adults. For all practical purposes, treatment is directed to patients who have already begun to have symptoms, either TIAs or ischemic lesions that are reversible to some extent.

The current treatment of atherothrombotic disease may be divided into four parts: (1) management in the acute phase, (2) measures to restore the circulation and arrest the pathologic process, (3) physical therapy and rehabilitation, and (4) measures to prevent further strokes and progression of vascular disease.

Management in the Acute Phase The relative advantages of placing the seriously ill acute stroke patient in a neurologic special care or "stroke" unit have been the subject of many articles. It is our impression that the outcome—in terms of morbidity and mortality in the seriously ill stroke patient—is improved, though admittedly this is difficult to document (for details, see Ropper and also Brott and Reed). Like the well-organized coronary care unit, stroke units have the capability of expediting the evaluation and early rehabilitation of these patients. As already emphasized, the prevention of aspiration and of pneumonia are paramount, and probably avoidable. Also deserving attention are the prevention of venous thrombosis in the legs, pulmonary embolism, and coronary syndromes. Patients with impaired consciousness require special care of skin, eyes, mouth, bladder, and bowel. These measures are best provided in a unit with trained clinical staff and the technology to monitor blood pressure, pulmonary function, blood gases, and, when appropriate, intracranial pressure (page 740).

Measures to Restore the Circulation and Arrest the Pathologic Process Once a thrombotic stroke has developed fully (i.e., the completed stroke), none of the therapeutic measures so far devised has proved to be consistently effective in restoring the damaged cerebral tissue to a functional state. The influence of anticoagulants and thrombolysis at an early stage of stroke are discussed below. One's efforts must be directed to making a diagnosis of thrombosis at the earliest possible stage and circumventing the full catastrophe by all means available without risking the safety of the patient. Even when the symptoms and signs have become persistent, it is conceivable that some of the affected tissue, particularly at the edges of the infarct, has not been irreversibly damaged and will survive if perfusion can be re-established. On the assumption that

cerebral perfusion might be diminished by assuming the upright position, it is probably advisable for patients with a major stroke to remain nearly horizontal in bed for the first day. When sitting and walking begin, special attention should be given to maintenance of normal blood pressure (patients should avoid standing quietly or sitting with the feet down for prolonged periods, etc.).

Several studies have confirmed the prevalence of new or exaggerated hypertension following an ischemic stroke and its tendency to decline within days even without medications. The treatment of previously unappreciated hypertension is preferably deferred until the neurologic deficit has stabilized. We agree with Britton and colleagues that it is prudent to avoid antihypertensive drugs in the first few days unless there is active myocardial ischemia or the blood pressure is high enough to pose a risk to other organs, particularly the kidneys, or there is a special risk of cerebral hemorrhage as a result of the use of thrombolytic drugs.

Thrombolytic Agents Tissue plasminogen activators (recombinant t-PA and streptokinase), when administered intravenously, convert plasminogen to plasmin, the latter being a proteolytic enzyme capable of hydrolyzing fibrin, fibrinogen, and other clotting proteins. These drugs are effective in the treatment of coronary artery occlusion (but are associated with a 1 percent risk of cerebral hemorrhage), and they also have now been shown to have a role in the treatment of stroke.

The multicenter study organized by the National Institute of Neurological and Communicative Disorders and Stroke (see the NINCDS and Stroke rt-PA Stroke Study Group in the References) has provided evidence of benefit from *intravenous t-PA*. Treatment within 3 h of the onset of symptoms led to a 30 percent increase in the number of patients who remained with little or no neurologic deficit when re-examined 3 months after the stroke and when assessed 1 year later in the study by Kwiatkowski et al. It is not easy to comprehend why the benefits apparently extended to all types of ischemic stroke, including those due to occlusion of small vessels (lacunes), and why improvement was not at all apparent in the days immediately following treatment, only much later. The t-PA was administered in a dose of 0.9 mg/kg, 10 percent of which was given as an initial bolus, followed by an infusion of the remainder over 1 h. A dose of 90 mg was not exceeded, this being lower than the dose used for myocardial infarction. The relative improvement in neurologic state came at the expense of a 6 percent risk of symptomatic cerebral hemorrhage, i.e., a far lower rate than in most previous studies (some of the hemorrhages were into the area of infarction without causing symptomatic worsening). Patients with massive infarcts (ones that encompassed more than two-thirds of the territory of the middle cerebral artery) or with high scores on a clinical stroke scale devised for the National Institutes of Health (NIH) study or with uncontrolled hypertension or who were more than 80 years of age or who had recently received anticoagulants (except aspirin) were excluded from this study. Further analysis of the NINCDS trial has revealed that patients who were treated earlier within the 3-h time frame had more benefit than those treated later; indeed, the administration of t-PA in the time period between 2.5 and 3 h after the stroke was of little value.

Comparable data from the randomized European Cooperative Acute Stroke Study (ECASS; see Hacke et al), which included 620 patients, identified two situations in which t-PA administered intravenously within 6 h, at a slightly higher dose than in the above trial (1.1 mg/kg, to a maximum of 100 mg), led to an improved neurologic outcome, but the overall results of this trial were con-

sidered to be unfavorable largely because of a high rate of cerebral hemorrhage. In a second trial (ECASS II) in 800 patients, using the same dose as in the NINCDS-sponsored trial but giving the thrombolytic drug up to 6 h after the stroke, no benefit could be confirmed and the rate of symptomatic hemorrhage was 8.8 percent (compared with 3.4 percent in untreated patients). Yet a subgroup of patients with carotid–middle cerebral artery strokes of moderate severity—specifically those with moderate-sized infarcts from occlusion of vessels distal to the carotid artery and adequate collateral circulation through surface vessels—did appear to benefit. In some patients with basilar artery occlusion with coma of only brief duration and those without extensive thrombosis, prompt t-PA treatment also resulted in an overall improvement in neurologic function, but there were numerous exceptions.

In all these trials, patients with large cerebral infarctions had poor outcomes and suffered a high incidence of cerebral hemorrhage. It has been concluded, therefore, that the presence of blood in the first CT scan and evidence of extensive infarction, occupying most of the MCA territory, precludes this mode of therapy. In two similar trials conducted by the European MAST-I groups (see the Multicentre Acute Stroke Trial in References), using streptokinase within 6 h of stroke, there was actually an adverse outcome—the treated group having an excess of early deaths; this trial had a 21 percent incidence of symptomatic cerebral hemorrhage and an 18 percent incidence of hemorrhagic infarctions.

At the present time the use of intravenous t-PA therapy can be advocated only in patients who arrive in the emergency department and can be fully evaluated within 3 h of the onset of a stroke, preferably even earlier (thus excluding those who awaken from a night's sleep with the symptoms) and have no hemorrhage on the CT scan. Generally also excluded are those in whom the deficit is either very small (e.g., hand affected only, dysarthria alone, minor aphasia) or, more importantly, so large as to implicate the entire territory of the middle cerebral artery. Although seemingly a promising approach to acute stroke, the use of acute thrombolytic therapy depends on the very early identification of a restricted group of patients; therefore this therapy is applicable to only a limited proportion of stroke patients who present to the emergency department (approximately 5 percent) or those who have strokes while under observation in the hospital. It is noteworthy that attempts to reproduce the beneficial effects of t-PA in a community setting have been disappointing largely because of deviations from treatment guidelines and an excess number of hemorrhages (Katzan et al). Nonetheless, acute intravenous thrombolysis that is managed closely by experienced individuals using validated protocols is a compelling treatment at the moment for acute ischemic stroke. Public health education should increase the numbers of stroke patients who seek early attention and thus raise the proportion who are eligible for t-PA treatment.

Thrombolytics injected intra-arterially can in some instances dissolve occlusions of the middle cerebral and basilar arteries and, if administered within hours, reduce the neurologic deficit. However, the routine intra-arterial injection of thrombolytics into infarcted tissue has produced a high incidence of cerebral hemorrhage, approaching 20 percent in some studies and leaving the overall morbidity about the same in treated and untreated patients. There is also a high incidence of reocclusion of the treated vessel. The exception, in our limited experience, has been basilar artery thrombosis without cerebellar infarctions, where large neurologic deficits are at times reversed with fewer complications. Treatment even several hours after the first symptoms may stop progression,

but the lack of a systematic study of this approach makes it difficult to endorse without reservation. Mechanical lysis of an intra-arterial clot may be as effective.

Acute Surgical Revascularization Rarely is the patient who has had a stroke brought to medical attention within a few minutes of onset, although this may happen when a patient is in the hospital for another reason. If it can be established that the common or internal carotid artery has just become thrombosed, intravenous or preferably intra-arterial t-PA or mechanical lysis of the clot may be effective. We have had some experience with immediate surgical removal of the clot or the performance of a bypass to restore function. Ojemann and colleagues operated on 55 such patients as an emergency procedure; 26 of these had stenotic vessels and 29 acutely thrombosed vessels. Of the latter, circulation was restored in 21, with an excellent or good clinical result in 16. In 26 patients with stenotic carotid arteries, an excellent or good result was obtained in 19. Usually several hours will have elapsed before the diagnosis is established. If the interval is longer than 12 h, opening the occluded vessel is usually of little value and may present additional dangers. Reoperation after carotid endarterectomy is a special circumstance in which rapid removal of a clot is performed more or less routinely.

Treatment of Infarctive Cerebral Edema and Raised Intracranial Pressure In the first few days following massive cerebral infarction, brain edema of the necrotic tissue may threaten life. Most often this occurs with a complete infarction in the territory of the middle cerebral artery; some degree of mass effect is evident on a CT scan in the first 24 h. Additional infarction in the territory of the anterior cerebral artery (total carotid occlusion) worsens the situation. Clinical deterioration occurs within several days of the stroke (usually worst on the third day, sometimes later) but may evolve as quickly as several hours after the onset (Fig. 34-18). The clinical signs of worsening—drowsiness, a fixed (but not necessarily enlarged) pupil, and a Babinski sign on the side of the infarction—are all due to secondary tissue shifts, as described in Chaps. 17 and 30. In such instances, controlled hyperventilation may be useful as a temporizing maneuver. Frank has shown that clinical deterioration is not always associated with an initial elevation of intracranial pressure. It may therefore be advisable, in selected cases, to measure the ICP directly before embarking on an aggressive medical regimen to lower the pressure.

Intravenous mannitol in doses of 1 g/kg, then 50 g every 2 or 3 h, may forestall further deterioration, but most of these patients, once comatose, are likely to die unless drastic measures are taken. Corticosteroids are probably of little value; several trials have failed to demonstrate their efficacy.

In the past several years there has been renewed interest in *hemicraniectomy* as a means of reducing the mass effect and intracranial pressure in these extreme circumstances. Our success in salvaging several patients even after a period of coma—similar to reported series by Schwab, Carter, Delshaw, and Rengachary and coworkers—indicates that hemicraniectomy combined with an overlying duraplasty may be undertaken if the patient is progressing from a stuporous state to coma and imaging studies show increasing mass effect. Of the 63 patients with severe brain swelling and coma in the series of Schwab et al, 46 survived and none remained severely disabled. (But there is no question that a number of such patients will remain with hemiplegia.) An anterior temporal lobectomy was performed in addition to the craniotomy in some

cases, but its effect was not clear. The value of surgical decompression has not been limited to patients with right-hemispheric strokes; those with initially limited degrees of aphasia may also be appropriate candidates, but the family must understand the risks involved and the likelihood that the stroke deficits will persist. After a protracted period of coma with bilaterally enlarged pupils or with evidence that the midbrain has been irrevocably damaged, the procedure is probably futile but there have been exceptions. Many in the field remain skeptical of these aggressive approaches, and a randomized trial is under way to settle the issue.

In the special case of large *cerebellar infarctions*, usually from occlusion of a vertebral artery, swelling may compress the lower brainstem. This type of stroke carries the risk of sudden respiratory arrest. Hydrocephalus usually develops as a prelude to this event and is manifest as drowsiness and stupor, increased tone in the legs, and Babinski signs; other sentinel signs are gaze paresis, sixth nerve palsy, or hemiparesis ipsilateral to the ataxia (Kanis and Ropper). At times it may be difficult to differentiate the effects of increasing hydrocephalus from those of a thrombus propagation in the basilar artery (Lehrich et al). Cerebellar swelling may occur with or without an associated lateral medullary stroke. The situation is comparable to medullary compression caused by cerebellar hemorrhage (page 715). Surgical decompression of the infarcted and swollen tissue should be undertaken almost as soon as cerebellar edema becomes clinically apparent by the emergence of hydrocephalus or brainstem signs, since further swelling can be anticipated. This complication can usually be anticipated in the first 3 or 4 days after a large cerebellar stroke. A brief period of observation before committing to surgery is not unreasonable if the fourth ventricle and peribrainstem cisterns are patent and the patient is awake. Mannitol may be used to prepare the patient for surgery or if a period of observation is anticipated. As in the case of cerebellar hemorrhage, ventricular drainage alone is usually inadequate and, in any case, is unnecessary if the pressure is relieved by craniectomy and resection of infarcted tissue.

Anticoagulant Drugs Several considerations weigh in any discussion of the use of anticoagulant treatment of stroke. First is the distinction between anticoagulation to prevent the progression of an acute stroke and the prophylactic use of anticoagulation for the prevention of future strokes after the occurrence of TIAs or an initial stroke. In the latter instance, the pivotal issue is whether the stroke or TIA is atherothrombotic or cardioembolic. As discussed further on, several studies point conclusively to a role for anticoagulation in certain cardioembolic cases, while the indications in atherothrombotic disease are less certain.

Warfarin and heparin have been used extensively to prevent TIAs and reduce the chances of an impending stroke. These anti-coagulants may halt the advance of a progressive thrombotic stroke, but they are clearly not effective in all cases and numerous recent studies and position papers have questioned their value altogether (see for example, the Report of the Joint Stroke Guideline Development Committee authored by Coull et al). In deciding whether to use anticoagulants, one faces the question of where in the course of the stroke the patient stands when first examined. One fact seems definite—that the administration of anticoagulants is not of great value once the stroke is fully developed, whether in a patient with a lacunar infarct or one with a massive infarction and hemiplegia. It is as yet uncertain whether the long-term use of anticoagulants prevents the recurrence of a thrombotic stroke; in these cases, the incidence of complicating hemorrhage probably outweighs the

value of anticoagulants (atrial fibrillation is an exception—see further on).

The two situations in which the immediate administration of heparin has drawn the most support from our own clinical practice are in fluctuating basilar artery thrombosis and in impending carotid artery occlusion from thrombosis or dissection (see further on). In these situations, the administration of heparin may be initiated while the nature of the illness is being clarified; the drug is then discontinued if contraindicated by new findings. It must be acknowledged that satisfactory clinical studies in support of this approach of acute anticoagulation have not been carried out. The issue of heparinization in cases of recent cardioembolic cerebral infarction is addressed further on in this chapter, under “Embolic Infarction.” However, in anticipation of the later discussion it can again be stated that there is little evidence in support of heparin use in most strokes.

In the event heparin is given, if t-PA has not been used in the preceding 24 h, the heparin may be given intravenously, beginning with a bolus of 100 U/kg followed by a continuous drip (1000 U/h) and adjusted according to the partial thromboplastin time (PTT). Bleeding into any organ may occur when the PTT is much greater than 3 times the pretreatment level. When the PTT exceeds 100 s, it is preferable to discontinue the heparin, check the blood clotting values, and then reinstitute the infusion at a lower rate (rather than simply lower the infusion rate). In circumstances of fluctuating basilar artery ischemia, it has been our practice to permit higher values of PTT.

The use of low-molecular-weight heparin (anti-factor Xa enoxaparin or nadroparin) given subcutaneously within the first 48 h of the onset of symptoms may improve outcome from stroke. In a limited randomized trial, there was no increase in the frequency of hemorrhagic transformation of the ischemic region when compared to placebo treatment (Kay et al). Because the outcome measures in this study were coarse (death or dependence 6 months after stroke), further investigations of this approach need to be carried out. We can only infer that the use of low-molecular-weight heparin (approximately 4000 U subcutaneously, twice daily) appears to be safe and is possibly beneficial.

Whether anticoagulant therapy is effective in preventing strokes in patients with TIAs or recent stroke is a question that has never been answered satisfactorily. Swanson has reviewed several trials evaluating heparin (including the International Stroke Trial and the TOAST study) and suggested that there was no net benefit from heparin in acute stroke because of an excess of cerebral hemorrhages. However, there was in these series a low incidence, estimated as 2 percent, of recurrent stroke in the first weeks after a cerebral infarction in the untreated groups. An early recurrent stroke rate this low almost precludes demonstrating a benefit from the use of heparin or heparinoid drugs.

The long-term use of warfarin following atherothrombotic stroke is also still under critical analysis. To date it seems to be of some slight value in the prevention of further thrombosis and embolism. There are data to suggest that the greatest usefulness of warfarin is in the first 2 to 4 months following the onset of ischemic attack(s); after that time the risk of intracranial hemorrhage may exceed the benefits of anticoagulant therapy (Sandok et al). However, in comparison to aspirin, discussed below, there is no reason to favor warfarin in cases of atherothrombotic stroke. This was amply shown in the so-called WARSS study (not including cardioembolic stroke) published by Mohr and colleagues (2001); over 2 years the recurrent stroke rate was about 16 percent in both groups

and, surprisingly the rate of cerebral hemorrhage was similar (near 2 percent). In contrast to the situation with atherothrombotic disease, warfarin has been found to be superior for prevention of a second stroke in cardioembolic disease, as discussed further on.

Of course, the use of anticoagulant drugs makes an accurate diagnosis imperative. Intracranial hemorrhage must be excluded by CT scan. An estimation of prothrombin and partial thromboplastin activity is needed before therapy is started, but if this is not feasible, the initial doses of anticoagulant drugs can usually be given safely if there is no clinical evidence of bleeding anywhere in the body and there has been no recent surgery. Warfarin therapy, beginning with a dose of 5 to 10 mg daily, is relatively safe provided that the international normalized ratio (INR) is brought to 2 to 3 (formerly measured as a prothrombin time between 16 and 19 s) and the level is determined regularly (once a day for the first 5 days, then two or three times a week for a week or two, and finally once every several weeks). There is no reliable evidence that complications are more frequent in the presence of hypertension if the INR is not allowed to exceed two to three times normal; therefore the authors have not withheld anticoagulant therapy in these patients. However, when the blood pressure is greater than 220/120 mmHg, an attempt is made to lower it gradually at the same time. Numerous drugs may alter the anticoagulant effects of the coumarins or add to the risk of bleeding—aspirin, cholestyramine, alcohol, barbiturates, carbamazepine, cephalosporin and quinolone antibiotics, sulfa drugs, and high-dosage penicillin being the most important ones. The INR must be determined regularly if the administration of warfarin is necessary. Hemorrhagic skin necrosis is a rare but dangerous complication. It is due to a paradoxical microthrombosis of skin vessels and is liable to occur in patients with unsuspected deficiencies of endogenous clotting proteins (S and C). Although the disseminated form of skin necrosis occurs within days of initiating warfarin therapy, we have seen one patient with a form of this lesion following local skin injury after months on treatment.

Any type of serious bleeding from warfarin overdosage demands immediate administration of fresh plasma and large doses of vitamin K. An INR above 5 in a patient who must remain anticoagulated—for example, one with a prosthetic heart valve—may be corrected with small doses of vitamin K (0.5 to 2 mg), preferably given intravenously.

The problem that continues to plague all attempts to use long-term anticoagulants, as already noted for heparin in the acute situation, is the risk of hemorrhage, which approaches 10 percent, with a mortality of 1 percent. The risk of intracranial hemorrhage has been estimated by Whisnant and colleagues to be 5 percent overall and considerably higher in elderly patients who have been treated for more than 1 year. Thus, it would appear that with long-term administration of anticoagulants, except in certain circumstances—such as a severely stenotic cerebral vessel, atrial fibrillation, prosthetic heart valve, and certain blood disorders—the risk of hemorrhage outweighs the benefit from prevention of stroke.

Antiplatelet Drugs Aspirin (325 mg daily) has proved to be perhaps the most consistently useful drug in the prevention of thrombotic and embolic strokes. One currently favored approach, based in part on the above-mentioned WARSS trial, is to simply administer aspirin in all cases of acute stroke (except perhaps if t-PA has been used). The acetyl moiety of aspirin combines with the platelet membrane and inhibits platelet cyclo-oxygenase, thus preventing the production of thromboxane A₂, a vasoconstricting prostaglan-

din, and also prostacyclin, a vasodilating prostaglandin. In patients who cannot tolerate aspirin, the platelet aggregate inhibitor clopidogrel or a similar drug (such as *ticlopidine* or *dipyridamole*) can be substituted (see below).

A number of controlled studies have attested to the therapeutic value of aspirin and ticlopidine, clopidogrel, or dipyridamole, but it is important not to exaggerate the magnitude of their effects. These studies have been critically reviewed by Tijssen and by Algra and colleagues. With few exceptions, it can be concluded that aspirin is beneficial in preventing stroke; whether low doses (50 to 100 mg) and high doses (1000 to 1500 mg) provide equivalent protection is still uncertain. From a review of these studies, it appears that both dosages are effective and that the addition of dipyridamole further reduces the risk of stroke by a small amount. Ticlopidine and clopidogrel are believed by some, on the basis of clinical trials, to be marginally more effective than aspirin for the prevention of stroke, but they are far more expensive, and ticlopidine is potentially toxic (neutropenia). Dipyridamole in high doses has not been as well tolerated by our patients because of induced dizziness. The combined use of these drugs with aspirin has not been extensively examined, but recent data from the PROFESS trial (Prevention Regimen for Effectively Avoiding Second Strokes) has suggested that there may be an increased risk of cerebral hemorrhage when aspirin is combined with clopidogrel; our patients have not experienced such events, but perhaps the combination should be used with caution.

These studies notwithstanding, the therapeutic effectiveness of aspirin is still rather slight. The cumulative evidence from trials with aspirin alone indicates that a dose of aspirin of at least 30 mg/day reduces by 13 percent, at most, the progression or recurrence of stroke (Algra et al). Moreover, in each of the trials, a significant number of subsequent ischemic strokes occurred in patients while they were receiving aspirin.

The best course of treatment for patients who have lacunar or atherothrombotic strokes while already receiving antiplatelet medications is not clear. Control of blood pressure and the administration of a lipid-lowering drug is advisable, even if lipid levels are normal. Switching to warfarin from anti-platelet agents is sensible in some circumstances but should be done with caution.

Other Forms of Medical Treatment Treatment by hemodilution was popularized by the studies of Wood and Fleischer, who showed a high incidence of short-term improvement when the hematocrit was reduced to approximately 33 percent. That lowering blood viscosity improves regional blood flow in the heart had been known for some time, and a similar effect on the brain has been demonstrated by CBF studies. Earlier observations had shown a reduction in the overall neurologic deficit, but almost all larger randomized trials—which included patients in many settings who were treated at various times up to 48 h after stroke—failed to confirm any such benefit, and the use of this treatment has been virtually abandoned. Nevertheless, we continue to see a few patients whose hemiparesis and aphasia have improved during and just after removal of a unit or more of blood and replacement with albumin and saline. While this treatment cannot be recommended as a routine approach, it may have some merit in selected situations, such as fluctuating stroke. Therapies aimed at improving blood flow by enhancing cardiac output (aminophylline, pressor agents), by improving the microcirculation (mannitol, glycerol, dextran), or by use of a large number of vasodilating drugs (see below) have failed to show consistent benefits, but several are still under study.

Hyperbaric oxygen may reduce ischemic deficits temporarily but has no sustained effect. Induced hypothermia limits the size of ischemic stroke, but it is technically difficult to administer and often has serious side effects.

Calcium channel blockers of the types administered for cardiac disease have also been found to increase CBF and to reduce lactic acidosis in stroke patients. However, several multicenter clinical trials that compared calcium channel blockers with placebo did not establish a difference in outcome in the two groups. There has also been interest, as noted earlier in this chapter, in drugs that inhibit excitatory amino acid transmitters and free-radical scavengers such as dimethyl sulfoxide (DMSO) and growth factors, but so far none of these has been successfully applied to humans.

Despite some experimental evidence that certain vasodilators, such as CO₂ and papaverine, increase CBF, none has proved beneficial in carefully studied human stroke cases at the stage of TIAs, thrombosis in evolution, or established stroke. Vasodilators may actually be harmful, at least on theoretical grounds, since by lowering the systemic blood pressure or dilating vessels in normal brain tissue (the autoregulatory mechanisms are lost in vessels within the infarct), they may reduce the intracranial anastomotic flow. Moreover, the vessels in the margin of the infarct (border zone) are already maximally dilated. New discoveries regarding the role of nitric oxide in vascular control will probably give rise to new pharmacologic agents, which will have to be evaluated.

Surgery and Angioplasty for Symptomatic Carotid Stenosis
Comments have already been made concerning the opening of an occluded carotid artery soon after a stroke. Here we discuss the patient who has passed the acute period, when surgery is safer, or who has TIAs. The region that most often lends itself to such therapy is the carotid sinus (the bulbous expansion of the internal carotid artery just above its origin from the common carotid). Other sites suitable for surgical management include the common carotid, innominate, and subclavian arteries. Operation on the vertebral artery at its origin has proved successful only in exceptional circumstances. In recent years balloon angioplasty and stenting of the carotid artery have become increasingly popular as an alternative to surgery (see below).

Surgery and angioplasty, in our opinion, are as yet applicable mainly to the group of patients with *symptomatic* carotid artery stenosis (the asymptomatic ones are discussed below) who have substantial extracranial stenosis but not complete occlusion, and, in special instances, in those with nonstenotic ulcerated plaques. Those with stenosis constitute less than 20 percent of all patients with TIAs (Marshall); but from the perspective of surgical therapy, the term *symptomatic* encompasses both TIAs and small strokes ipsilateral to the stenosis. There is now convincing evidence that well-executed surgery in appropriately chosen cases arrests the TIAs and diminishes the risk of future strokes. These views have received strong affirmation from two well-designed randomized studies—the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST). The conclusion, reached in each of these studies, was that carotid endarterectomy for symptomatic lesions causing severe degrees of stenosis (>70 to 80 percent reduction in diameter) is effective in reducing the incidence of ipsilateral hemispherical strokes. These two trials differed in the method of estimating the degree of stenosis, but when adjustments are made, the results are comparable (Donnan et al). Patients in the European study with mild or moderate stenosis (up to 70 percent) did not benefit from endar-

terectomy. In the North American study, however, they did so, but to a lesser extent than the group with severe stenosis. Further analysis of the North American trial by Gasecki and colleagues has indicated that the risk of cerebral infarction on the side of the symptomatic stenosis is increased if there is a contralateral carotid stenosis but that operated patients (on the side of symptomatic stenosis) still had fewer strokes than those treated with medication alone. In those with bilateral carotid disease, the risk of stroke after 2 years was 69 percent, and if operated, 22 percent. In the final analysis, *the relative benefits of surgery or medical treatment (anticoagulation or aspirin) depend mainly on the true surgical risk*—i.e., on the record of an individual surgeon. If the surgeon, by an independent audit of his procedures, has an established operative complication rate of no more than 4 to 5 percent and preferably lower, then surgery can be recommended in symptomatic patients with carotid stenosis greater than 70 percent. This benefit extends to elderly patients and, indeed, it has been shown on a statistical basis to be most evident in patients over age 75 (see the reanalysis of NASCET data by Alomamowitch and colleagues).

Before operation or angioplasty, the existence of the lesion and its extent must be determined. Arteriography, the procedure that yields the best images and most accurate measurements of the residual lumen, carries a very small risk of worsening the stroke or producing new focal signs (this notion has never been documented systematically). Severe stenosis is reflected in conventional angiography by the filling of the distal branches of the external carotid artery before the branches of the middle cerebral artery are opacified—a reversal of the usual filling pattern, indicating low flow in the distal carotid circulation. Increasingly the diagnosis of carotid stenosis is being made by noninvasive methods, but with both ultrasound and magnetic resonance arteriography, there is difficulty in quantifying severe stenosis and separating it from complete carotid artery occlusion. Perfusion CT imaging may provide a more accurate alternative at low risk (the volume of dye required may still be prohibitive in patients with renal failure).

If the patient is in good medical condition, has normal vessels on the contralateral side, and has normal cardiac function (no heart failure, uncontrolled angina, or recent infarction), these lesions can usually be dealt with safely by endarterectomy. The procedure is not, however, innocuous. It may be followed by a new *hemiplegia or aphasia that becomes evident immediately or soon after endarterectomy*, usually by the time the patient arrives in the recovery room. In general, surgeons prefer to return the patient to the operating room and open the artery, as discussed earlier on. An intimal flap at the distal end of the endarterectomy and varying amounts of fresh clot proximal to it are usually encountered; but after removal and repair of the vessel, the effects of the stroke, if one has occurred, are not usually improved.

An uncommon but rather striking *hyperperfusion syndrome* develops several days to a week after carotid endarterectomy. The features are headache, focal deficits, seizures, brain edema, or cerebral hemorrhage; these are thought to reflect an abrupt loss of autoregulatory ability of the cerebral vasculature in the face of hypertension and increased perfusion on the side of the recently opened artery. Unilateral severe headache is the commonest symptom and may be the only manifestation. On occasion the cerebral edema is so massive as to lead to death (Breen et al). Treatment is by control of hypertension; it is unclear whether anticonvulsant medications are required if there has been a single seizure, but they seem valuable to us. We mention here that an identical syndrome of focal cerebral deficits and brain edema, perhaps with the excep-

tion of seizures, has been seen, rarely and with no explanation, in migraineurs, including two cases with which we are familiar.

For intracranial internal carotid stenosis or for thrombi that extend into the siphon and stem of the middle cerebral artery, a transcranial (superficial temporal–middle cerebral) anastomosis had in the past been employed. Though this operation is technically feasible, its therapeutic value has been discounted by the careful multicenter study of Barnett and collaborators, who found that it did not produce a reduction in TIAs, strokes, or deaths. There may still be particular circumstances that justify its use.

Carotid angioplasty and stenting has been alluded to several times earlier. Its role in clinical practice is still being determined, but it offers an alternative to surgery if the patient is too ill to undergo an endarterectomy. Direct comparisons are being made to surgery in several organized studies. In one randomized trial reported by the CAVATAS investigators, the incidence of minor (nonstroke) complications was lower in patients who had angioplasty and stenting. This has not been our experience, where sizable groin hematomas have been common. Also, a higher proportion of these patients than those who had undergone endarterectomy had restenosis. Otherwise, the recurrent stroke rates were similar, 10 percent for both groups.

Asymptomatic Carotid Stenosis Finally, there is the problem of the asymptomatic carotid bruit or incidentally discovered stenosis. The population study by Heyman and associates has shed some light on this. They found, not surprisingly, that cervical bruits in men constituted a risk for death from ischemic heart disease. They also noted that the presence of asymptomatic bruits in men (but not in women) did carry a slightly increased risk of stroke but, more importantly, that the subsequent stroke often did not coincide in its angioanatomic locus and laterality with the cervical bruit. Similar findings have been reported by Ford and coworkers and by Chambers and Norris. On the other hand, Wiebers and colleagues found that patients with asymptomatic carotid bruits who were followed for 5 years were approximately three times more likely to have ischemic strokes than an age- and sex-matched population sample without carotid bruits.

In an attempt to clarify the role of surgery for asymptomatic carotid stenosis, the Asymptomatic Carotid Atherosclerotic Study (ACAS), as reported by their Executive Committee, has suggested that the frequency of strokes can be reduced from 11 to 5 percent over 5 years by removing the plaque in asymptomatic patients in whom there is a stenosis greater than 60 percent (diameter). These findings have been tempered by a reanalysis of the ACAS data, pointing out that almost half of the strokes in these patients were lacunar or cardioembolic in origin (Inzitari et al.). Data from a recent European trial, encompassing 3120 patients, obtained similar results [MRC Asymptomatic Carotid Surgery Trial (ACST) Collaborative Group]. The latter study has indicated that asymptomatic carotid stenosis of over 70 percent carries only a 2 percent annual risk of stroke over a 5-year period and that the risk is reduced to 1 percent with endarterectomy. It was concluded that endarterectomy may be justified for asymptomatic carotid stenosis of this degree, but the authors emphasized that an audited surgical risk below 3 percent is required to obtain favorable results. From the results of several trials, it can be concluded that endarterectomy does not reduce strokes in patients who have asymptomatic carotid stenosis with luminal narrowing that is less than 70 percent of normal diameter. All these comments probably apply to patients who are about to undergo major surgery such as cardiac bypass

grafting, but adequate studies of this circumstance have not been carried out.

The benefits of surgery for asymptomatic carotid stenosis seem to us to be marginal and we counsel caution until more definite data on this matter have been obtained. Also, as already noted, the neurologist's advice should be tempered by the documented surgical risk in his particular institution. Our practice with asymptomatic cases has been to re-evaluate the lumen of the internal carotid artery (by ultrasound) at 6- to 12-month intervals. Only if the lumen is decreasing in size and becomes narrowed to 1.5 mm or less or if there is an event that could be construed as a TIA referable to the stenotic side is surgery considered. In the case of an asymptomatic but progressive stenosis larger than 1.5 mm, there is still considerable controversy about treatment; anticoagulation or antiplatelet agents are reasonable alternatives to surgery.

We generally agree with the guidelines for carotid endarterectomy set down by the American Heart Association as reported by Moore and colleagues, but there must be a careful evaluation of the circumstances in each patient.

Physical Therapy and Rehabilitation In all but the most seriously ill patients, beginning within a few days of the stroke, the paralyzed limbs should ideally be carried through a full range of passive movement several times a day. The purpose is to avoid contracture (and periarthritis), especially at the shoulder, elbow, hip, and ankle. Soreness and aching in the paralyzed limbs should not be allowed to interfere with exercises. Patients should be moved from bed to chair as soon as the stroke is completed and blood pressure is stable. Prophylaxis for deep venous thrombosis is appropriate if the patient cannot be mobilized. An assessment for swallowing difficulty should be made early during recovery and dietary adjustments made if there is a risk of aspiration. Nearly all hemiplegics regain the ability to walk to some extent, usually within a 3- to 6-month period, and this should be a primary aim in rehabilitation. The presence of deep sensory loss or anosognosia in addition to hemiplegia is the main limiting factor. A short or long leg brace is often required. By teaching patients with cerebellar ataxia new strategies, balance and gait disorders can be made less disabling. As motor function improves and if mentality is preserved, instruction in the activities of daily living and the use of various special devices can help the patient to become at least partly independent in the home. What little research is available on the effectiveness of stroke rehabilitation suggests that a greater intensity of physical therapy does indeed achieve better scores on some measures of walking ability and dexterity. In a randomized trial, Kwakkel and colleagues achieved these results by applying an additional 30 min per day beyond conventional physical therapy of focused treatments to the leg or arm, 5 days per week, for 20 weeks. Other studies have demonstrated clearly the now well-known undesirable effects of immobilizing a limb in a splint after a stroke.

The neural substrates of improvement after stroke are just beginning to be studied. A wealth of clinical experience and physiologic and radiographic data have demonstrated that the injured brain has some degree of plasticity; remodeling of brain tissue and reorganization of neural function continue for months after even large motor deficits. Experimental work in monkeys and limited data from patients suggest that improvement can be obtained by restraining the normal limb and forcing use of the sound limb. This may reflect functional expansion of the cortical motor representation into adjacent undamaged cortical areas, indicating the potential

for some degree of reorganization that corresponds to clinical recovery.

Speech and language therapy are particularly valuable in identifying the risk of aspiration as noted above. Specific therapy should be given in appropriate cases, and certainly improves the morale of the patient and family. Further comments on the value of such therapy can be found in Chap. 23, on language disturbances.

Preventive Measures Since the primary objective in the treatment of atherosclerotic disease is prevention, efforts to control the risk factors must continue. The carotid vessels, being readily accessible, must always be examined for the presence of a bruit; the latter quite reliably indicates a stenosis, though not all stenoses cause a bruit and some bruits heard bilaterally are transmitted sounds from a stenotic aortic valve. Ultrasound examination of the carotid is justified in almost all patients with TIAs and ischemic stroke. While a *self-audible bruit* occasionally indicates carotid stenosis, dissection, or fibromuscular dysplasia, it is usually benign and in some instances associated with an enlarged, superiorly displaced jugular bulb—a benign anatomic variant that can be discerned on CT scan (Adler and Ropper). Other instances are attributable to raised intracranial pressure (pseudotumor cerebri). The management of patients with asymptomatic carotid bruits has been considered above.

For patients who have had a stroke from atherosclerotic disease and are functional, preventive measures consist of reducing the future occurrence of strokes. Such measures include the following: (1) aspirin—which has been shown to reduce the risk of second stroke slightly, but its effect, as already noted, should not be overestimated (see page 697); (2) any required antihypertensive agents—whether given therapeutically or for diagnostic procedures, should be administered with caution; (3) cholesterol-lowering drugs should be administered unless the cholesterol level is already low or there is a contraindication; (4) smoking cessation is mandatory and the patient should be supported in such efforts; and (5) particular care should be taken to maintain the systemic blood pressure, oxygenation, and intracranial blood flow during general surgical procedures, especially in elderly patients.

The ultimate solution of the problems of ischemic infarction and TIAs lies in more fundamental fields—namely, the prevention or alleviation of hypertension and atherosclerosis.

Embolic Infarction

As already stated, *this is the commonest cause of stroke*. The characteristic feature is the abrupt onset of a focal neurologic deficit. In most cases of cerebral embolism, the embolic material consists of a fragment that has broken away from a thrombus within the heart. Somewhat less frequently the source is intra-arterial, from the distal end of a thrombus within the lumen of an occluded or severely stenotic carotid or vertebral artery or the distal end of a carotid dissection, or possibly from an atheromatous plaque that has ulcerated into the lumen of the carotid sinus. Single or sequential emboli may also arise from large atheromatous plaques in the ascending aorta. Thrombotic or infected material (endocarditis) that adhere to the aortic or mitral heart valves and break away are also well appreciated sources of embolism. Embolism due to fat, tumor cells (atrial myxoma), fibrocartilage, amniotic fluid, or air seldom enters into the differential diagnosis of stroke except in special circumstances.

The embolus usually becomes arrested at a bifurcation or other

site of natural narrowing of the lumen of an intracranial vessel, and ischemic infarction follows. The infarction is pale, hemorrhagic, or mixed; hemorrhagic infarction nearly always indicates embolism, though most are pale. Any region of the brain may be affected, the territory of the middle cerebral artery, particularly the superior division, being the most frequently involved. The two cerebral hemispheres are approximately equally affected. Large embolic clots can block large vessels (sometimes the carotids in the neck or at their termination intracranially), while tiny fragments may reach vessels as small as 0.2 mm in diameter usually with inconsequential effects. The embolic material may remain arrested and plug the lumen solidly, but more often it breaks into fragments that enter smaller vessels and disappear, so that even careful pathologic examination fails to reveal their final location. In this instance, the clinical effects may clear in hours. The anatomic diagnosis must then be made by inference, e.g., absence of a vascular occlusion at the proper site to explain the infarct; absence of atherosclerosis or other cause of occlusion in the offending cerebral vessel; presence of a source of emboli, atrial fibrillation, or infarcts in other organs such as the kidneys and spleen; the occurrence of hemorrhagic infarction; and finally the clinical history, which is characterized by an absolutely abrupt onset, as described below.

Because of the rapidity with which embolic occlusion develops, there is not much time for collateral influx to become established. Thus, sparing of the territory distal to the site of occlusion is not as evident as in thrombosis. However, the vascular anatomy and ischemia-modifying factors mentioned above, under “The Ischemic Stroke,” are still operative and influence the size and magnitude of the infarct.

Brain embolism is predominantly a manifestation of heart disease, and fully 75 percent of cardiogenic emboli lodge in the brain. The commonest identifiable cause is *chronic or recent atrial fibrillation*, the source of the embolus being a mural thrombus within the atrial appendage (Table 34-7). Patients with chronic atrial fibrillation are about six times more liable to stroke than an age-matched population with normal cardiac rhythm (Wolf et al) and the risk is considerably higher if there is also rheumatic valvular disease as mentioned earlier. Furthermore, the risk conferred by the presence of atrial fibrillation varies with age, being 1 percent per year in persons younger than 65, and as high as 8 percent per year in those over 75 with additional risk factors. These levels of risk are of prime importance in determining the advisability of anticoagulation, as discussed below. Embolism may also occur during paroxysmal atrial fibrillation or flutter. Mural thrombus deposited on the damaged endocardium overlying a myocardial infarct in the left ventricle, particularly if there is an aneurysmal sac, is an important source of cerebral emboli, as is a thrombus associated with severe mitral stenosis without atrial fibrillation. Emboli tend to occur in the first few weeks after an acute myocardial infarction, but Loh and colleagues found that a lesser degree of risk persists for up to 5 years. Cardiac catheterization or surgery, especially valvuloplasty, may disseminate fragments from a thrombus or a calcified valve. Mitral and aortic valve prostheses are additional important sources of embolism.

Another source of embolism is the carotid or vertebral artery, where clot forming on an ulcerated atheromatous plaque may be detached and carried to an intracranial branch (artery-to-artery embolism). A similar phenomenon may occur with arterial dissections and sometimes with fibromuscular disease of the carotid or vertebral arteries.

Atheromatous plaques in the ascending aorta have been rec-

Table 34-7
Causes of cerebral embolism

1. Cardiac origin
 - a. Atrial fibrillation and other arrhythmias (with rheumatic, atherosclerotic, hypertensive, congenital, or syphilitic heart disease)
 - b. Myocardial infarction with mural thrombus
 - c. Acute and subacute bacterial endocarditis
 - d. Heart disease without arrhythmia or mural thrombus (mitral stenosis, myocarditis, etc.)
 - e. Complications of cardiac surgery
 - f. Valve prostheses
 - g. Nonbacterial thrombotic (marantic) endocardial vegetations
 - h. Prolapsed mitral valve
 - i. Paradoxical embolism with congenital heart disease (e.g., patent foramen ovale)
 - j. Myxoma
2. Noncardiac origin
 - a. Atherosclerosis of aorta and carotid arteries (mural thrombus, atheromatous material)
 - b. From sites of dissection and/or fibromuscular dysplasia of carotid and vertebrobasilar arteries
 - c. Thrombus in pulmonary veins
 - d. Fat, tumor, or air
 - e. Complications of neck and thoracic surgery
 - f. Pelvic and lower extremity venous thrombosis in presence of right-to-left cardiac shunt
3. Undetermined origin

ognized in the last decades to be a more frequent source of embolism than had been appreciated. Amarenco and colleagues reported that as many as 38 percent of a group of patients with no discernible cause for embolic stroke had echogenic atherosclerotic plaques in the aortic arch that were greater than 4 mm in thickness, a size thought to be associated on a statistical basis with strokes. Disseminated cholesterol emboli are known to occur in the cerebral circulation and may be dispersed in other organs as well; rarely, this is sufficiently severe to cause an encephalopathy and pleocytosis in the spinal fluid.

Paradoxical embolism can occur when an abnormal communication exists between the right and left sides of the heart (particularly a patent foramen ovale, or PFO) or when both ventricles communicate with the aorta; thus embolic material arising in the veins of the lower extremities or pelvis or elsewhere in the systemic venous circulation can bypass the pulmonary circulation and reach the cerebral vessels. Pulmonary hypertension (often from previous pulmonary embolism) favors the occurrence of paradoxical embolism, but this may occur with a PFO even in the absence of pulmonary hypertension. Of 30 patients in whom a PFO could be demonstrated, 17 had evidence of a right-to-left shunt; brain infarction was associated with positive phlebography of the legs and abnormal pulmonary scintigraphy (Itoh et al). Several studies indicated that the presence of a small atrial septal aneurysm adjacent to the patient foramen increases the likelihood of stroke. In the series of Mas and colleagues, patients ages 18 to 55 who had a stroke were followed for 4 years; the risk of second stroke was 2 percent in those with a PFO alone and 15 percent among those with both a PFO and an atrial septal aneurysm (curiously, the risk among those with neither congenital abnormality was 4 percent—higher

than for PFO). This mechanism comes into play mainly in considering the causes of stroke in the younger patient. Subendocardial fibroelastosis, idiopathic myocardial hypertrophy, cardiac myxomas, and cardiac lesions of trichinosis are rare causes of embolism.

The vegetations of acute and subacute bacterial endocarditis give rise to several different lesions in the brain (page 606). Mycotic aneurysm is a rare complication of septic embolism and may be a source of intracerebral or subarachnoid hemorrhage. *Marantic* or *nonbacterial thrombotic endocarditis* is a frequently overlooked cause of cerebral embolism; at times it produces a baffling clinical picture, especially when associated, as it often is, with carcinomatosis, cachexia from any cause, or lupus erythematosus. This subject is discussed on page 735.

Mitral valve prolapse may be a source of emboli, especially in young patients, but its importance has probably been overestimated. The initial impetus for considering this abnormality as a source of embolus came from the study of Barnett and colleagues of a group of 60 patients who had TIAs or partial strokes and were under 45 years of age; prolapse was detected (by echocardiography and a characteristic midsystolic click) in 24 patients but in only 5 of 60 age-matched controls. However, in several subsequent large studies (Sandok and Giuliani and Jones et al), only a very small proportion of strokes in young patients could be attributed to prolapse; even then, the connection was only inferred by the exclusion of other causes of stroke. Indeed, in a recent study using stringent criteria for the echocardiographic diagnosis of prolapse, Gilon and colleagues could not establish any relation to stroke. Rice and colleagues have described a family with premature stroke in association with valve prolapse and a similar relationship has been reported in twins; the same may occur in Ehlers-Danlos disease.

The *pulmonary veins* are a potential if infrequent source of cerebral emboli, as indicated by the occurrence of cerebral abscesses in association with pulmonary suppurative disease and by the high incidence of cerebral deposits secondary to pulmonary carcinoma. In Osler-Weber-Rendu disease, pulmonary shunts serve as a conduit for emboli. As remarked above, surgery of the neck and thorax can be complicated by cerebral embolism. A rare type is that which follows thyroidectomy, where thrombosis in the stump of the superior thyroid artery extends proximally until a section of the clot, protruding into the lumen of the carotid, is carried into the cerebral arteries.

During *cerebral arteriography*, emboli may arise from the tip of the catheter, or manipulation of the catheter may dislodge atheromatous material from the aorta or carotid or vertebral arteries and account for some of the accidents during this procedure. Transcranial Doppler insonation has suggested that small emboli frequently arise during these procedures; a study by Bendszus and colleagues found that 23 of 100 consecutive patients had new cortical lesions shown on diffusion-weighted MRI just after cerebral arteriography. However, none of these were symptomatic and with good technique, emboli from vascular catheters are infrequent.

Cerebral embolism must always have occurred when secondary tumor is deposited in the brain, and cerebral embolism regularly accompanies septicemia, but a mass of tumor cells or bacteria is seldom large enough to occlude a cerebral artery and produce the picture of stroke. Nevertheless, tumor embolism with stroke has been reported from cardiac myxomas and occasionally with other tumors. It must be distinguished from embolism due to marantic endocarditis that complicates malignant neoplasms (nonbacterial thrombotic endocarditis, discussed further on). Cerebral *fat embolism* is related to severe bone trauma. As a rule, the emboli are

minute and widely dispersed, giving rise first to pulmonary symptoms and then to multiple dermal (anterior axillary fold and elsewhere) and cerebral petechial hemorrhages. Accordingly, the clinical picture is more of an encephalopathy and not strictly focal, as it is in a stroke, although in some instances it may have focal features. Cerebral *air embolism* is a rare complication of abortion, scuba diving, or cranial, cervical, or thoracic operations involving large venous sinuses; it was formerly encountered as a complication of pneumothorax therapy. Clinically, this condition may be difficult to separate from the deficits following hypotension or hypoxia, which frequently coexist. Hyperbaric treatment may be effective if instituted early.

Despite the large number of established sources of emboli, the point of origin cannot be determined in about 30 percent of presumed embolic infarctions. In such cases, emboli may have originated from thrombi in the cardiac chambers but have left behind no residual clot and may be undetectable by even sophisticated methods such as transesophageal echocardiography and newer MR techniques. Others may be due to atheromatous material arising from the aorta. If extensive evaluation fails to disclose the origin, the odds still favor a source in the left heart. Not infrequently the diagnosis of cerebral embolism is made at autopsy without finding a source. The search for a thrombotic nidus may not have been sufficiently thorough in these cases, and small thrombi in the atrial appendage, endocardium (between the papillary muscles of the heart), the aorta and its branches, or pulmonary veins may have been overlooked. Nevertheless, in some cases, even when studied carefully postmortem, no source of embolic material can be discovered.

Clinical Picture Of all strokes, those due to cerebral embolism develop most rapidly, "like a bolt out of the blue." As a rule, the full-blown picture evolves within seconds, exemplifying most strikingly the temporal profile of a stroke. With rare exceptions, there are no warning episodes. The embolus strikes at any time of the day or night. Getting up to go to the bathroom is a time of danger. Only occasionally and for unclear reasons, the clinical picture unfolds more gradually, over many hours, with some fluctuation of symptoms. Possibly, in these cases, the embolus initiates a thrombotic process in the occluded vessel.

The neurologic picture will depend on the artery involved and the site of obstruction. The syndromes related to each angioanatomic territory are the same as those outlined earlier in this chapter, under "Neurovascular Syndromes." A large embolus may plug the distal internal carotid artery or the stem of the middle cerebral artery, producing the full-blown syndromes that follow occlusion of these arteries. More often the embolus passes into one of the branches of the middle cerebral artery, producing a strikingly focal disorder such as a motor speech disorder, a monoplegia, or a receptive type of aphasia. Any fragment of the middle cerebral syndrome or the complete picture may occur; the same is true for the anterior and posterior cerebral arteries, which are affected at a lower frequency than the middle cerebral because of their lower rates of blood flow.

Embolic material entering the vertebrobasilar system occasionally stops in the vertebral artery just below its union with the basilar; more often it traverses the vertebral and also the basilar artery, which is larger, and is not arrested until it reaches the upper bifurcation, where it produces the abrupt onset of coma and total paralysis or one of the related "top of the basilar" syndromes, described earlier in the chapter. Or the embolus may enter one or both

posterior cerebral arteries and, by infarction of the visual cortex, cause unilateral or bilateral homonymous hemianopia. The medial temporal lobe or thalamus and subthalamus may be affected as a consequence of occlusion of the temporal branches or of small penetrating vessels that arise from the posterior cerebral artery, resulting in a number of disorders of memory, sensation, and movement. Embolic infarction of the undersurface of the cerebellum is not infrequent (Figs. 34-1 and 34-19); in addition to ataxia, there are often telltale signs of lateral medullary ischemia. Embolic material rarely enters the penetrating branches of the pons.

It is important to repeat that an embolus may produce a severe neurologic deficit that is only temporary; symptoms disappear as the embolus fragments. In other words, embolism is a common cause of a single evanescent stroke that may reasonably be called a prolonged TIA. Also, as already pointed out, several emboli can give rise to multiple scattered infarcts or two or three transient attacks of differing pattern or, rarely, of almost identical pattern.

Also of interest are the symptoms caused by an embolus as it traverses a large vessel as mentioned on page 688. This "*migrating, or traveling, embolus syndrome*" is most evident in cases of posterior cerebral artery occlusion, either from a cardiogenic source or from a thrombus in the vertebral artery ("artery-to-artery" embolism; see Koroshetz and Ropper). Minutes or more before the hemianopia develops, the patient may report fleeting dizziness or vertigo, diplopia, or dysarthria, the result of transient occlusion of the origins of small penetrating vessels as the embolus traverses the basilar artery. Small residual areas of infarction within the brainstem or cerebellum can be seen on MRI or found at autopsy and some of the signs of brainstem infarction may persist.

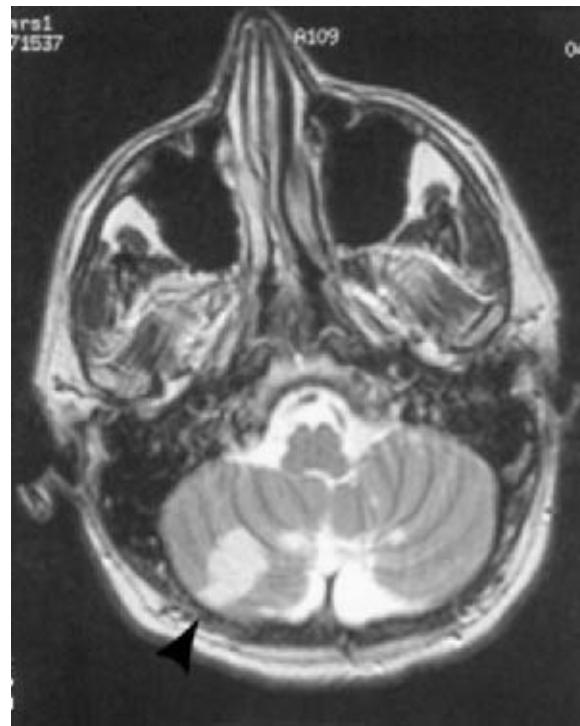

Figure 34-19. Early inferior cerebellar cortical infarction (arrowhead). T2-weighted MRI showing the lesion which encompasses the surface of the cerebellum and the immediately underlying tissue, typical of an embolic stroke, in the territory of the right posterior inferior cerebellar artery. There is a small infarction on the undersurface of the left cerebellum as well, further indicative of embolism.

Although the abruptness with which the stroke develops and the lack of prodromal symptoms point strongly to embolism, the diagnosis is based on the total clinical picture. As already emphasized, the presence of atrial fibrillation, a history of myocardial infarction (recent or in the preceding months), cardiac valvular disease or a prosthetic valve, or the occurrence of embolism to other vascular territories of the brain or to other regions of the body all support the diagnosis of embolism. This diagnosis always merits careful consideration in young persons, in whom atherosclerosis is unlikely. In instances in which the cause of embolisms cannot be ascertained, the practice is nevertheless to class them as thromboembolic.

Laboratory Findings Not infrequently the first sign of myocardial infarction is the occurrence of cerebral embolism; therefore it is advisable that an *ECG and echocardiogram be obtained in all patients with stroke of uncertain origin*, particularly since about 20 percent of myocardial infarctions are of the "silent" variety; if the ECG does not yield relevant information, prolonged study of heart rhythm with Holter monitoring should be undertaken. Also, as indicated earlier, it is advisable in the elderly or in patients with severe atherosclerosis to image the aortic arch with ultrasound or MRA, looking for plaques greater than 4 mm in thickness (Amarenco et al).

Transesophageal echocardiography, which has a higher sensitivity than transthoracic echocardiography, is an important test in the evaluation of stroke in younger patients, in whom a PFO may be a mechanism for paradoxical embolism, and in older patients with arteriopathy, in whom an atrial clot or an aortic plaque may be responsible. In a study of 824 patients at the Cleveland Clinic (Leung and associates), transesophageal echocardiography detected a potential source of embolism in 50 percent, an atrial clot in 7 percent, and a complex aortic atheroma in 13 percent of those with normal transthoracic studies. The precise indications for this test, however, have not been clearly determined, and various studies give widely varying estimates of its usefulness in detecting a cardiac thrombus.

In some 30 percent of cases, cerebral embolism produces a hemorrhagic infarct. CT scanning or MRI may be helpful in showing the more intense hemorrhagic infarcts, particularly if the scan is repeated on the second or third day or later. Only in a minority of these instances do red cells enter the CSF—rarely as many as 10,000/mm³. In the milder cases of hemorrhagic infarction, a slight xanthochromia may appear after a few days.

Septic embolism resulting from *subacute bacterial endocarditis* may cause the white blood cells (WBCs) in the CSF to be increased, up to 200/mm³ but occasionally much higher; the proportion of lymphocytes and polymorphonuclear cells varies with the acuteness of the inflammatory reaction. There may also be an equal number of red blood cells and a faint xanthochromia. The protein content is elevated but the glucose content is normal. However, no bacteria are seen or obtained by culture. By contrast, the CSF formula in septic embolism from *acute bacterial endocarditis* may be that of a purulent meningitis.

Course and Prognosis The remarks concerning the *immediate prognosis* of atherothrombotic infarction apply to embolic infarction as well. Most patients survive the initial insult, and in many the neurologic deficit may recede relatively rapidly, as indicated above. Progressive brain swelling occurs in a small proportion, less than 5 percent, and mainly in patients with embolic occlusion of

the distal carotid or the stem of the middle cerebral artery and in a larger proportion of sizable cerebellar infarcts. In the case of massive cerebral edema, management follows along the same lines as that for atherosclerotic thrombotic infarction (page 695). The *eventual prognosis* is determined by the occurrence of further emboli and the gravity of the underlying illness—cardiac failure, myocardial infarction, bacterial endocarditis, malignancy, and so on.

In a small number of cases, the first episode of cerebral embolism will be followed by another, frequently with severe consequences if the second stroke affects the opposite hemisphere. There is no certain way of predicting when the second embolus will strike. However, the occurrence of this second event, once thought to be as high as 20 percent, has been revised downward, to perhaps 2 percent, based on several large trials that were designed to test the effects of anticoagulation (see the review of Swanson). This has a bearing on the choice of early treatment after embolic stroke.

Treatment and Prevention Three phases of therapy—(1) general medical management in the acute phase, (2) measures directed to restoring the circulation, and (3) physical therapy and rehabilitation—are much the same as described earlier, under "Atherothrombotic Infarction." Issues pertaining to the prevention of recurrent embolism are discussed below. Thrombolysis has been successful to the extent indicated previously, under "Thrombolytic Therapy" (page 694), and should be attempted by intravenous injection of t-PA when practical. There is no evidence that the risk of symptomatic hemorrhage (6 to 20 percent) from this treatment is any higher than in other types of stroke. Embolectomy at the bifurcation of the common carotid artery has usually failed; it is therefore rarely attempted. Similarly, embolectomy of the middle cerebral artery has been successful only in rare cases and is rarely undertaken. However, intra-arterial thrombolysis, by a catheter or thrombolytic agent, is being studied by several means, mainly as a method of restoring cerebral circulation in the period beyond the 3 h of opportunity for intravenous thrombolysis.

Of prime importance is the *prevention of cerebral embolism*; this applies both to patients who have had an episode of embolism and to those who have not but are at risk of doing so. The long-term use of anticoagulants has proved to be effective in the prevention of embolism in cases of atrial fibrillation, myocardial infarction, and valve prosthesis, as noted below. The roles of aspirin and warfarin depend on the specific circumstances and presumed origin of the embolus.

The most convincing evidence favoring the efficacy of anticoagulants in the prevention of embolism in one group of patients has been presented by the Boston Area Anticoagulant Trial for Atrial Fibrillation. The special group of patients at risk for stroke from chronic atrial fibrillation was maintained for 2 years on warfarin (INR of 1.5 to 2); there were 212 anticoagulated patients and 208 controls. Recurrent strokes were reduced by 86 percent in the warfarin group, and the death rate was also lower. One fatal hemorrhage occurred in each group; minor hemorrhages occurred in 38 of the warfarin group and in 21 of the control group. In a similar study from Copenhagen, the incidence of stroke in a group receiving warfarin was calculated to be 2 percent per year, in comparison to 5.5 percent per year in an untreated group. Several subsequent trials have attested to the efficacy of warfarin in the prevention of stroke in patients with nonrheumatic atrial fibrillation (Singer). Subsequent studies have suggested that an INR between 2 and 3

confers better protection than levels below 2. It should be pointed out, however, that patients below 65 years of age in these trials did not clearly benefit from long-term prophylactic anticoagulation unless there were additional risk factors such as diabetes, hypertension, congestive heart failure, or cardiac valvular disease. This group, (called *lone fibrillators*) which embodies a low risk for stroke, constitutes about one-third of adults with atrial fibrillation. Aspirin does not appear to afford the same degree of protective benefit in these circumstances, but some studies suggest a slightly better outcome than with no treatment; it has been used in younger patients and in those unable to take warfarin.

In patients with atrial fibrillation of recent onset, an attempt should be made to restore normal sinus rhythm by the use of electrical cardioversion or a trial of antiarrhythmic drugs. If these fail, prophylactic anticoagulant therapy is recommended. Before attempting cardioversion of more long-standing atrial fibrillation, anticoagulation for several days or longer is recommended.

With regard to aspirin treatment when the stroke is of unknown origin but presumed to be embolic, the data are uncertain. Most large trials comparing aspirin to warfarin have studied patients in whom cardiogenic embolus is not implicated (such as in the earlier mentioned WARSS study), but there are probably many cases that have a cardiac source nonetheless (see earlier discussion of treatment for thrombotic stroke).

There is no unanimity of opinion about the use and timing of anticoagulation with warfarin after an embolic stroke, in part because the risk of recurrent stroke in the first days is low (see comments on pages 696). On the basis of the aforementioned large trials of acute anticoagulation that show a 2 percent frequency of early recurrent stroke, many clinicians prefer to start warfarin and await its effects rather than using heparin. Nonetheless, once a firm diagnosis of embolic occlusion has been made, and particularly if there has been a recent myocardial infarction, a recent onset of atrial fibrillation, or a demonstrated cardiac thrombus on the echocardiogram, our customary practice has been to begin heparin on the same or the next day, generally without a loading dose, followed by the institution of warfarin on the same or the two following days. However, many of our colleagues no longer use heparin in this setting, and others even forgo the use of warfarin unless a definite source of embolism is detected by echocardiography. The recent trend has been to avoid heparin and simply start warfarin if it is indicated. Whether the newer low-molecular-weight heparins, mentioned earlier in the chapter, yield an advantage over conventional heparin treatment is not known. In patients with very large cerebral infarcts that have a component of deep (basal ganglionic) tissue damage and especially patients who are also hypertensive, there is a distinct risk of anticoagulant-related hemorrhage into the acute infarct (Shields et al.). In these patients, anticoagulation therapy should perhaps be avoided in the acute setting.

Also in our opinion, the use of anticoagulant therapy is desirable for at least several weeks or months in most patients with acute myocardial infarction, especially if the left side of the heart is involved. In cerebral embolism associated with subacute bacterial endocarditis, anticoagulant therapy should be used cautiously because of the danger of intracranial bleeding, and one proceeds instead with antibiotics. We have generally not anticoagulated these patients.

Valvuloplasty, removal of verrucous lesions in endocarditis, and amputation of the atrial appendage have substantially reduced the incidence of embolism in the now infrequent rheumatic heart disease. The need for special care in preventing emboli that arise

from the cardiac chambers or the aortic arch from entering the carotid arteries during the performance of valvuloplasty is appreciated by all cardiac surgeons.

Generalized Brain Ischemia and Hypoxia (See Chap. 40)

This constitutes a special group of infarctions that follow cardiac arrest and other forms of prolonged hypotension or hypoxia. In the case of reduced blood flow to the cerebral hemispheres, there is a tendency for focal infarctions to occur in the regions of lowest blood flow that lie between the major surface arteries, so-called watershed infarctions. In the extreme case, there is global infarction of the brain accompanied by the clinical syndrome of brain death. Pure hypoxia-anoxia produces another type of damage in areas susceptible to reduced oxygen delivery, mainly the hippocampi; here a Korsakoff syndrome results. Most often, ischemic and hypoxic states coexist and may produce complex patterns of cerebral damage. This topic is discussed fully in Chap. 40, "The Acquired Metabolic Diseases of the Nervous System." The special problem of cerebral ischemia during cardiac surgery with the use of a bypass pump is discussed further on in the section on "Stroke with Cardiac Surgery".

LESS COMMON CAUSES OF OCCLUSIVE CEREBROVASCULAR DISEASE

(See also pages 730 to 734)

Fibromuscular Dysplasia

This is a segmental, nonatheromatous, noninflammatory arterial disease of unknown etiology. It is uncommon (0.5 percent of 61,000 arteriograms in the series of So et al.), but it is being reported with increasing frequency because of improved arteriographic techniques. In our experience, it has often been an incidental finding in asymptomatic individuals undergoing aortic angiography.

First described in the renal artery by Leadbetter and Burkland in 1938, fibromuscular dysplasia is now known to affect other vessels, including cervicocerebral ones. The internal carotid artery is involved most frequently, followed by the vertebral and cerebral arteries. The radiologic picture consists of a series of transverse constrictions, giving the appearance of an irregular string of beads or a tubular narrowing; it is observed bilaterally in 75 percent of cases. Usually only the extracranial part of the artery is involved. In the series of Houser and colleagues, 42 of 44 patients were women, and 75 percent were over 50 years of age. All of the patients reported by So and coworkers were women, ranging in age from 41 to 70 years. Cerebral ischemia may be associated with the process but the rate of this complication has not been established. Our impression is that it is low. Among 79 untreated asymptomatic patients followed for an average of 5 years, 3 had a cerebral infarct 4 to 18 years after the initial diagnosis in the study by Corrin et al. Also, between 7 and 20 percent of affected individuals are found to have intracranial saccular aneurysms (rarely a giant aneurysm), which may be a source of subarachnoid hemorrhage, and 12 percent develop arterial dissections, as described below.

The pathology of this disease has been summarized by Schievink and colleagues. The narrowed arterial segments show degeneration of elastic tissue and irregular arrays of fibrous and smooth muscle tissue in a mucous ground substance. Dilatations are due to atrophy of the coat of the vessel wall. There is atherosclerosis

in some and arterial dissection in others. Usually vascular occlusion is not present, though there may be marked stenosis. In some instances the mechanism of the cerebral ischemic lesion is unexplained. Possibly thrombi form in the pouches or in relation to intraluminal septa.

So and colleagues have recommended excision of the affected segments of the carotid artery if the neurologic symptoms are related to them and conservative therapy if the fibromuscular dysplasia is an incidental arteriographic finding in an asymptomatic patient. It is now possible to dilate the affected vessel by means of endovascular techniques, and several case reports have suggested that benefit is achieved at lower risk in this way than with surgical excision. Associated intracranial saccular aneurysms should be sought by arteriography or magnetic resonance angiography and surgically obliterated if their size warrants it (page 722). It is not known if anticoagulation or antiplatelet therapy confer protection from stroke.

Dissection of the Cervical and Intracranial Vessels

Internal Carotid Artery Dissection

It has long been appreciated that the process formerly known as Erdheim's medionecrosis aortica cystica, the main cause of aortic dissection, may extend into the common carotid arteries, occluding them and causing massive infarction of the cerebral hemispheres. Examples of such an occurrence were cited by Weisman and Adams in 1944 in their study of the neurology of dissecting aneurysms of the aorta. In more recent years, attention has been drawn to the occurrence of spontaneous dissection of the internal carotid artery and the fact that it is an important cause of hemiplegia in young adults. Several large series of such cases have been reported in separate studies by Ojemann, Mokri, and Bogousslavsky and their colleagues.

Traumatic or apparently spontaneous carotid dissection is a not uncommon cause of stroke, particularly in younger individuals. Bogousslavsky and colleagues found 30 instances (comprising both genders) in 1200 consecutive patients with a first stroke (2.5 percent). It should be suspected in young adult women (typically in their late thirties or early forties), who seem especially susceptible to the condition, either as a spontaneous event or in relation to a whiplash injury, bouts of violent coughing, or direct trauma to the head or neck, which need not be severe—e.g., being struck in the neck by a golf or tennis ball. We have also encountered cases that occurred during pregnancy and immediately after delivery. Indeed, it is questionable if many cervical arterial dissections are truly “spontaneous,” since most can be connected to some strenuous event. Three of our patients over the years had a carotid dissection that was manifest as a hemiplegia days after blunt head injury. A small number of patients have fibromuscular disease, as discussed above; the Ehlers-Danlos and Marfan syndromes, osteogenesis imperfecta, and alpha-1-antitrypsin deficiency are also associated with an increased risk of vascular dissection. One of these conditions should be suspected if multiple extracranial vessels are involved in spontaneous dissections (neck and thoracic trauma are more common causes of this configuration).

It is of interest that a few patients with carotid dissection have had warning attacks of unilateral cranial or facial pain, followed, within minutes to days, by signs of ischemia in the territory of the internal carotid artery. The pain is nonthrobbing and centered most

often in and around the eye; less often, it is in the frontal or temporal regions, angle of the mandible, or high anterior neck over the carotid artery. Rapid and marked relief of the pain after the administration of corticosteroids is virtually a diagnostic feature (see below). The ischemic manifestations consist of transient attacks in the territory of the internal carotid, followed frequently by the signs of hemispherical stroke, which may evolve smoothly over a period of a few minutes to hours or over several days in a fluctuating or stepwise fashion. A unilateral Horner syndrome is often present. Cervical bruit—sometimes audible to the patient, amaurosis fugax, faintness and syncope, and facial numbness are less common symptoms. Most of the patients described by Mokri and coworkers presented with one of two distinct syndromes: (1) unilateral headache associated with an ipsilateral Horner syndrome or (2) unilateral headache and delayed focal cerebral ischemic symptoms. Some patients have evidence of involvement of the vagus, spinal accessory, or hypoglossal nerve; these nerves lie in close proximity to the carotid artery and are nourished by small branches from it.

In most cases, dissection of the internal carotid artery can be detected by ultrasound and confirmed by MRI, which shows a double lumen, and by MRA. These procedures may obviate the need for arteriography. The latter procedure reveals an elongated, irregular, narrow column of dye, usually beginning 1.5 to 3 cm above the carotid bifurcation and extending to the base of the skull, a picture that Fisher has called the *string sign*. There may be a tapered occlusion or an outpouching at the upper end of the string. Less often the dissection is confined to the midcervical region, and occasionally it extends into the middle cerebral artery or involves the opposite carotid artery or the vertebral and basilar arteries.

The extensive study by Mokri and colleagues showed that a complete or excellent recovery occurred in 85 percent of patients with the angiographic signs of dissection; mainly, these were patients without stroke. The outcome in cases complicated by stroke is far less benign. About one-quarter of such patients succumb and one-half of the survivors remain seriously impaired (Bogousslavsky et al). In the remainder, early recanalization of the occluded artery can be observed (as determined by ultrasonography), with good functional recovery. Pseudoaneurysms form in a small proportion of patients and generally do not require surgical repair; they also do not preclude cautious anticoagulation.

The pathogenesis of spontaneous carotid dissection is at present uncertain. In most of the recently reported cases, cystic medial necrosis has not been found on microscopic examination of the involved artery. In some, there was a disorganization of the media and internal elastic lamina, but the specificity of these changes is in doubt, since Ojemann and colleagues noted similar changes in some of their control cases. In a small proportion of cases there are the changes of fibromuscular dysplasia, as noted earlier. A more thorough study of these vessels in routine autopsy material is needed.

Treatment The treatment has usually been immediate anticoagulation to prevent embolism—using first heparin, then warfarin—but it must be acknowledged that this approach has not been demonstrated to be more successful than careful observation. Once a stroke has occurred, even though embolic in most cases, prompt reopening of the artery can at times prove beneficial; this is currently performed by endovascular techniques. Despite numerous publications demonstrating the ability of skilled operators to reopen a dissection by endovascular methods, acute intervention has not been studied in a way that allows a judgment regarding its value. Whether stent placement is additionally beneficial has also not been

determined. Interesting, and of both therapeutic and diagnostic value, is the relief of pain afforded by corticosteroids in cervical and intracranial dissections, as mentioned above. Most neurologists take the approach that warfarin, if used, may be discontinued after several months or a year, when angiography or MRA shows the lumen of the carotid artery to be patent, or at least reduced to no more than 50 percent of the normal diameter, and smooth-walled.

Vertebral Artery Dissection Dissection of these arteries is less common than dissection of the extracranial carotid artery but is being recognized with increasing frequency. It may originate in the neck and extend into the intracranial portion of the vessel or remain isolated to either of these segments. In both instances there is a tendency to form pseudoaneurysms, but this is more likely with the intracranial type, and only in the latter is there a risk of rupture through the adventitia, leading to a subarachnoid hemorrhage. Rapid and extreme rotational movement of the neck is the most common identifiable cause, as in turning the head to back up a car. Chiropractic manipulation has been one precipitant. Extending the neck to have one's hair washed, and swinging a golf club have also led to dissection. Forceful coughing may also cause dissection, as in the carotid vessels. There is no female predominance (in contrast to carotid dissection), but the previously cited intrinsic weaknesses of the vascular wall from Ehlers-Danlos disease and fibromuscular dysplasia are risk factors.

The dissection usually originates in the C1-C2 segment of the vessel, where it is mobile but tethered as it leaves the transverse foramen of the axis and turns sharply to enter the cranium. The symptoms, mainly vertigo, derive from the lateral medullary syndrome, often with additional features referable to the pons or midbrain, particularly diplopia and dysarthria. The clinical manifestations in our experience have fluctuated over minutes and hours, quite unlike the usual vertebrobasilar TIA.

Less common strokes include artery-to-artery embolism to the posterior cerebral territory or, a syndrome that has come to our attention several times in the past few years, a centrally placed infarction of the cervical spinal cord, presumably from occlusion of the anterior spinal artery.

The diagnosis of vertebral dissection should be suspected if persistent occipitonal pain is prominent and follows one of the known precipitants—such as chiropractic manipulation of the neck, head trauma, or Valsalva straining or coughing activities—but it may otherwise escape detection until the full-blown medullary or cerebellar stroke is established. The latter may follow the inciting event by several days or weeks or even longer, obscuring the relationship. Axial MRI images, particularly the T1-weighted sequences, show a double lumen in the dissected vessel, and skillful ultrasound investigation documents the same. Mokri et al have found that some patients have evidence of spontaneous or traumatic dissection of multiple extracranial vessels; this also occurs as a consequence of dissection of the aortic arch from chest trauma.

Treatment This has usually been with heparin anticoagulation followed for a period by warfarin, but the precise duration of treatment is difficult to determine and the same uncertainties as to effectiveness of anticoagulation and of stent placement discussed above in regard to carotid dissection pertain here. Whether there is an inordinate risk of subarachnoid hemorrhage with intracranial dissection has not been settled. The usual practice is to repeat an imaging or ultrasound study several months after the dissection and discontinue the anticoagulation if the vessel lumen has been re-established sufficiently to allow good blood flow. Pseudoaneu-

rysts in the cervical portions of the vessels generally do not require specific treatment.

As with other dissections, corticosteroids may relieve the initial associated pain.

Intracranial Arterial Dissection Dissections of intracranial arteries are less common than extracranial dissections and present in several ways. A number of times we have misinterpreted the arteriographic appearance of a short segment of narrowing of the basilar or proximal middle cerebral arteries, assuming these changes to represent embolism or arteritis when in fact they proved to be dissections of the vessel wall. In the case of purely intracranial dissection of the middle cerebral or basilar arteries, there is usually no preceding trauma, but a few patients have had minor head injuries, extreme coughing, or other Valsalva-producing events (e.g., after childbirth)—or they had used cocaine. The typical picture is of fluctuating symptoms referable to the affected circulation and severe cranial pain on the side of the occlusion—retro-orbital in the case of middle cerebral dissection, occipital in the case of basilar dissection, occipital combined with supraorbital in the case of vertebral dissection (see above). A few have had sudden strokes that suggested embolic infarction, and a small number present with subarachnoid hemorrhage.

Treatment This is primarily with anticoagulation and follow-up arteriography. It is notable that corticosteroids have relieved the cranial and retro-orbital pain in our cases, and dramatic relief of pain within an hour is a virtually diagnostic. Endovascular revascularization has been attempted with mixed results, the main problem being catastrophic and usually fatal vessel rupture during angioplasty.

Moyamoya Disease

Moyamoya is a Japanese word for a “cloud of smoke” or “haze”; it has been used in recent years to refer to an *extensive basal cerebral rete mirabile*—a network of small anastomotic vessels at the base of the brain around and distal to the circle of Willis, seen in carotid arteriograms, along with segmental stenosis or occlusion of the terminal parts of both internal carotid arteries.

Nishimoto and Takeuchi have reported on 111 cases that were selected on the basis of these two radiologic criteria. The condition was observed mainly in infants, children, and adolescents (more than half the patients were less than 10 years of age, and only 4 of the 111 were above age 40). All of the patients were Japanese; both males and females were affected, and 8 were siblings. The symptom that led to medical examination was usually a sudden weakness of an arm, leg, or both on one side. The weakness tended to clear rapidly but recurred in some instances. Headache, convulsions, impaired mental clarity, visual disturbance, and nystagmus occurred less frequently. In older patients, subarachnoid hemorrhage was the most common initial manifestation. Other symptoms and signs were speech disturbance, sensory impairment, involuntary movements, and unsteady gait. Only 6 of the entire series became worse after the initial illness, and 4 died. Characteristics noted by others include prolonged TIAs (this accords with our experience), characteristically induced by hyperventilation or hyperthermia, parenchymal rather than subarachnoid hemorrhages (most are situated in the basal ganglia or thalamus), and an unusual “rebuildup” EEG phenomenon in which high-voltage slow waves reappear 5 min after the end of hyperventilation.

Postmortem examination of these cases has yielded a reason-

ably clear picture of the distal carotid lesion. The adventitia, media, and internal elastic laminae of the stenotic or occluded arteries were normal, but the intima was greatly thickened by fibrous tissue. No inflammatory cells or atheromata were seen. In a few cases, hypoplasia of the vessel with absent muscularis has been described. The rete mirabile consists of a fine network of vessels over the basal surface (in the pia-arachnoid), which, according to Yamashita and coworkers, reveal microaneurysm formation due to weakness of the internal elastic lamina and thinness of the vessel wall. The latter lesion is the source of subarachnoid hemorrhage. Thus one part of the symptomatology is traced to the distal carotid stenosis and another to the rupture of the vascular network.

This form of cerebrovascular disease is not limited to the Japanese. The authors have periodically observed such patients, as have others, in the United States, western Europe, and Australia. Opinion is divided as to whether the basal rete mirabile represents a congenital vascular malformation (i.e., a persistence of the embryonal network) or a rich collateral vascularization secondary to a congenital hypoplasia, acquired stenosis, or occlusion of the internal carotid arteries early in life. The association between moyamoya, Down syndrome, and certain HLA types favors a hereditary basis (Kitahara et al).

Treatment The treatment of moyamoya is far from satisfactory. Certain surgical measures have been employed, including transplantation of a vascular muscle flap, omentum, or pedicle containing the superficial temporal artery to the pial surface of the frontal lobe, with the idea of creating neovascularization of the cortical convexity. These measures have reportedly reduced the number of ischemic attacks, but whether they alter the natural history of the illness cannot be stated. Anticoagulation has been considered risky in view of the possibility of cerebral hemorrhage, but there are no systematic studies.

Binswanger Disease

Binswanger disease has been mentioned briefly in the discussion of the course and prognosis of atherosclerotic infarction and as a cause of dementia in Chaps. 21 and 39. The term has come to denote a widespread degeneration of cerebral white matter having a vascular causation and observed in the context of hypertension, atherosclerosis of the small blood vessels, and multiple strokes (see page 909). Hemiparesis, dysarthria, TIAs, and typical lacunar or cortical strokes are admixed in many cases. The process has been associated with a particular radiologic appearance that reflects the confluence of areas of white matter changes. The term *leukoareosis*, meant to describe the less intense appearance of periventricular tissues in imaging studies, complicates the matter, since this condition is also assumed to have a vascular basis, and the term has been used indiscriminately, particularly by some radiologists, as equivalent to *Binswanger disease*. Whether multiple discrete lacunes in the deep white matter constitutes Binswanger disease may be a semantic issue, but we adhere to the notion that the former is characterized by a more confluent and widespread ischemic and gliotic change in the deep white matter.

Dementia, a pseudobulbar state, and a gait disorder, alone or in combination, are the main features of Binswanger cases. They have been attributed to the cumulative effects of the ischemic changes and specifically to the white matter degeneration. The pathologic basis of such a clinical entity has not been well delineated. More importantly, the gliosis that is found in white matter has been assumed to represent a special type of ischemic change,

but the vessels in these regions have never been adequately studied (by serial sections). Yet another problem, as mentioned, is to distinguish such a state from deficits produced by the cumulative effect of numerous larger lacunes, which have for a century been known to cause the aforementioned syndromes of dementia, gait disturbance, and a pseudobulbar syndrome. From time to time, imaging studies of the brain disclose large regions of white matter change or the occurrence of multiple infarctions in the absence of hypertension, and it is not clear how such cases should be classified. Some prove to be areas of demyelination or metabolic dysmyelination, others are mitochondrial disorders, and perhaps some are related to the familial syndrome discussed below. Fabry disease also enters into the differential diagnosis of multiple small infarctions in the cerebrum that may coalesce into areas of white matter damage (page 839). Readers should consult the reviews by Babikian and Ropper, by Caplan, and by Mohr and Mast.

Familial Subcortical Infarction (CADASIL)

A process similar to Binswanger leukoencephalopathy, but without hypertension, has been identified as an autosomal dominant familial trait linked in several families to a mutation on chromosome 19. It had been described previously under a number of names, including *hereditary multi-infarct dementia*. The acronym CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is now applied. In these patients, recurrent small strokes, often beginning in early adulthood, culminate in a subcortical dementia. Migraine headaches, often with neurologic accompaniments, may precede the strokes by several years, as may numerous and varied TIAs that are attributed, probably incorrectly, to the migraine. Some individuals display few clinical changes; others are demented or have strokes that simulate lacunes. We are unable to comment on the encephalopathy and coma, in some cases accompanied by fever, described by Schon and colleagues. It seems to represent another very rare condition.

The familial nature of the process may not be appreciated because genetic penetrance is not complete until after 60 years of age. On MRI scans, clinically unaffected family members may show substantial changes in the white matter well before strokes or dementia arises. In some cases, particularly in Japan, early alopecia and lumbar spondylosis have been associated with CADASIL.

The MRI and CT appearance of multiple confluent white matter lesions of various sizes, many quite small and concentrated around the basal ganglia and periventricular areas, is similar to that in Binswanger disease. When these are asymmetrical and periventricular, they are difficult to distinguish from the lesions of multiple sclerosis. In the autopsy cases studied by Jung and colleagues, numerous partially cavitated infarctions were found in the white matter and basal ganglia. In the regions of these infarctions were small vessels, 100 to 200 mm diameter, in which the media contained basophilic granular deposits with degeneration of the smooth muscle fibers. Attribution of the white matter degeneration to these vascular changes presents the same problems as in Binswanger disease, particularly in view of patency of most of the many small vessels in the material. Again, the relation of the vascular changes to lesions in the brain has not been studied in serial sections. Nevertheless, CADASIL is probably the main cause of sporadic instances of what otherwise passes for Binswanger disease but without the obligate hypertension of the latter. Also, migraine headaches are not a component of Binswanger disease.

The responsible mutation on chromosome 19 of the Notch 3 gene, in the same locus as the gene for familial hemiplegic migraine, has been characterized by Joutel and colleagues; this provides a diagnostic test that can be performed on the blood or skin. However, the mechanism by which this leads to the vasculopathy or white matter changes is not clear. The diagnosis can also be confirmed by finding eosinophilic inclusions in the arterioles of a skin biopsy (osmophilic with electron microscopy). Awareness of this apparently vascular form of white matter degeneration adds to the list of inherited leukoencephalopathies, the others being inherited metabolic disturbances, as discussed in Chap. 38.

Amyloid Angiopathy

This process is discussed further on in relation to lobar cerebral hemorrhages in the elderly. The angiopathy consists of the deposition of amyloid in the media and adventitia of small vessels, predominantly in the meninges, cortex, and cortical penetrating vessels. The incidence at autopsy of vascular amyloid deposition in the brain is related to the age of the population studied; rates of 12 percent are cited in patients above 85 years of age (the same changes are present in over 25 percent of individuals with Alzheimer disease, but the nature of the amyloid is different in the two conditions). Over the last few years, however, our colleague Greenberg has emphasized certain clinical features associated solely with cerebrovascular amyloidosis. Of interest here are multiple TIAs, some with migrainous features such as spreading sensory symptoms, and fairly rapid progression to dementia. Telltale signs of small hemorrhages that are more characteristic of diffuse cerebrovascular amyloid are often present in these cases. These old hemorrhages are seen to advantage with gradient echo sequences on the MRI. The frequency of this interesting condition in the elderly is unclear. There is a separate familial amyloidotic condition of diffuse white matter degeneration with dementia, associated in some families with calcification in the occipital lobes.

Strokes in Children and Young Adults

As indicated in Table 34-2, it is probable that ischemic necrosis of cerebral tissue can occur in utero. The resulting stroke is usually referred to as *congenital hemiplegia*. However, very little is known about the underlying vascular lesions, so that nothing further can be said about them here.

The occurrence of acute hemiplegia in infants and children is a well-recognized phenomenon. In a series of 555 consecutive postmortem examinations at the Children's Medical Center in Boston, there were 48 cases (8.7 percent) of occlusive vascular disease of the brain (Banker). The occlusions were both embolic (mainly associated with congenital heart disease) and thrombotic, and the latter were actually more common in veins than in arteries. Similarly, stroke is not an uncommon event in young adults (15 to 45 years). This group accounts for an estimated 3 percent of cerebral infarctions. In terms of causation, this group is remarkably heterogeneous. In a series of 144 such patients, more than 40 possible etiologies were identified (H. P. Adams et al.). Nevertheless, 78 percent of the group could be accounted for by three categories, more or less equal in size: atherosclerotic thrombotic infarction (usually with a recognized risk factor); cardiogenic embolism (particularly in association with rheumatic heart disease, bacterial and verrucous endocarditis, paradoxical embolism through patent foramen ovale, and prosthetic valves); and nonatherosclerotic vascu-

lopathies (arterial trauma, dissection of the carotid artery, moyamoya, lupus erythematosus, drug-induced, vasculitis). Hematologically related disorders—use of oral contraceptives (see further on), the postpartum state, and hypercoagulable states—were the probable causes in 15 percent of the 144 patients. The presence of antiphospholipid or anticardiolipin antibodies (lupus anticoagulant) appears to explain some of these cases and is discussed further under “Stroke as a Complication of Hematologic Disease”; the majority of these patients are women in their thirties without manifest systemic lupus erythematosus.

Despite the attention they have received as a cause of strokes in the juvenile period, the frequency of thrombophilic disorders due to inherited deficiencies of naturally occurring anticoagulant factors is low. The main inherited prothrombotic clotting defects are summarized in Table 34-8. They predispose primarily to cerebral venous clotting. Most arise from partial protein deficiencies due to heterozygous mutations in the genes encoding proteins that are important factors in the clotting cascade (antithrombin III, proteins S and C) and those due to disturbances of clotting balance (resistance to activated protein C, or factor V Leiden mutation, and prothrombin mutations as well as excess factor VIII) (see discussion by Brown and Bevan). However, when they are homozygous, these mutations may be associated with devastating neonatal hemorrhagic conditions. In some series that report cases of strokes in youth, such that of Becker and colleagues, up to half of the cases had one of these disorders, the commonest being the factor V Leiden mutation, but others have found this mutation to be much less frequent, and that is consonant with our experience. Nevertheless, in children with unexplained stroke, particularly venous and especially if there has been a previous thrombosis or if the strokes are recurrent, it is advisable to carry out an extensive hematologic investigation, especially including testing for antiphospholipid antibody (an acquired defect), as described on page 735. Establishing a diagnosis of a prothrombotic clotting gene variant has therapeutic significance, since strokes are prone to occur in the setting of such additional risks as the use of oral contraceptives or smoking. In adults, the evaluation for inherited clotting defects is far less fruitful. Furthermore, it should be kept in mind that the levels of proteins C and S and of antithrombin are temporarily depressed after stroke, so that any detected abnormalities must be confirmed months later.

Persistent cerebral ischemia and infarction may occasionally complicate migraine in young persons. The combination of migraine and “the Pill” is particularly hazardous, as detailed below. Similarly, despite the common occurrence of mitral valve prolapse in young adults, it is probably only rarely a cause of stroke (see comments on page 710). Stroke due to either arterial or venous occlusion occurs occasionally in association with ulcerative colitis and to a lesser extent with regional enteritis. Evidence points to a hypercoagulable state during exacerbations of inflammatory bowel disease, but a precise defect in coagulation has not been identified. Meningovascular syphilis and fungal and tuberculous meningitis and other forms of chronic basal meningitis are considerations in this age group; the strokes are usually of the cavitary lacunar type, resulting from infectious-inflammatory occlusion of small basal vessels.

Sickle cell anemia is a rare but important cause of stroke in children of African ancestry; acute hemiplegia is the most common manifestation, but all types of focal cerebral disorders have been observed. The pathologic findings are those of infarction, large and small; their basis is assumed to be vascular obstruction associated with the sickling process. Intracranial bleeding (subdural, subarach-

Table 34-8
Stroke associated with genetic disorders

		GENE	INHERITANCE	STRUCTURES AFFECTED	GENERAL POPULATION (%)	WITH CEREBRAL THROMBOSIS (%)
Causes of arterial or venous infarction						
Activated protein C resistance	Leiden factor V mutation		AR	v	2–15	5–20
Prothrombin 20210	Prothrombin		AR	v	0.1	1–5

noid, and intracerebral) and cerebral venous thrombosis may also complicate sickle cell anemia, and—perhaps because of autopsplenectomy—there is an increased incidence of pneumococcal meningitis. Treatment of the cerebral circulatory disorder, based presumably on sludging of red blood cells, is with intravenous hydration and transfusion. Cerebral venous sinus thrombosis in young children and neonates represents a special problem, difficult to diagnose, and with a poor prognosis (see de Veber et al).

Certain hereditary metabolic diseases (*homocystinuria* and *Fabry angiokeratosis*) and the mitochondrial disorder *MELAS* (mitochondrial encephalomyopathy, lactic acidosis, and stroke), discussed on page 839, may give rise to strokes in children or young adults; investigation of these causes is undertaken if the aforementioned diagnoses have been excluded.

Overall, in children and young adults with ischemic stroke, the main diagnoses to be considered are carotid and vertebral dissection, drug abuse (mainly cocaine), thrombosis induced by birth control pills (see below), antiphospholipid antibody syndrome, and patent foramen ovale (PFO). Migraine might be added to this list, but it is a diagnosis by exclusion in these circumstances and CADASIL, albeit rare, should also be considered if migraine headaches and TIAs precede a stroke. Inherited prothrombotic states—such as those caused by the various clotting factor deficiencies discussed above, Fabry disease, moyamoya, and Takayasu arteritis—arise in the younger age group and require exploration if clinical circumstances suggest on the basis of unusual TIAs (orthostatic or hyperventilation induced), Down syndrome, or strong family history of strokes in youth.

Oral Contraceptives, Estrogen, and Cerebral Infarction The early studies of Longstreth and Swanson and of Vessey et al clearly indicated that women who take oral contraceptives in the childbearing years—particularly if they are older than 35 years of age and also smoke, are hypertensive, or have migraine—are at increased risk of cerebral infarction as well as of ischemic heart disease and subarachnoid hemorrhage. Cerebral infarction in these cases is due to arterial occlusion, occurring in both the carotid–middle cerebral and vertebrobasilar territories. In most of the reported fatal cases, the thrombosed artery has been free of atheroma or other disease. This has been taken to indicate that embolism is responsible for the strokes, but the source of embolism can rarely be demonstrated. Cerebral and noncerebral venous thromboses are other relatively rare complications. These observations, coupled with evidence that estrogen alters the coagulability of the blood, suggest that a state of hypercoagulability is an important factor in the genesis of contraceptive-associated infarction.

The vascular lesion underlying cerebral thrombosis in women taking oral contraceptives has been studied by Irey and colleagues. It consists of nodular intimal hyperplasia of eccentric distribution with increased acid mucopolysaccharides and replication of the internal elastic lamina. Similar changes have been found in pregnancy and in humans and animals receiving exogenous steroids, including estrogens. Whether these promote *in situ* thrombosis is not known. Mainly at increased risk of stroke are women taking high-dose (0.50-mg) estrogen pills; lowering the estrogen content has substantially reduced this risk. The use of progestin-only pills (POPs) or of Norplant (subcutaneously implanted capsules of progestin) alone has not been associated with an increased risk of stroke (Petitti et al). It has also become clear that mutations of the prothrombin gene are far more frequent in patients who have cerebral venous thrombosis while on oral contraceptive pills. These genetic abnormalities are thought by Martinelli and associates to account for 35 percent of idiopathic cases of cerebral vein thrombosis; they contend that contraceptives increase the risk 20-fold.

Stroke in Pregnancy and the Postpartum Period

In addition to the eclamptic state, there is an increased incidence of cerebrovascular events during pregnancy and the postpartum period. The risk of both cerebral infarction and intracerebral hemorrhage appears to be mainly in the 6-week period after delivery rather than during the pregnancy itself (Kittner et al). Fisher has reviewed the literature and has himself analyzed 12 postpartum, 9 puerperal, and 14 contraceptive cases, as well as 9 patients receiving estrogen therapy; arterial thrombosis was demonstrated in half of the group. Most of the focal vascular lesions during pregnancy were due to arterial occlusion in the second and third trimesters and in the first week after delivery. Venous occlusion tended to occur 1 to 4 weeks postpartum. In Rochester, New York, the incidence rate of stroke during pregnancy was 6.2 per 100,000, but it doubled with each advance in age from 25 to 29, 30 to 39, and 40 to 49 years. Included in most series are cases of cardiac disease, particularly valve-related embolism. It is perhaps surprising that subarachnoid hemorrhage is not more frequent during the Valsalva activity of childbirth. Carotid artery dissection may also be encountered late in pregnancy or soon after delivery.

The occurrence of paradoxical embolus is always a consideration in pregnancy because of a tendency to form clots in the pelvic and leg veins, coupled with increased right heart pressures.

Amniotic fluid embolus may also cause stroke in this manner and should be suspected in multiparous women who have had uterine tears. In the latter, there are almost invariably signs of acute pulmonary disease from simultaneous occlusion of lung vessels. A rare peripartum cardiomyopathy is yet another source of embolic stroke.

Stroke with Cardiac Surgery

Incident to cardiac arrest and bypass surgery there is risk of both generalized and focal hypoxia-ischemia of the brain. Improved operative techniques have lessened the incidence of these complications, but they are still distressingly frequent. Fortunately, most of these cerebral disorders are transient. Atherosclerotic plaques may be dislodged during cross-clamping of the proximal aorta and are an important source of cerebral emboli. In the last decade the incidence of stroke related to cardiac surgery has dropped to between 2 and 3 percent in large series numbering thousands of patients (Libman et al, Algren and Aren). Advanced age, congestive heart failure, and more complex surgeries have been listed as risk factors for stroke in various reports. In a retrospective study by Dashe and colleagues, 2.2 percent had strokes, and the risk was greatly increased (greater than 70 percent) on the side of a carotid stenosis. Curiously, almost one-fifth of postoperative strokes have been of lacunar type. In one prospective study of 2108 patients who underwent coronary operations in several institutions, 3 percent had strokes or TIAs and the same number had a deterioration of cognitive function; mostly the adverse effects occurred in older patients and were transient (Roach et al).

Mohr and coworkers examined 100 consecutive cases pre- and postoperatively and observed two types of complications—one occurring immediately after the operation and the other after an interval of days or weeks. The immediate neurologic disorder consisted of a delay in awakening from the anesthesia; subsequently there was slowness in thinking, disorientation, agitation, combativeness, visual hallucinations, and poor registration and recall of what was happening. These symptoms, in the form of a confusional state sometimes verging on delirium or acute psychosis, usually cleared within 5 to 7 days, although some patients were not entirely normal mentally some weeks later. As the confusion cleared, about half of the patients were found to have small visual field defects, dyscalculia, oculomotor ataxia, alexia, or defects of perception suggestive of lesions in the parieto-occipital regions. The immediate effects were attributed to hypotension and various types of embolism (atherosclerotic, air, silicon, fat, platelets). The delayed effects were more clearly embolic and were especially frequent in patients having prosthetic valve replacements. However, they also occurred subsequent to arterial homografts.

In addition to overt and covert strokes, a degree of cognitive decline and depression is to be expected in a proportion of patients undergoing coronary artery bypass grafting. The frequency of these changes is reported to be between 40 and 70 percent (see page 363). It is our impression that many of these neurologic complications, both small strokes and cognitive abnormalities, pass unnoticed in many cardiac surgical units. This was emphasized in the study by McKhann and colleagues, who extensively tested several neuropsychologic areas and found that only 12 percent of patients escaped some type of early cognitive problem. However, several other studies, such as the one by Mülges and colleagues, have suggested that only a small proportion (13 percent in their series) have permanent effects 5 years after operation. Others have reported

higher rates, but it is clear that the cognitive problems improve over time in the majority of patients.

The use of Doppler insonation of the middle cerebral arteries is being studied to detect transient signals called HITs (high-intensity transients) as a manifestation of small emboli during surgery—but, as in cerebral arteriography, the clinical importance of these emboli is not known.

The special stroke problems relating to prosthetic heart valves—mainly infective endocarditis causing embolic strokes and anticoagulant-related cerebral hemorrhage—are described in appropriate sections of this chapter.

INTRACRANIAL HEMORRHAGE

This is the third most frequent cause of stroke. Although more than a dozen causes of nontraumatic intracranial hemorrhage are listed in Table 34-9, primary or hypertensive (“spontaneous”) intracerebral hemorrhage, ruptured saccular aneurysm and vascular malformation, and hemorrhage associated with the use of anticoagulants or thrombolytic agents account for the majority. Cerebrovascular amyloidosis and bleeding disorders account for a small number. The small brainstem hemorrhages secondary to temporal lobe herniation and brainstem compression (Duret hemorrhages), hypertensive encephalopathy, and brain purpura might be included in this group, but they do not simulate a stroke.

Primary (Hypertensive) Intracerebral Hemorrhage

This is the mundane “spontaneous” brain hemorrhage. It is due predominantly to chronic hypertension and degenerative changes in cerebral arteries. In recent decades, with increased awareness of the need to control blood pressure, the proportion of hemorrhages attributable to causes other than hypertension has greatly increased; more than half such hemorrhages on our services now occur in

Table 34-9
Causes of intracranial hemorrhage (including intracerebral, subarachnoid, ventricular, and subdural)

1. Primary (hypertensive) intracerebral hemorrhage
2. Ruptured saccular aneurysm
3. Ruptured AVM; less often, venous and dural vascular malformations
4. Cavernous angioma
5. Trauma including posttraumatic delayed apoplexy
6. Hemorrhagic disorders: leukemia, aplastic anemia, thrombocytopenic purpura, liver disease, complication of anticoagulant or thrombolytic therapy, hypofibrinogenemia, hemophilia, Christmas disease, etc.
7. Hemorrhage into primary and secondary brain tumors
8. Septic embolism, mycotic aneurysm
9. With hemorrhagic infarction, arterial or venous
10. With inflammatory and infectious disease of the arteries and veins
11. With arterial amyloidosis
12. Miscellaneous rare types: vasopressor drugs, cocaine, moyamoya, herpes simplex encephalitis, vertebral artery dissection, acute necrotizing hemorrhagic encephalitis (Hurst disease), tularemia, anthrax, etc.

normotensive individuals, and the hemorrhages more often than previously arise in locations that are not typical for hypertension. Nevertheless, the hypertensive cerebral hemorrhage serves as a paradigm for understanding and managing the cerebral hemorrhage.

In order of frequency, the most common sites of a cerebral hemorrhage are (1) the putamen and adjacent internal capsule (50 percent); (2) the central white matter of the temporal, parietal, or frontal lobes (lobar hemorrhages, not strictly associated with hypertension); (3) the thalamus; (4) a cerebellar hemisphere; and (5) the pons (see Weisberg et al). The vessel involved is usually a penetrating artery that originates from a larger trunk vessel. About 2 percent of primary hemorrhages are multiple. Rarely the bleeding is solely intraventricular, possibly from the choroid plexus. The problem is one of bleeding that occurs within brain tissue; rupture of arteries lying in the subarachnoid space is practically unknown apart from aneurysms and some vascular malformations.

The extravasation of blood forms a roughly circular or oval mass that disrupts the tissue and grows in volume as the bleeding continues (Fig. 34-20). Adjacent brain tissue is distorted and compressed. If the hemorrhage is large, midline structures are displaced to the opposite side and reticular activating and respiratory centers can be compromised, leading to coma and death in the manner described in Chap. 17. Both the size and the location of the clot determine the degree of upper brainstem compression (Andrew et al). Rupture or seepage into the ventricular system may occur, and the CSF becomes bloody in these cases. However, a hemorrhage of this type almost never ruptures through the cerebral cortex. When the hemorrhage is small and located at a distance from the ventricles, the CSF may remain clear even on repeated examination.

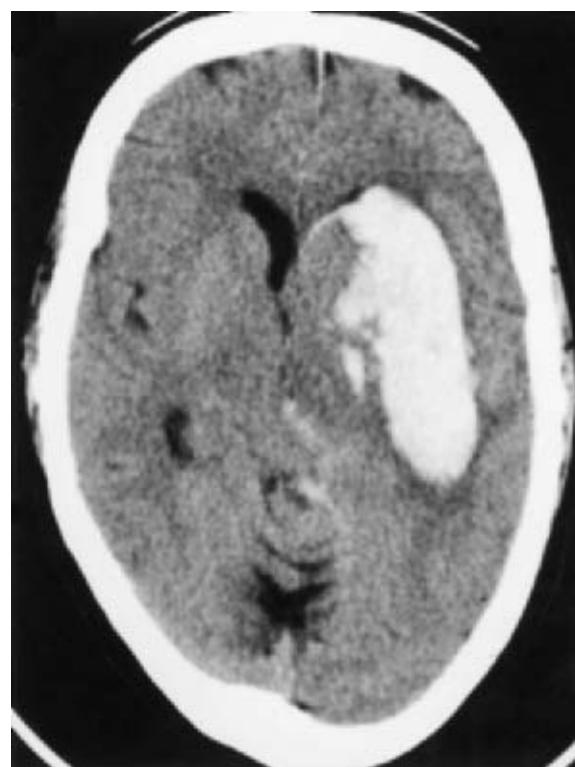

Figure 34-20. An unenhanced CT scan showing the typical picture of a massive primary (hypertensive) hemorrhage in the basal ganglia. The third ventricle and ipsilateral lateral ventricle are compressed and displaced by the expanding mass (12 h after onset of stroke).

tions. In the first hours and days following the hemorrhage, a limited amount of edema accumulates around the clot and adds to the mass effect. Hydrocephalus may occur as a result of bleeding into the ventricular system or from compression of the third ventricle.

Extravasated blood undergoes a predictable series of changes. At first fluid, it clots within hours. Before the clot forms, red cells may settle in the dependent part of the hematoma and form a meniscus with the plasma above; this is particularly prone to occur in cases of anticoagulant-induced hemorrhage. A fluid-fluid level is then observed on scans ("hematocrit effect"). Only masses of red blood cells (RBCs) and proteins are found within the hematoma; rarely one sees a few remnants of destroyed brain tissue. The hematoma is surrounded by petechial hemorrhages from torn arterioles and venules. Within a few days, hemoglobin products, mainly hemosiderin and hematoidin, begin to appear. The hemosiderin forms within histiocytes that have phagocytized RBCs and takes the form of ferritin granules, which stain positively for iron. As oxyhemoglobin is liberated from the RBCs and becomes deoxygenated, methemoglobin is formed. This begins within a few days and imparts a brownish hue to the periphery of the clot. Phagocytosis of RBCs begins within 24 h, and hemosiderin is first observed around the margins of the clot in 5 to 6 days. The clot changes color gradually, over a few weeks, from dark red to pale red, and the border of golden-brown hemosiderin widens. The edema disappears over many days or weeks. In 2 to 3 months, larger clots are filled with a chrome-colored mush, which is slowly absorbed, leaving a smooth-walled cavity (slit hemorrhage) or a yellow-brown scar. The iron pigment (hematin) becomes dispersed and studs adjacent astrocytes and neurons. It may persist well beyond the border of the hemorrhage for years.

In CT scans, fresh blood is visualized as a white mass as soon as it is shed. The mass effect and the surrounding extruded serum and edema are hypodense. After 2 to 3 weeks, the surrounding edema begins to recede and the density of the hematoma decreases, first at the periphery. Gradually the clot becomes isodense with brain. There may be a ring of enhancement from the hemosiderin-filled macrophages and the reacting cells forming the capsule of the hemorrhage. By MRI, either in conventional T1- or T2-weighted images, the hemorrhage is not easily visible in the 2 or 3 days after bleeding, since oxyhemoglobin is diamagnetic or, at most, is slightly hypointense, so that only the mass effect is evident. After several days the surrounding edema is hyperintense in T2-weighted images. As deoxyhemoglobin and methemoglobin form, the hematoma signal becomes bright on T1-weighted images and dark on T2. As the hematoma becomes subacute, the dark images gradually brighten. When methemoglobin disappears and only hemosiderin remains, the entire remaining mass is hypodense on T2-weighted images, as are the surrounding deposits of iron. MR images that display areas of magnetic susceptibility will show hemorrhages earlier and detect remnants of deposited hemosiderin even years afterwards.

Hemorrhages may be described as massive, moderate, small, slit, and petechial. *Massive* refers to hemorrhages several centimeters in diameter; *small* applies to those 1 to 2 cm in diameter and less than 20 mL in volume; a moderate-sized hemorrhage, of course, falls between these two, both in diameter and in volume. *Slit* refers to an old collapsed hypertensive or traumatic hemorrhage that lies just beneath the cortex.

Pathogenesis The hypertensive vascular lesion that leads to arterial rupture in some cases appears to arise from an arterial wall

altered by the effects of hypertension, i.e., the change referred to in a preceding section as segmental lipohyalinoses and the false aneurysm (microaneurysm) of Charcot-Bouchard. Ross Russell has affirmed the relationship of these microaneurysms to hypertension and hypertensive hemorrhage and their frequent localization on penetrating small arteries and arterioles of the basal ganglia, thalamus, pons, and subcortical white matter. However, in the few hemorrhages examined in serial sections by our colleague C. M. Fisher, the bleeding could not be traced to Charcot-Bouchard aneurysms. Takebayashi and coworkers, in an electron microscopic study, found breaks in the elastic lamina at multiple sites, almost always at bifurcations of the small vessels. Possibly these represent sites of secondary rupture from tearing of small vessels by the expanding hematoma.

Clinical Picture Of all the cerebrovascular diseases, brain hemorrhage is the most dramatic and from ancient times has been surrounded by "an aura of mystery and inevitability." It has been given its own name, "apoplexy." The prototype is an obese, plethoric, hypertensive male who, while sane and sound, falls senseless to the ground—impervious to shouts, shaking, and pinching—breathes stertorously, and dies in a few hours. A massive blood clot escapes from the brain as it is removed postmortem. With smaller hemorrhages, the clinical picture conforms more closely to the usual temporal profile of a stroke, i.e., an abrupt onset of symptoms that evolve gradually and steadily over minutes or hours, depending on the size of the ruptured artery and the speed of bleeding.

Several general features of intracerebral hemorrhage should be emphasized. *Acute reactive hypertension*, far exceeding the patient's chronic hypertensive level, is a feature that should always suggest hemorrhage; it is seen with moderate and large clots situated in deep regions. *Vomiting* at the onset of intracerebral hemorrhage occurs much more frequently than with infarction and should always suggest bleeding as the cause of an acute hemiparesis. Severe headache is generally considered to be an accompaniment of intracerebral hemorrhage and in many cases it is, but in almost 50 percent of our cases headache has been absent or mild in degree. *Nuchal rigidity* is found frequently; but again, it is so often absent or mild that failure to find it should does not eliminate the diagnosis. (Stiffness of the neck characteristically disappears as coma deepens). It should also be noted that the patient is often alert and responding accurately when first seen. This can be true even when the CSF is grossly bloody; thus the adage that hemorrhage into the ventricular system always precipitates coma is quite incorrect. Only if bleeding into the ventricles is massive will coma result. *Seizures*, usually focal, occur in the first few days in some 10 percent of cases of supratentorial hemorrhage, rarely at the time of the ictus but more commonly as a delayed event, months or even years after the hemorrhage, in association with subcortical slit hemorrhages. The fundi often show hypertensive changes in the arterioles. Rarely, white-centered retinal hemorrhages (Roth spots) or fresh preretinal (subhyaloid) hemorrhages occur; the latter are much more common with ruptured aneurysm, arteriovenous malformation, or severe trauma. *Headache, acute hypertension, and vomiting* with a focal neurologic deficit are therefore the cardinal features and serve most dependably to distinguish hemorrhage from ischemic stroke.

Very small hemorrhages in "silent" regions of the brain may escape clinical detection. Hemorrhages that complicate the administration of anticoagulants, like those from some vascular malformations, may evolve at a slower pace. Usually there are no warn-

ings or prodromal symptoms; headache, dizziness, epistaxis, or other symptoms do not occur with any consistency. There is no age predilection except that the average age of occurrence is lower than in thrombotic infarction, and neither sex is more disposed. The incidence of hypertensive cerebral hemorrhage is higher in African Americans than in whites and seems recently to have been reported with increasing frequency in Japanese. In the majority of cases, the hemorrhage has its onset while the patient is up and active; onset during sleep is a rarity.

There has long been a notion that acute hypertension precipitates the hemorrhage in some cases. This is based on the occurrence of apoplexy at moments of extreme fright or anger or intense excitement, presumably as the blood pressure rises abruptly beyond its chronically elevated level. The same has been described in relation to taking sympathomimetic medications such as phenylpropanolamine (Kernan et al), ephedra, or cocaine and to numerous other similar circumstances. However, in fully 90 percent of instances, the hemorrhage occurs when the patient is calm and unstressed (Caplan, 1993). The level of blood pressure rises early in the course of the hemorrhage, but the preceding chronic hypertension is usually of the "essential" type. Other causes of hypertension must always be considered—renal disease, renal artery stenosis, toxemia of pregnancy, pheochromocytoma, aldosteronism, adrenocorticotrophic hormone or corticosteroid excess and, of course, sympathetically active drugs.

There is ordinarily only one episode of hypertensive hemorrhage; recurrent bleeding from the same site, as happens with sacular aneurysm and arteriovenous malformation, is infrequent. However, it is now recognized by serial CT scanning that in many instances, as the patient's condition worsens over a few hours, there may be slight enlargement of the hematoma. In the series of Brott and colleagues, one-quarter of hematomas were found to have enlarged in the first hour and another 12 percent in the first day. Blood that has extravasated into cerebral tissue is absorbed slowly, over a period of months, during which time symptoms and signs recede. Hence the neurologic deficit is never transitory in intracerebral hemorrhage, as it so often is in embolism; for the same reason, one does not expect rapid improvement in the neurologic deficit from one examination to another.

The main types of cerebral hemorrhage are described below.

Putaminal Hemorrhage The most common syndrome is the one due to *putaminal hemorrhage*, with extension to the adjacent internal capsule (Fig. 34-20). The neurologic symptoms and signs vary slightly with the precise site and size of the extravasation, but hemiplegia from interruption of the capsule is a consistent feature of medium-sized and large clots. Vomiting occurs in about half the patients. Headache is frequent but not invariable. With large hemorrhages, patients lapse almost immediately into a stupor with hemiplegia, and their condition visibly deteriorates as the hours pass. More often, however, the patient complains of headache or of some other abnormal cephalic sensation. Within a few minutes the face sags on one side, speech becomes slurred or aphasic, the arm and leg gradually weaken, and the eyes tend to deviate away from the side of the paretic limbs. These events, occurring gradually over a period of a few minutes to a half hour, are strongly suggestive of intracerebral bleeding. The paralysis may worsen; a Babinski sign appears, at first unilaterally and then bilaterally; the affected limbs become flaccid; painful stimuli are not appreciated; speaking becomes impossible; and confusion gives way to stupor. The most advanced stages are characterized by signs of upper brainstem compression (coma); bilateral Babinski signs; deep, ir-

regular, or intermittent respiration; dilated, fixed pupils, first on the side of the clot; and occasionally by decerebrate rigidity.

The widespread use of CT scanning has disclosed the frequent occurrence of smaller putaminal hemorrhages, which in former times would have been misdiagnosed as embolic or thrombotic ischemic strokes (especially if the CSF was clear). With hemorrhages confined to the anterior segment of the putamen, the hemiplegia and hyperreflexia tend to be less severe and to clear more rapidly (Caplan). There is also prominent abulia, motor impersistence, temporary unilateral neglect, and—with left-sided lesions—nonfluent aphasia and dysgraphia. With posterior lesions, weakness is also less and is attended by sensory loss, hemianopia, impaired visual pursuit to the opposite side, Wernicke-type aphasia (left-sided lesions), and anosognosia (right-sided).

Caplan has also analyzed the effects of relatively pure *caudate hematoma*. Those extending laterally and posteriorly into the internal capsule behave much like large putaminal hemorrhages. Those extending medially into the lateral ventricle give rise to drowsiness, stupor, and either confusion and underactivity or restlessness and agitation.

Thalamic Hemorrhage The central feature here is severe sensory loss on the entire contralateral body. If large or moderate in size, thalamic hemorrhage also produces a hemiplegia or hemiparesis by compression or destruction of the adjacent internal capsule (Fig. 34-21). The sensory deficit is usually severe and involves all of the opposite side, including the trunk, and may exceed the motor weakness. A fluent aphasia may be present with lesions of the dominant side, and amorphosynthesis and contralateral neglect with lesions of the nondominant side. A homonymous field defect, if present, usually clears in a few days.

Thalamic hemorrhage, by virtue of its extension into the sub-

Figure 34-21. CT scan of a left thalamic hemorrhage that caused hemiplegia and hemisensory loss in a hypertensive patient. A small amount of blood is seen in the adjacent posterior third ventricle.

thalamus and high midbrain, may cause a series of ocular disturbances—pseudo-abducens palsies with one or both eyes turned asymmetrically inward and slightly downward, palsies of vertical and lateral gaze, forced deviation of the eyes downward, inequality of pupils with absence of light reaction, skew deviation with the eye ipsilateral to the hemorrhage assuming a higher position than the contralateral eye, ipsilateral ptosis and miosis (Horner syndrome), absence of convergence, retraction nystagmus, and tucking in (retraction) of the upper eyelids. Extension of the neck may be observed. Compression of the adjacent third ventricle leads to enlargement of the lateral ventricles, and this requires temporary drainage of the ventricles in a small proportion of patients. Small and moderate-sized hemorrhages that rupture into the third ventricle are seemingly associated with fewer neurologic deficits and better outcomes, but early hydrocephalus is almost invariable.

Pontine Hemorrhage Here deep coma usually ensues in a few minutes, and the clinical picture is dominated by total paralysis, decerebrate rigidity, and small (1-mm) pupils that react to light. Lateral eye movements, evoked by head turning or caloric testing, are impaired or absent. Death usually occurs within a few hours, but there are rare exceptions in which consciousness is retained and the clinical manifestations indicate a smaller lesion in the tegmentum of the pons (disturbances of lateral ocular movements, crossed sensory or motor disturbances, small pupils, and cranial nerve palsies) in addition to signs of bilateral corticospinal tract involvement. A small number of our patients with small tegmental hemorrhages and blood in the CSF have survived, with good functional recovery. In a series of 60 patients with pontine hemorrhage reviewed by Nakajima, 19 survived (8 of these had remained alert). Similarly, Wijdicks and St. Louis reported that 21 percent made a good recovery—mostly those who were alert on admission.

Cerebellar Hemorrhage This usually develops over a period of one to several hours, and loss of consciousness at the onset is unusual. Repeated vomiting is a prominent feature, along with occipital headache, vertigo, and inability to sit, stand, or walk. Often these are the only abnormalities, making it imperative to have the patient attempt to stand and walk; otherwise the examination may be falsely normal. In the early phase of the illness, other clinical signs of cerebellar disease may be minimal or lacking; only a minority of cases show nystagmus or cerebellar ataxia of the limbs, although these signs must always be sought. A mild ipsilateral facial weakness and a diminished corneal reflex are common. Dysarthria and dysphagia may be prominent in some cases but usually are absent. Contralateral hemiplegia and ipsilateral facial weakness do not occur unless there is displacement and compression of the medulla against the clivus. There is often paresis of conjugate lateral gaze to the side of the hemorrhage, forced deviation of the eyes to the opposite side, or an ipsilateral sixth nerve weakness. Vertical eye movements are retained. Other ocular signs include blepharospasm, involuntary closure of one eye, skew deviation, “ocular bobbing,” and small, often unequal pupils that continue to react until very late in the illness.

Occasionally, at the onset, there is a spastic paraparesis or a quadriplegia with preservation of consciousness. The plantar reflexes are flexor in the early stages but extensor later. When these signs occur, hydrocephalus is present and may require drainage. In the series of St. Louis et al, those with vermian clots and hydrocephalus were at the highest risk for deterioration. As the hours pass, and occasionally with unanticipated suddenness, the patient becomes stuporous and then comatose or suddenly apneic as a re-

sult of brainstem compression, at which point reversal of the syndrome, even by surgical therapy, is seldom successful.

Lobar Hemorrhage Bleeding in areas other than those listed above, specifically in the subcortical white matter of one of the lobes of hemisphere, is not associated strictly with hypertension; it is presented here for ease of exposition. Any number of other causes are usually responsible, the main ones being anticoagulation or thrombolytic therapy, arteriovenous malformation (discussed further on), trauma, and, in the elderly, amyloidosis of the cerebral vessels.

In a series of 26 cases of lobar hemorrhage, we found 11 to lie within the occipital lobe (with pain around the ipsilateral eye and a dense homonymous hemianopia); 7 in the temporal lobe (with pain in or anterior to the ear, partial hemianopia, and fluent aphasia); 4 in the frontal lobe (with frontal headache and contralateral hemiplegia, mainly of the arm); and 3 in the parietal lobe (with anterior temporal headache and hemisensory deficit contralaterally) (Ropper and Davis). The smaller hematomas simulate an embolic stroke in the same territory. The occurrence of a progressively worsening headache, vomiting, and drowsiness in conjunction with any one of these syndromes is virtually diagnostic, and, of course, a lobar hemorrhage is readily corroborated by an unenhanced CT scan. Of our 26 patients, 14 had had normal blood pressure, and in several of the fatal cases there was amyloidosis of the affected vessels (see further on). Also, 2 patients were receiving anticoagulants, 2 had an arteriovenous malformation, and 1 had a metastatic tumor. In a series of 22 patients with lobar clots reported by Kase and colleagues, 55 percent were normotensive; metastatic tumors, arteriovenous malformations, and blood dyscrasias were found in 14, 9, and 5 percent of the patients, respectively. The role of amyloid angiopathy in lobar hemorrhage in the elderly patient is discussed further on.

In the localization of an intracerebral hemorrhage, ocular signs are particularly important. In putaminal hemorrhage, the eyes are deviated to the side opposite the paralysis; in thalamic hemorrhage, the commonest ocular abnormality is downward deviation of the eyes and the pupils may be unreactive; in pontine hemorrhage, the eyeballs are fixed and the pupils are tiny but reactive; and in large cerebellar hemorrhage, the eyes are deviated laterally to the side opposite the lesion and ocular bobbing may occur.

Although the proper interpretation of this array of clinical data allows the correct diagnosis to be established in most cases, the ancillary examinations described below are definitive, especially in the diagnosis of small hemorrhages.

Laboratory Findings Among laboratory methods for the diagnosis of intracerebral hemorrhage, the CT scan occupies the foremost position. This procedure has proved totally reliable in the detection of hemorrhages that are 1.0 cm or more in diameter. Smaller pontine hemorrhages are visualized with less certainty. At the same time, coexisting hydrocephalus, tumor, cerebral swelling, and displacement of the intracranial contents are readily appreciated. MRI is particularly useful for demonstrating brainstem hemorrhages and residual hemorrhages, which remain visible long after they can no longer be seen by the CT scan (after 4 to 5 weeks). Hemosiderin and iron pigment have their own characteristic appearances, as described earlier.

In general, lumbar puncture is ill advised, for it may precipitate or aggravate an impending shift of central structures and herniation. The white cell count in the peripheral blood may rise tran-

sently to $15,000/\text{mm}^3$, a higher figure than in thrombosis. The sedimentation rate is mildly elevated in some patients.

Course and Prognosis The immediate prognosis for large and medium-sized cerebral clots is grave; some 30 to 35 percent of patients die in 1 to 30 days. Either the hemorrhage extends into the ventricular system or intracranial pressure is elevated to levels that preclude normal perfusion of the brain. Sometimes the hemorrhage itself seeps into vital centers such as the hypothalamus or midbrain. A formula that predicts outcome of hemorrhage based on clot size has been devised by Broderick and coworkers; it is mainly applicable to putaminal and thalamic hemorrhages. They found a close correlation with outcome. A volume of 30 mL or less, calculated from the CT scan, predicted a generally favorable outcome; only 1 of their 71 patients with clots larger than 30 mL had regained independent function by 1 month. By contrast, in patients with clots of 60 mL or larger and an initial Glasgow Coma Scale score of 8 or less, the mortality was 90 percent (this scale is detailed on page 754). As remarked earlier, it is the location of the hematoma, not simply its size, that determines the clinical effects. A clot 60 mL in volume is almost uniformly fatal if situated in the basal ganglia but may be more benign if located in the frontal or occipital lobe. From the studies of Diringer and colleagues, it appears that hydrocephalus is also an important predictor of poor outcome, and this accords with our experience.

In patients who survive—i.e., in those with smaller hemorrhages—there can be a surprising degree of restoration of function, since, in contrast to infarction, the hemorrhage has to some extent pushed brain tissue aside rather than destroyed it. Function may return very slowly, however, because extravasated blood takes time to be removed from the tissues. Also, since rebleeding from the same site is unlikely, the patient may live for many years. In some instances of medium-sized cerebral and cerebellar hemorrhages, papilledema appears after several days of increased intracranial pressure. This does not mean that the hemorrhage is increasing in size or swelling—only that papilledema is slow to develop. Healed scars impinging on the cortex are liable to be epileptogenic; the frequency of seizures after each type of hemorrhage has not been established, but it is lower than for ischemic strokes. There is probably no need to administer anticonvulsive medication unless a seizure has occurred.

The poor prognosis of all but the smallest pontine hemorrhages has already been mentioned. Cerebellar hemorrhages present special problems that are discussed below.

Treatment The management of patients with large intracerebral hemorrhages and coma includes the maintenance of adequate ventilation, use of controlled hyperventilation to a PCO_2 of 25 to 30 mmHg, monitoring of intracranial pressure in some cases and its control by the use of tissue-dehydrating agents such as mannitol (osmolality kept at 295 to 305 mosmol/L and Na at 145 to 150 meq), and limiting intravenous infusions to normal saline. Qureshi's group has offered data suggesting that aggressive measures to reduce intracranial pressure may be lifesaving and result in good outcome even in patients who have signs of transtentorial herniation. In our experience, this type of recovery is exceptional, but treatment may be justified in some patients whose medical condition allows it.

As mentioned, virtually all patients with intracerebral hemorrhage are hypertensive immediately after the stroke because of a generalized sympathoadrenal response. The natural trend is for the

blood pressure to diminish over several days; therefore active treatment in the acute stages has been a matter of controversy. Rapid reduction in blood pressure, in the hope of reducing further bleeding, is not recommended, since it risks compromising cerebral perfusion in cases of raised intracranial pressure. On the other hand, sustained mean blood pressures of greater than 110 mmHg may exaggerate cerebral edema and risk extension of the clot. It is at approximately this level of acute hypertension that the use of beta-blocking drugs (esmolol, labetalol) or angiotensin-converting enzyme (ACE) inhibitors is recommended. The major calcium channel blocking drugs are used less often for this purpose because of reports of adverse effects on intracranial pressure, although this information derives mainly from patients with brain tumors. Hayashi and associates have shown that blood pressure is lowered with nifedipine after cerebral hemorrhage, but intracranial pressure is raised, resulting in an unfavorable net reduction in cerebral perfusion pressure. We have, nevertheless, used this class of medication in patients with small and medium-sized clots without adverse effects. Diuretics are helpful in combination with any of the antihypertensive medications. More rapidly acting and titratable agents such as nitroprusside may be used in extreme situations, recognizing that they may further raise intracranial pressure.

Surgical evacuation of a hemispherical clot in the acute stage may occasionally be lifesaving, and we have referred numerous patients for surgical treatment when hemispherical hemorrhages were larger than 3 cm in diameter and the clinical state was deteriorating. The most successful surgical results have been in patients with lobar or moderate-sized putaminal hemorrhages. Although selected patients may be saved from progression to brain death, the focal neurologic deficit is not altered. Even this modest result requires that operation be carried out before or very soon after coma supervenes. But, on the basis of numerous small studies, it must be stated that surgical results have generally not been superior to those with medical measures alone (Waga and Yamamoto, Batjer et al, Juvela et al; Rabinstein et al). It would appear intuitively that the removal of an acutely formed clot from the cerebral hemispheres should be greatly beneficial, but it has been difficult to demonstrate this effect in various groups of patients. Once the patient becomes deeply comatose with dilated fixed pupils, the chance of any recovery is negligible. In part, disappointing results have been the result of combining patients in various stages of stupor and coma, undoubtedly with different levels of intracranial pressure and clots of various sizes and locations. Even in organized (if retrospective) studies in which clinical worsening was the reason for surgery, such as the one by Rabinstein and colleagues, only one-quarter of patients attained a state of functional independence. All of their patients who lost their brainstem reflexes and had extensor posturing died despite surgery; there are few exceptions to this observation.

In comatose patients with large hemorrhages, we have found that the placement of a device for constant monitoring of intracranial pressure enables the clinician to use medical measures with greater precision, as outlined in Chap. 17, but there is no evidence that outcome is significantly improved (Ropper and King). Whether hemicraniectomy is of value, as it is with large hemispherical strokes, is not known.

In contrast, the *surgical evacuation of cerebellar hematomas* is a generally accepted treatment and is a more urgent matter because of the proximity of the mass to the brainstem and the risk of abrupt progression to coma and respiratory failure. Also, hydrocephalus from compression of the fourth ventricle more often complicates the clinical picture and further raises intracranial pressure

(St. Louis et al). As a rule, a cerebellar hematoma of less than 2 cm in diameter leaves most patients awake and infrequently leads to deterioration, therefore not requiring surgery. Hematomas that are 4 cm or more in largest diameter, especially if located in the vermis, pose the greatest risk, and some surgeons have recommended evacuation of lesions of this size no matter what the clinical status of the patient. In determining the need for surgical evacuation, we have been guided by the state of consciousness, the mass effect caused by the clot as visualized on CT scan (particularly the degree of compression of the quadrigeminal cistern, as pointed out by Taneda and colleagues), and the presence of hydrocephalus. Often this requires daily or even more frequent CT scans. The patient who is stuporous or displays arrhythmic breathing is best intubated and brought to the operating room within hours or sooner. Once coma and pupillary changes supervene, few patients survive, even with surgery; however, rapid medical intervention with mannitol and hyperventilation, followed by surgical evacuation of the clot and drainage of the ventricles very soon after the onset of coma, has been successful in a few cases. Patients who are only drowsy and those with hematomas of 2 to 4 cm in diameter pose the greatest difficulty in deciding about surgery. If the level of consciousness is fluctuating or if there is obliteration of the perimesencephalic cisterns, particularly if coupled with hydrocephalus, we believe that the risk of surgery is less than that of a sudden deterioration. In only a very limited number of patients have we found it practical to perform only drainage of the enlarged ventricles, although some groups still favor this procedure and eschew a posterior fossa operation. In our experience, evacuation of the clot has been more important than reduction of hydrocephalus.

Spontaneous Subarachnoid Hemorrhage (Ruptured Saccular Aneurysm)

This is the fourth most frequent cerebrovascular disorder—following atherosclerosis, embolism, and primary intracerebral hem-

orrhage, but one that is often disastrous. Saccular aneurysms are also called “berry” aneurysms; actually they take the form of small, thin-walled blisters protruding from arteries of the circle of Willis or its major branches. Their rupture causes a flooding of the subarachnoid space with blood under high pressure. As a rule, the aneurysms are located at vessels bifurcations and branchings (Fig. 34-22) and are generally presumed to result from developmental defects in the media and elastica. An alternate theory holds that the aneurysmal process is initiated by focal destruction of the internal elastic membrane, which is produced by hemodynamic forces at the apices of bifurcations (Ferguson). As a result of the local weakness, the intima bulges outward, covered only by adventitia; the sac gradually enlarges and may finally rupture. Saccular aneurysms vary in size from 2 mm to 2 or 3 cm in diameter, averaging 7.5 mm (Wiebers et al). Those that rupture usually have a diameter of 10 mm or more (by angiography), but rupture also occurs, albeit less often, in those of smaller size. Aneurysms vary greatly in form. Some are round and connected to the parent artery by a narrow stalk, others are broad-based without a stalk, and still others take the form of narrow cylinders. The site of rupture is usually at the dome of the aneurysm, which may have one or more secondary sacculations. A review of the subject by Schievink is recommended for further details.

In routine autopsies, the incidence of unruptured aneurysms is almost 2 percent—excluding minor outpouchings of 3 mm or less. Aneurysms are multiple in 20 percent of patients. It has been estimated that 400,000 Americans harbor unruptured aneurysms and that there are an estimated 26,000 subarachnoid hemorrhages from them per year (Sahs et al). In childhood, rupture of saccular aneurysms is rare, and they are seldom found at routine postmortem examination; beyond childhood, they gradually increase in frequency to reach their peak incidence between 35 and 65 years (average 49 years). Therefore they cannot be regarded as fully formed congenital anomalies; rather, they appear to develop over the years on the basis of either a developmental or acquired arterial defect.

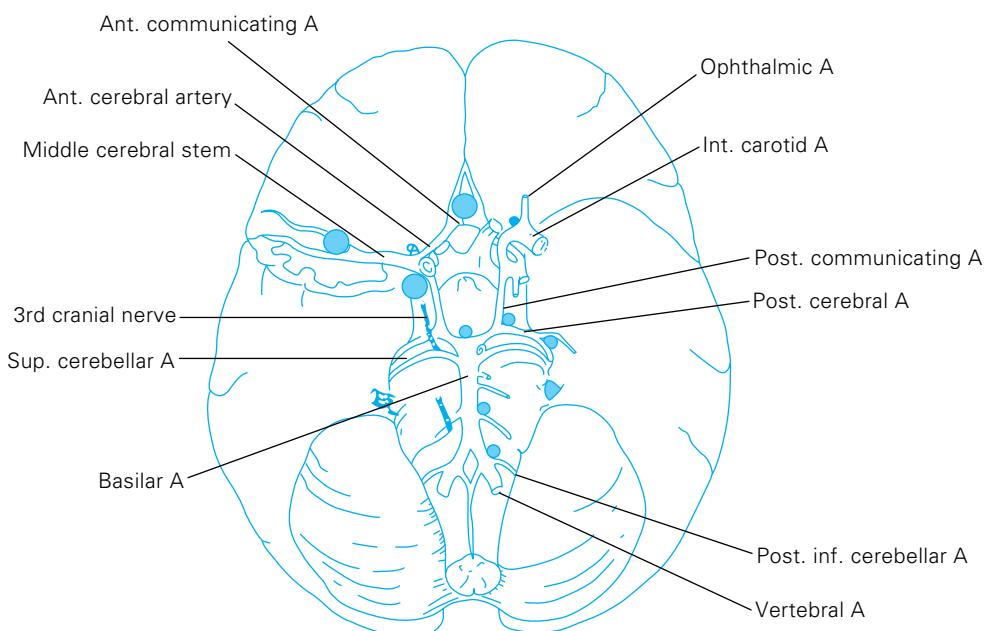

Figure 34-22. Diagram of the circle of Willis showing the principal sites of saccular aneurysms. Approximately 90 percent of aneurysms are on the anterior half of the circle. The sizes of the aneurysms depicted correspond roughly to the frequency of occurrence at those sites.

There is an increased incidence of congenital polycystic kidneys, fibromuscular dysplasia of the extracranial arteries, moyamoya, and coarctation of the aorta among persons with saccular aneurysms. A saccular aneurysm occurs in approximately 5 percent of cases of arteriovenous malformation, usually on the main feeding artery of the malformation.

Numerous reports have documented a familial occurrence of saccular aneurysms, lending support to the idea that genetic factors play a role in their development. The number of first-degree relatives found to harbor an unsuspected aneurysm has been about 4 percent in most series. This low rate, the finding that half of the discovered aneurysms are small, and the complications of surgery make routine screening of siblings, children, and parents of patients with ruptured aneurysms impractical, according to the Magnetic Resonance Angiography in Relatives of Patients with Subarachnoid Hemorrhage Study Group. However, since aneurysms of the familial variety tend to be larger at the time of rupture and more numerous than in patients who have sporadic ones, there are exceptions to this statement (Ruigrok et al).

While hypertension is more frequently present than in the general population, nevertheless aneurysms most often occur in persons with normal blood pressure. Pregnancy does not appear to be associated with an increased incidence of aneurysmal rupture, although there is always concern about the possibility of rupture during the straining of natural delivery. Atherosclerosis, though present in the walls of some saccular aneurysms, probably plays no part in their formation or enlargement.

Approximately 90 to 95 percent of saccular aneurysms lie on the anterior part of the circle of Willis (Fig. 34-22). The four most common sites are (1) the proximal portions of the anterior communicating artery, (2) at the origin of the posterior communicating artery from the stem of the internal carotid, (3) at the first major bifurcation of the middle cerebral artery, and (4) at the bifurcation of the internal carotid into middle and anterior cerebral arteries. Other sites include the internal carotid artery in the cavernous sinus, at the origin of the ophthalmic artery, the junction of the posterior communicating and posterior cerebral arteries, the bifurcation of the basilar artery, and the origins of the three cerebellar arteries. Aneurysms that rupture in the cavernous sinus may give rise to an arteriovenous fistula (page 749).

There are several types of aneurysm other than saccular, e.g., mycotic, fusiform, diffuse, and globular. The mycotic aneurysm is caused by a septic embolus that weakens the wall of the vessel in which it lodges (page 727). The others are named for their predominant morphologic characteristics and consist of enlargement or dilatation of the entire circumference of the involved vessels, usually the internal carotid, vertebral, or basilar arteries. The latter are also referred to as arteriosclerotic aneurysms, since they frequently show atheromatous deposition in their walls, but it is likely that they are at least partly developmental in nature. Some are gigantic and press on neighboring structures or become occluded by thrombus; they rupture only infrequently (see further on).

Clinical Syndrome With rupture of the aneurysm, blood under high pressure is forced into the subarachnoid space (usually in relation to the circle of Willis), and the resulting clinical events assume one of three patterns: (1) the patient is stricken with an excruciating generalized headache and vomiting and falls unconscious almost immediately; (2) headache develops in the same manner but the patient remains relatively lucid—the most common syndrome; (3) rarely, consciousness is lost quickly with-

out any preceding complaint. Decerebrate rigidity and brief clonic jerking of the limbs may occur at the onset of the hemorrhage, in association with unconsciousness. If the hemorrhage is massive, death may ensue in a matter of minutes or hours, so that ruptured aneurysm must be considered in the differential diagnosis of sudden death. A considerable proportion of such patients probably never reach a hospital. Persistent deep coma is accompanied by irregular respirations, attacks of extensor rigidity, and finally respiratory arrest and circulatory collapse. In these rapidly fatal cases, the subarachnoid blood has greatly increased the intracranial pressure to a level that approaches arterial pressure and caused a marked reduction in cerebral perfusion. In some instances the hemorrhage has dissected intracerebrally and entered the ventricular system.

Rupture of the aneurysm usually occurs while the patient is active rather than during sleep, and in a few instances during sexual intercourse, straining at stool, lifting heavy objects, or other sustained exertion (see page 160). Momentary Valsalva maneuvers, as in coughing or sneezing, have generally not caused aneurysmal rupture (they may cause arterial dissection). In patients who survive the initial rupture, the most feared complication is rerupture, an event that may occur at any time from minutes up to 2 or 3 weeks.

In less severe cases, consciousness, if lost, may be regained within a few minutes or hours, but a residuum of drowsiness, confusion, and amnesia accompanied by severe headache and stiff neck persists for several days. It is not uncommon for the drowsiness and confusion to last 10 days or longer. Since the hemorrhage is confined to the subarachnoid space, there are few if any focal neurologic signs. That is to say, gross lateralizing signs in the form of hemiplegia, hemiparesis, homonymous hemianopia, or aphasia are absent in the majority of cases. On occasion, a jet of blood emanating from an aneurysm may rupture into the adjacent brain or clot in the insular cistern and produce a hemiparesis or other focal syndrome. There may also be a focal syndrome from acute or delayed ischemia in the territory of the aneurysm-bearing artery. Usually this occurs several days after a large subarachnoid hemorrhage. The pathogenesis of such manifestations is not fully understood, but a transitory fall in pressure in the circulation distal to the aneurysm is postulated in early cases and vasospasm is responsible for the later focal signs. Transient deficits are not common, but they do constitute reliable indicators of the site of the ruptured aneurysm (see below).

Convulsive seizures, usually brief and generalized, occur in 10 to 25 percent of cases according to Hart et al (but far less often in our experience) in relation to acute bleeding or rebleeding. These early seizures do not correlate with the location of the aneurysm and do not appear to alter the prognosis.

Prior to rupture, saccular aneurysms are usually asymptomatic. Exceptionally, if large enough to compress pain-sensitive structures, they may cause localized cranial pain. With a cavernous or anterolaterally situated aneurysm on the first part of the middle cerebral artery, the pain may be projected to the orbit. An aneurysm on the posteroinferior or anteroinferior cerebellar artery may cause unilateral occipital or cervical pain. The presence of a partial oculomotor palsy with dilated pupil may be indicative of an aneurysm of the posterior communicating–internal carotid junction (less often posterior communicating–posterior cerebral junction). Occasionally, large aneurysms just anterior to the cavernous sinus may compress the optic nerves or chiasm, third nerve, hypothalamus, or pituitary gland. In the cavernous sinus they may compress the third, fourth, or sixth nerve or the ophthalmic division of the fifth nerve. A monocular visual field defect may also develop with a

supraclinoid aneurysm near the anterior and middle cerebral bifurcation or the ophthalmic-carotid bifurcation.

Whether a small leak of blood from an aneurysm may serve as a warning sign of rupture ("warning leak") has been disputed. We have seen several cases where an acute and severe exertional or spontaneous headache was found to be associated with a small subarachnoid hemorrhage that was discovered by lumbar puncture; more often the headache is unrelated to hemorrhage and is attributable to migraine. This latter "thunderclap headache," which may be a variant of migraine, is discussed on page 160. A headache similar to that caused by subarachnoid hemorrhage may also be the reflection of pituitary apoplexy, cerebral venous thrombosis, hypertensive encephalopathy, intracranial hypotension, intracranial arterial dissection, and a condition characterized by diffuse cerebral vasospasm. This last entity may be spontaneous or due to the ingestion of sympathomimetic or serotonergic drugs (see further on, under "Diffuse and Focal Cerebral Vasospasm.") The details of the CSF examination assume great importance in the diagnosis of subarachnoid hemorrhage and the exclusion of the disorders mentioned above.

Vasospasm *Delayed hemiplegia* and other focal deficits usually appear 3 to 12 days after rupture and rarely before or after this period. These delayed syndromes and the focal narrowing of a large artery or arteries, seen on angiography, are referred to as *vasospasm*. Fisher and coworkers have shown that spasm is most frequent in arteries surrounded by the largest collections of clotted subarachnoid blood. The vasospasm appears to be a direct effect of blood or some blood product, possibly hematin or a platelet product, on the adventitia of the artery. Areas of ischemic infarction in the territory of the vessel bearing the aneurysm, without thrombosis or other changes in the vessel, is the usual finding in such cases. These ischemic lesions are often multiple and occur with great frequency, according to Hijdra and associates (in 57 of 176 prospectively studied patients and a comparable number in large series collected before more modern approaches to treatment became available).

After a few days, arteries in chronic spasm undergo a series of morphologic changes. The smooth muscle cells of the media become necrotic, and the adventitia is infiltrated with neutrophilic leukocytes, mast cells, and red blood corpuscles, some of which have migrated to a subendothelial position (Chiyatte and Sundt). We favor the idea that these changes are caused by products of hemolyzed blood seeping inward from the pia-arachnoid into the muscularis of the artery.

The clinical features of cerebral vasospasm depend on the affected blood vessel but typically include a fluctuating hemiparesis or aphasia and increasing confusion that must be distinguished from the effects of hydrocephalus (see below). In the past, an arteriogram was required to verify the diagnosis, although it is not often performed now because of the slight associated risk of worsening vascular spasm and the ease with which the condition can be recognized by its clinical presentation. Severe vasospasm can be visualized with MRA and spinal CT techniques. Transcranial Doppler measurements are an indirect and easier way of following, by observations of blood flow velocity, the caliber of the main vessels at the base of the brain. Almost all patients have a greatly increased velocity of blood flow in the affected vessel that can be detected by this method in the days after hemorrhage. However, progressive elevation of flow velocity in any one vessel (especially if over 175 cm/s) suggests that focal vasospasm is occurring. There is a reasonable correlation between these findings and the radio-

graphic appearance of vasospasm, but the clinical manifestations of ischemia depend on additional factors such as collateral blood supply and the cerebral perfusion pressure.

Hydrocephalus If a large amount of blood ruptures into the ventricular system or floods the basal subarachnoid space, it may find its way into the ventricles through the foramina of Luschka and Magendie. The patient then may become confused or unconscious as a result of *acute hydrocephalus*. The clinical signs are greatly improved by draining the ventricles, either by external ventriculostomy or, in selected cases, by lumbar puncture. A *subacute hydrocephalus* due to blockage of the CSF pathways by blood may appear after 2 to 4 weeks.

Anatomic-Clinical Correlations of Aneurysms In most patients the neurologic manifestations do not point to the exact site of the aneurysm, but it can often be inferred from the location of the main clot on CT scan. A collection of blood in the anterior interhemispheric fissure indicates rupture of an anterior communicating artery aneurysm; in the sylvian fissure, a middle cerebral artery aneurysm; in the anterior perimesencephalic cistern, a posterior communicating or distal basilar artery aneurysm; and so on. In some instances clinical signs provide clues to its localization, as follows: (1) third nerve palsy (ptosis, diplopia, dilatation of pupil, and divergent strabismus), as stated above, usually indicates an aneurysm at the junction of the posterior communicating artery and the internal carotid artery—the third nerve passes immediately lateral to this point; (2) transient paresis of one or both of the lower limbs at the onset of the hemorrhage suggests an anterior communicating aneurysm that has interfered with the circulation in the anterior cerebral arteries; (3) hemiparesis or aphasia points to an aneurysm at the first major bifurcation of the middle cerebral artery; (4) unilateral blindness indicates an aneurysm lying anteromedially in the circle of Willis (at the origin of the ophthalmic artery or at the bifurcation of the internal carotid artery); (5) a state of retained consciousness with akinetic mutism or abulia (sometimes associated with paraparesis) favors a location on the anterior communicating artery, with ischemia of or hemorrhage into one or both of the frontal lobes or hypothalamus (with or without acute hydrocephalus); (6) the side on which the aneurysm lies may be indicated by a unilateral preponderance of headache or preretinal hemorrhage, the occurrence of monocular pain, or, rarely, lateralization of an intracranial sound heard at the time of rupture of the aneurysm. Sixth nerve palsy, unilateral or bilateral, is usually attributable to raised intracranial pressure and is seldom of localizing value.

In summary, the clinical sequence of sudden severe headache, vomiting, collapse, relative preservation of consciousness with few or no lateralizing signs, and neck stiffness is diagnostic of subarachnoid hemorrhage due to a ruptured saccular aneurysm.

Other clinical data may be of assistance in reaching a correct diagnosis. Almost all patients are hypertensive for one or several days following the bleed, but preceding hypertension is only slightly more common than in the general population. Levels of 200 mmHg systolic are seen occasionally just after rupture, but usually the pressure is elevated only moderately and fluctuates with the degree of head pain. Spontaneous intracranial bleeding with normal blood pressure should also suggest ruptured aneurysm or arteriovenous malformation and, rarely, hemorrhage into a cerebral tumor. Nuchal rigidity is usually present but occasionally absent, and the main complaint of pain may be referable to the interscapular region or even the low back rather than to the head. Examination of the fundi frequently reveals smooth-surfaced, sharply

outlined collections of blood that cover the retinal vessels—the so-called preretinal or subhyaloid hemorrhages; Roth spots are seen occasionally. Bilateral Babinski signs are found in the first few days following rupture if there is hydrocephalus. Fever up to 39°C (102.2°F) may be seen in the first week, but most patients are afebrile. Rarely, escaping blood enters the subdural space and produces a hematoma, evacuation of which may be lifesaving.

Laboratory Findings A CT scan will detect blood locally or diffusely in the subarachnoid spaces or within the brain or ventricular system in more than 90 percent of cases and in practically all cases in which the hemorrhage has been severe enough to cause momentary or persistent loss of consciousness (Fig. 34-23). This should therefore be the initial investigative procedure. The blood may appear as a subtle shadow along the tentorium or in the sylvian or adjacent fissures. A large localized collection of subarachnoid blood or a hematoma in brain tissue or within the sylvian fissure indicates the adjacent location of the aneurysm and the likely region of subsequent vasospasm, as already noted. When two or more aneurysms are visualized by arteriography, the CT scan may identify the one that had ruptured by the clot that surrounds it. Also, coexistent hydrocephalus will be demonstrable. If the CT scan documents subarachnoid blood with certainty, a spinal tap is not necessary. MRI can also detect blood in the proton density sequence; after a day has passed, this can also be done with the fluid attenuated inversion recovery (FLAIR) technique.

In all other cases, where subarachnoid hemorrhage is suspected but not apparent on imaging studies, a lumbar puncture should be undertaken. Usually the CSF becomes grossly bloody within 30 min of the hemorrhage, with RBC counts up to 1 million/

mm³ or even higher. With a relatively mild hemorrhage, there may be only a few thousand cells, but it is unlikely that a severe headache syndrome from subarachnoid hemorrhage would be associated with fewer than a several hundred cells. It is also probably not possible for an aneurysm to rupture entirely into brain tissue without some leakage of blood into the subarachnoid fluid. In other words, the diagnosis of ruptured saccular aneurysm (by lumbar puncture) is essentially excluded if blood is not present in the CSF. Xanthochromia is found after centrifugation if several hours or more have elapsed from the moment of the ictus. In a patient who reports a headache that is consistent with subarachnoid hemorrhage but the occurrence was several days earlier, the CT scan may be normal and xanthochromia the only diagnostic finding. To determine whether xanthochromia is present, fresh CSF must be centrifuged in a tube with a conical bottom and the supernatant compared to clear water in good light. It has been our experience that most hospital laboratories cannot be depended on to give accurate results for this test. Also helpful after several days is the MRI taken with the FLAIR sequence, which will demonstrate blood (the proton density sequence is more sensitive to blood in the first day).

The problem of a “traumatic tap” often clouds the early diagnosis and several aids to detecting this misleading laboratory result are discussed in Chap. 2. Here it is reiterated that in addition to the absence of xanthochromia, the most important are the clearing of blood as one continues to collect fluid and a marked reduction in the number of RBCs in serial tubes of spinal fluid. A normal opening pressure suggests puncture of a local vessel rather than a ruptured aneurysm. The combination of subarachnoid hemorrhage and a traumatic tap generally requires that vascular imaging procedures be performed to resolve the issue. The CSF in the first days

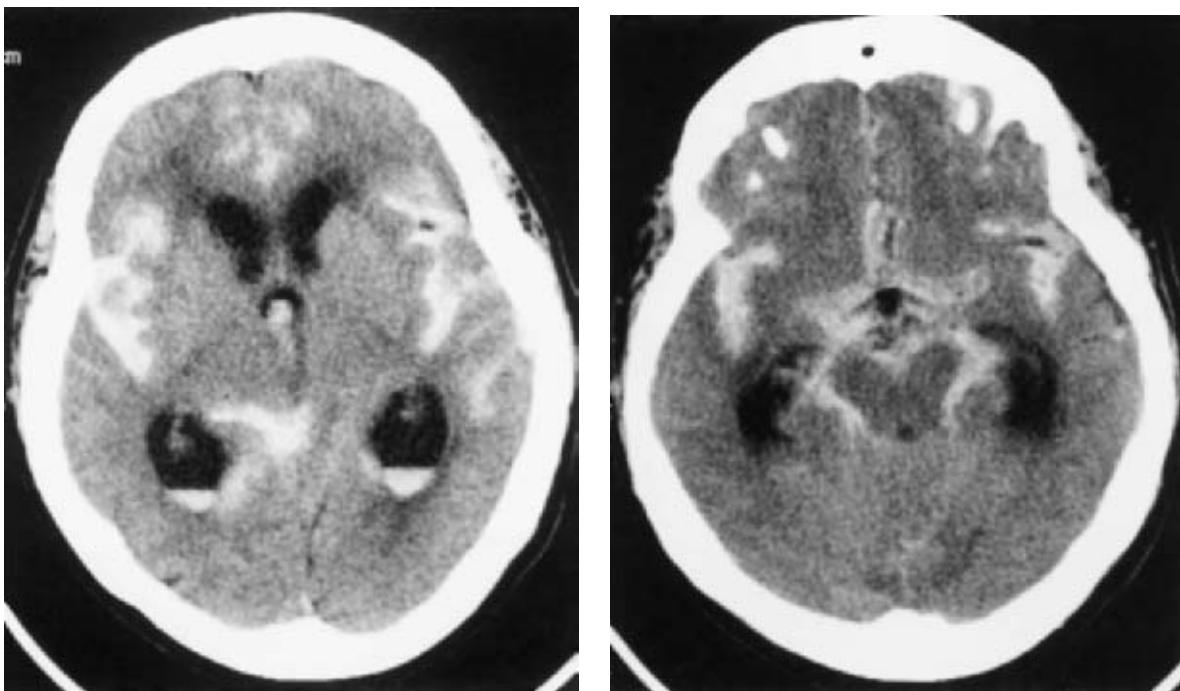

Figure 34-23. Subarachnoid hemorrhage due to rupture of a basilar artery aneurysm. *Left:* Axial CT scan image at the level of the lateral ventricles showing widespread blood in the subarachnoid spaces and layering within the ventricles with resultant hydrocephalus. There is a blood-CSF level in the posterior horns of the lateral ventricles, typical of recent bleeding. *Right:* At the level of the basal cisterns, blood can be seen surrounding the brainstem, in the anterior sylvian fissures and the anterior interhemispheric fissure. The temporal horns of the lateral ventricles are again enlarged, reflecting acute hydrocephalus.

is under increased pressure, as high as 500 mmH₂O—an important finding in differentiating spontaneous subarachnoid hemorrhage from a traumatic tap. The proportion of WBCs to RBCs in the CSF is usually the same as in the circulating blood (approximately 1:700), but in some patients a brisk CSF leukocytosis appears within 48 h, sometimes reaching more than 1000 cells per cubic millimeter. The protein is slightly or moderately elevated and in some instances glucose is mildly reduced.

Carotid and vertebral angiography is the only certain means of demonstrating an aneurysm and does so in over 90 percent of patients in whom the correct diagnosis of spontaneous subarachnoid hemorrhage is made on clinical grounds. MRI with modern scanners (Fig. 34-24) detects most aneurysms of the basal vessels and of their first branches but may not yet be of sufficient sensitivity to replace conventional angiography in cases where an aneurysm is strongly suspected but too small to be detected by MRA. Even when MRA demonstrates the aneurysm, the surgeon usually requires the kind of anatomic definition that can be obtained only by conventional angiography. The most up-to-date CT technology scanning with contrast infusion has certainly begun to equal the detail provided by conventional angiography and has additional advantages of showing the lesion in relation to the adjacent brain and skull in multiple views. (Fig. 34-24)

Associated Systemic Changes Acute subarachnoid hemorrhage is associated with several characteristic responses in the systemic circulation, water balance, and cardiac function. The ECG changes include symmetrically large peaked T waves and other alterations suggesting subendocardial or myocardial ischemia. Also there is a tendency to develop hyponatremia; this abnormality and its relationship to intravascular volume depletion plays a key role in treatment, as discussed further on. Albuminuria and glycosuria may be present for a few days. Rarely, diabetes insipidus occurs in the acute stages, but water retention or a natriuresis is more frequent. There may be a leukocytosis of 15,000 to 18,000 cells per cubic millimeter, but the sedimentation rate is usually normal.

Course and Prognosis The outstanding characteristic of this condition, mentioned earlier, is the tendency for the hemorrhage to recur from the same site. This threat colors all prognostications and

dominates modern treatment strategies. Unfortunately there appears to be no way of determining reliably which patients will bleed again. The cause of recurrent bleeding is not understood but may be related to naturally occurring mechanisms of clot formation and lysis at the site of initial rupture, usually at the dome of the aneurysm.

Patients with the typical clinical picture of spontaneous subarachnoid hemorrhage in whom an aneurysm or arteriovenous malformation cannot be demonstrated angiographically have a distinctly better prognosis than those in whom the lesion is visualized (Nishioka et al). In a series of 323 angiographically negative cases followed for an average of 10 years, there was rebleeding in only 12 (Hawkins et al). After 22 years, 69 percent of these patients had survived. It is customary in most centers to repeat the arteriogram in several weeks, because it has been observed that vascular spasm may have earlier obscured the aneurysm. It is advantageous to obtain x-rays from several different angles in order to expose those views that were obscured by adjacent overlying vessels. If the first study involves all cerebral vessels and utilizes several views of the basal circulation, it has been our experience that the second arteriogram is infrequently more revealing but our practice is to repeat it nonetheless.

Another clinical circumstance with a favorable outcome is limited *perimesencephalic hemorrhage*, described by van Gijn and colleagues. The cisterns surrounding the midbrain and upper pons are symmetrically filled with blood, the headache is mild, and signs of vasospasm do not develop. No aneurysm is found at the expected site for blood in this region, i.e., at the top of the basilar artery. The patient usually does well and a second arteriogram is probably not required. It has been speculated that the bleeding has a venous rather than an aneurysmal source.

As regards prognosis of aneurysmal hemorrhage, McKissick and colleagues decades ago found that the patient's state of consciousness at the time of arteriography was the single best index of outcome, and this remains true today. Their data, representative of the status of aneurysm management in the 1950s and consonant with the natural history before the advent of modern surgical and intensive care techniques, indicated that of every 100 patients reaching a hospital and coming to arteriography, 17 were stuporous or comatose and 83 appeared to be recovering from the ictus. At

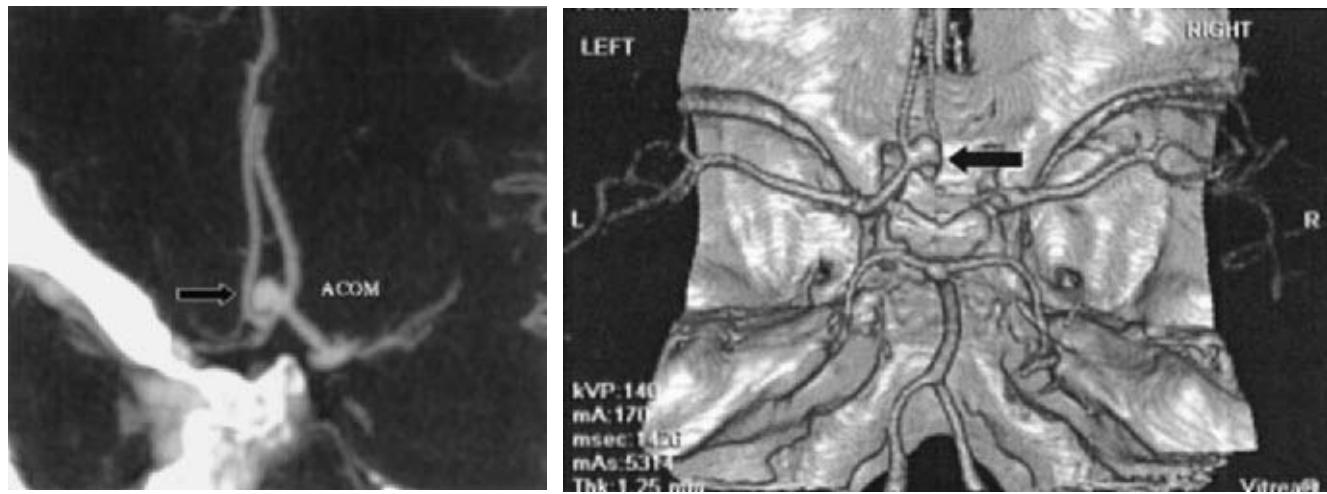

Figure 34-24. Berry aneurysm of the anterior communicating aneurysm. *A*. Magnetic resonance angiogram; *B*. CT angiography showing the aneurysm in relation to the adjacent bony and vascular structures.

the end of the following 6 months, 8 of every 100 patients had died of the original hemorrhage and 59 had had a recurrence (with 40 deaths), making a total of 48 deaths and 52 survivors. In regard to recurrence of bleeding, it was found that of 50 patients seen on the first day of the illness, 5 rebled in the first week (all fatal), 8 in the second week (5 fatal), 6 in the third and fourth weeks (4 fatal), and 2 in the next 4 weeks (2 fatal), making a total of 21 recurrences (16 fatal) in 8 weeks.

The most comprehensive long-term analysis of the natural history of the disease is contained in the report of the Cooperative Study of Intracranial Aneurysms and Subarachnoid Hemorrhage (Sahs et al). This study was based on long-term observations of 568 patients who sustained an aneurysmal bleed between 1958 and 1965 and were managed only by a conservative medical program. A follow-up search in 1981 and 1982 disclosed that 378, or two-thirds of the patients, had died; 40 percent of the deaths had occurred within 6 months of the original hemorrhage. For the patients who survived the original hemorrhage for 6 months, the chances of survival during the next two decades were significantly worse than those of a matched normal population. Rebleeding occurred at a rate of 2.2 percent per year during the first decade and 0.86 percent per year during the second. Rebleeding episodes were fatal in 78 percent of cases. These statistics, however, also reflect the outcome prior to the modern era of microsurgery and neurologic intensive care management.

One would expect these figures to have improved in recent years, but the change has not been striking. In a prospective clinical trial conducted by the International Cooperative Study in 1990 and based on observations of 3521 patients (surgery performed in 83 percent), it was found, at the 6-month evaluation, that 26 percent of the patients had died and 58 percent had made a good recovery (Kassell et al). Vasospasm and rebleeding were the leading causes of morbidity and mortality in those who survived the initial bleed.

In respect to rebleeding, all series indicate that the risk is greatest in the first day but extends for weeks. The observations of Aoyagi and Hayakawa are similar to those of other series; they found that rebleeding occurred within 2 weeks in 20 percent of patients, with a peak incidence in the 24 h after the initial episode.

Treatment This is influenced by the neurologic and general medical state of the patient as well as by the location and morphology of the aneurysm. Ideally, all patients should have the aneurysmal sac obliterated, but the mortality is high if the patient is stuporous or comatose (grade IV or V, see below). Before deciding on a course of action, it has been useful to assess the patient with reference to the widely employed scale introduced by Botterell and refined by Hunt and Hess, as follows:

- Grade I. Asymptomatic or with slight headache and stiff neck
- Grade II. Moderate to severe headache and nuchal rigidity but no focal or lateralizing neurologic signs
- Grade III. Drowsiness, confusion, and mild focal deficit
- Grade IV. Persistent stupor or semicomma, early decerebrate rigidity and vegetative disturbances
- Grade V. Deep coma and decerebrate rigidity

The general medical management in the acute stage includes the following, all or in part: bed rest, fluid administration to maintain above-normal circulating blood volume and central venous pressure, use of elastic stockings and stool softeners; administration of beta blockers, calcium channel blockers, intravenous nitropruss-

ide, or other medication to reduce greatly elevated blood pressure and then maintain systolic blood pressure at 150 mmHg or less; and pain-relieving medication for headache (this alone will often reduce the hypertension). The prevention of systemic venous thrombosis is critical, usually accomplished by the use of cyclically inflated whole-leg compression boots. The use of anticonvulsants is controversial; many neurosurgeons administer them early, with a view of preventing a seizure-induced risk of rebleeding. We have generally avoided them unless a seizure has occurred.

Calcium channel blockers are being used extensively to reduce the incidence of stroke from vasospasm. Nimodipine 60 mg, administered orally every 4 h, is currently favored. Although calcium channel blockers do not alter the incidence of angiographically demonstrated vasospasm, they have reduced the number of strokes in each of five randomized studies, beginning with the one conducted by Allen and colleagues. Several groups have been using angioplasty techniques to dilate vasospastic vessels and reporting symptomatic improvement, but there are as yet insufficient controlled data to judge the merits and safety of this procedure.

The most notable advances have been in the techniques for the obliteration of aneurysms, particularly the operating microscope and endovascular approaches, and in the management of circulatory volume. In the majority of patients intravascular volume is depleted in the days after subarachnoid hemorrhage. This, in turn, greatly increases the chances of ischemic infarction from vasospasm, though it does not alter its incidence or severity. In part, this volume contraction can be attributed to bed rest, but sodium loss, probably resulting from the release of atrial natriuretic factor (ANF), a potent oligopeptide stimulator of sodium loss in renal tubules, may also be a factor. Hyponatremia develops in the first week after hemorrhage, but it is unclear whether this also results from the natriuretic effects of ANF or is an effect of antidiuretic hormone, causing water retention. The work of Diringer and co-workers suggests that both mechanisms are operative, but we would emphasize that it is the volume depletion, not hyponatremia per se, that is of the greatest clinical consequence.

Both the risk of rerupture of the aneurysm and some of the secondary problems that arise because of the massive amount of blood in the subarachnoid space can be obviated by early obliteration of the aneurysm. Because of the changes in water balance and the risk of delayed stroke from vasospasm, there has been an emphasis on early volume expansion and sodium repletion by the intravenous infusion of crystalloids. As Solomon and Fink have pointed out, this can be accomplished with relative safety and without fear of aneurysmal rupture if blood pressure is allowed to rise only minimally. And, of course, fluid replacement and a modest elevation of blood pressure become completely safe if the aneurysm has been surgically occluded. Thus the current approach is to operate early, within 36 h if possible, on all patients in grades I and II and then to increase intravascular volume and maintain normal or above-normal blood pressures. This eliminates the risk of rebleeding, with its high mortality, and helps prevent the second cause of morbidity, stroke from vasospasm. The timing of surgery or endovascular treatment for grade III patients is still controversial, but if their medical condition allows, they too probably benefit from the same early and aggressive approach. In grade IV patients, the outcome is generally dismal, no matter what course is taken, but we have usually counseled against early operation; some neurosurgeons disagree. The insertion of ventricular drains into both frontal horns has occasionally raised a patient with severe hydrocephalus to a better grade and facilitated early operation. In the

hands of experienced anesthesiologists and cerebrovascular surgeons, the operative mortality, even in grade III and IV patients, has now been reduced to 2 to 3 percent. For a detailed account of the operative approach to each of the major classes of saccular aneurysm, the reader is referred to the monograph by Ojemann and colleagues.

Several alternative therapeutic measures are still being studied. Among these, endovascular obliteration of the lumen of the aneurysm holds the most promise. This has become the preferred approach for aneurysms that are surgically inaccessible—for example, those in the cavernous sinus—or for patients whose medical state precludes an operation. Among several trials that have compared surgery with endovascular placement of coils in the aneurysm, several have shown a slight superiority of the latter. For example, the International Subarachnoid Aneurysm Trial Group randomly assigned over 2000 patients to surgery or platinum coil placement; the overall rate of death or dependence at 1 year was 24 percent in the endovascular group and 31 percent in the operated group. Doubtless, further studies will continue to clarify the relative benefits of the treatment. We would comment that the skill of the surgeon and the quality of postoperative care are major determinants of outcome; perhaps the simplicity of endovascular treatment and the improvements in the training of interventional specialists will prove its advantage over time.

Because of the current approach of ablating the aneurysm early, the previously popular use of antifibrinolytic agents as a means of impeding lysis of the clot at the site of aneurysmal rupture has been generally abandoned. Repeated drainage of the CSF by lumbar puncture is also no longer practiced as a routine. One lumbar puncture is generally carried out for diagnostic purposes if the CT scan is inconclusive; thereafter spinal fluid drainage is performed only for the relief of intractable headache or to detect recurrence of bleeding. As mentioned earlier, patients with stupor or coma who have massive hydrocephalus often benefit from decompression of the ventricular system. This is accomplished initially by external drainage and may require permanent shunting if the hydrocephalus returns. The risk of infection of the external shunt tubing is high if it is left in place for much more than 3 days. Replacement with a new tube, preferably at another site, reduces this risk.

Unruptured Intracranial Aneurysms Not infrequently, cerebral angiography, MRI, MRA, or CT scanning performed for an unrelated reason, discloses the presence of an unruptured saccular aneurysm. Or, a second or third aneurysm is found during the angiogram to assess a ruptured one. There is now a reasonable body of information about the natural history of these lesions. Wiebers and colleagues observed 65 patients with one or more unruptured aneurysms for at least 5 years after their detection. The only clinical feature of significance relative to rupture was aneurysmal size. None of 44 aneurysms smaller than 10 mm in diameter had ruptured, whereas 8 of 29 aneurysms 1 cm or larger eventually did so, with a fatal outcome in 7 cases. Two large studies have attempted to refine these statistical data. In the older Cooperative Study of Intracranial Aneurysms, none of the aneurysms less than 7 mm diameter "had further trouble." A more recent and quite sizable cooperative study that included 4060 patients and gathered data prospectively for 5 years, conducted by the International Study of Unruptured Intracranial Aneurysms Investigators, found an extremely low rate of rupture, about 0.1 percent yearly, for aneurysms smaller than 7 mm in diameter, an annual risk of 0.5 percent was

found for aneurysms between 7 and 10 mm, and a risk ranging from 0.6 to 3.5 percent for lesions between 13 and 24 mm (depending on location). The risk ranged up to 10 percent for aneurysms greater than 25 mm diameter. The yearly rates for rupture were higher in all categories if there had been prior bleeding from another site. The location of the lesion also had great bearing on the risk of rupture, as did increasing age; notably, vertebrobasilar and posterior cerebral aneurysms bled at a rate many times higher than the others. The importance of such data is underscored by the comparison to the risk of surgery and endovascular treatment, which begin to exceed the risk of bleeding within 5 years in the smaller aneurysms located in the carotid circulation.

Giant Aneurysms As has been stated, these are believed to be congenital anomalies even when there is considerable atherosclerosis in their walls. They may become enormous in size, by definition greater than 2.5 cm in diameter, but sometimes twice or more as large. Most are located on a carotid, basilar, anterior, or middle cerebral artery. They grow slowly by accretion of blood clot within their lumens or by the organization of surface blood clots from small leaks. At a certain point they may compress adjacent structures, e.g., those in the cavernous sinus, optic nerve, or lower cranial nerves. The giant fusiform aneurysm of the midbasilar artery, with signs of brainstem ischemia and lower cranial nerve palsies, is a relatively common form. Clotting within the aneurysm may cause ischemic infarction in its territory of supply. Giant aneurysms may rupture and cause subarachnoid hemorrhage, but not nearly as often as saccular aneurysms. This clinical observation has been confirmed by the International Study, referred to above.

Treatment is surgical if the lesion is symptomatic and it is accessible; treatment is with endovascular techniques if the lesion is in the vertebral or midbasilar artery. Obliteration of the lumen, coupled with vascular bypass procedures, has been successful in the hands of a few cerebrovascular neurosurgeons, but the morbidity is high. Some aneurysms can be ligated at their necks, others by trapping or by the use of an intravascular detachable balloon. Drake has summarized his experience in the treatment of 174 such cases. Ojemann and colleagues have also had singular success in treating these lesions by a combination of surgical techniques; in more than 40 cases, half of them trapped and half obliterated, there was not a single fatality. Some have been wrapped in muslin or similar material with mixed results. We have followed one such patient operated by T. Sundt over 25 years ago. Recent attempts at stabilizing the expansion of the aneurysm by stenting are under study.

Arteriovenous Malformations of the Brain

An arteriovenous malformation (AVM) consists of a tangle of dilated vessels that form an abnormal communication between the arterial and venous systems, really an arteriovenous fistula. It is a developmental abnormality representing persistence of an embryonic pattern of blood vessels and is not a neoplasm, but the constituent vessels may proliferate and enlarge with the passage of time. Arteriovenous malformations have been designated by a number of other terms, such as *angioma* and *arteriovenous aneurysm*, but these are less appropriate; *angioma* suggests a tumor, and the term *aneurysm* is generally reserved for the lesions described in the preceding section. Venous malformations, consisting purely of distended veins deep in the white matter, are a separate entity;

they may be the cause of seizures and headaches but seldom of hemorrhage. When a small hemorrhage occurs in relation to venous malformation, it is usually due to an associated cavernous malformation.

Vascular malformations vary in size from a small blemish a few millimeters in diameter lying in the cortex or white matter to a huge mass of tortuous channels constituting an AV shunt of sufficient magnitude, in rare instances, to raise cardiac output. Hypertrophic dilated arterial feeders can be seen approaching the main lesion and to break up into a network of thin-walled blood vessels that connect directly with draining veins. The latter often form greatly dilated, pulsating channels, carrying away arterial blood. The tangled blood vessels interposed between arteries and veins are abnormally thin and do not have the structure of normal arteries or veins. Arteriovenous malformations occur in all parts of the cerebrum, brainstem, and cerebellum (and spinal cord), but the larger ones are more frequently found in the central part of a cerebral hemisphere, commonly forming a wedge-shaped lesion extending from the cortex to the ventricle. Some lie on the dural surface of the brain or spinal cord, but these most often turn out to be direct arteriovenous fistulas, as discussed further on.

When hemorrhage occurs, blood may enter the subarachnoid space, producing a picture almost identical to that of ruptured saccular aneurysm, but generally less severe; since most AVMs lie within cerebral tissue, bleeding is more than likely to be intracerebral as well, causing a hemiparesis, hemiplegia, and so forth, or even death.

Arteriovenous malformations are about one-tenth as common as saccular aneurysms and about equally frequent in males and females. The two lesions—AVM and saccular aneurysm (on the main feeding artery of the AVM)—are associated in about 5 percent of cases; the conjunction increases with the size of the AVM and the age of the patient (Miayasa et al). Rarely, AVMs occur in more than one member of a family in the same generation or successive ones.

For a review of the embryologic theories of formation of AVMs, the reader is directed to the article by Fleetwood and Steinberg.

Clinical Features Bleeding or seizures are the main modes of presentation. Most AVMs are clinically silent for a long time, but sooner or later they bleed. The first hemorrhage may be fatal, but in more than 90 percent of cases the bleeding stops and the patient survives. The rate of hemorrhage in untreated patients is established to be 2 to 4 percent per year, far lower than for aneurysms. The mortality rate in two major series (Crawford et al, Ondra et al) has been 1 to 2 percent per year but as high as 6 to 9 percent in the immediate year following a first hemorrhage. The matter of an increased risk of AVM rupture during pregnancy has been disputed. The weight of evidence suggests that the risk is not raised by pregnancy alone, but—as with saccular aneurysm—that parturition and Valsalva activity is always a source of concern. Before rupture, chronic, recurrent headache may be a complaint; usually the headache is of a nondescript type, but a classic migraine with or without neurologic accompaniment occurs in about 10 percent of patients—probably with greater frequency than it does in the general population. Most of the lesions associated with migraine-like headaches lie in the parieto-occipital region of one cerebral hemisphere, and about two-thirds of such patients have a family history of migraine.

Huge AVMs may produce a slowly progressive neurologic deficit because of compression of neighboring structures by the

enlarging mass of vessels and by shunting of blood through greatly dilated vascular channels (“intracerebral steal”), resulting in hypoperfusion of the surrounding brain (Homan et al). When the vein of Galen is enlarged as a result of drainage from an adjacent AVM, hydrocephalus may result. Not infrequently one or both carotid arteries pulsate unusually forcefully in the neck. A systolic bruit heard over the carotid in the neck or over the mastoid process or the eyeballs in a young adult is almost pathognomonic of an AVM. However, such bruits have been heard in fewer than 25 percent of our patients. Exercise that increases the pulse pressure may bring out a bruit if none is present at rest.

The blood pressure may be elevated or normal; it is axiomatic that the occurrence of intracranial bleeding with a previously normal blood pressure should raise the suspicion of an AVM, but also of ruptured saccular aneurysm, bleeding diathesis, cerebral vessel amyloidosis, or hemorrhage into a tumor. Rarely, inspection of the eye grounds discloses a retinal vascular malformation that is co-extensive with a similar lesion of the optic nerve and basal portions of the brain. Cutaneous, orbital, and nasopharyngeal AVMs may occasionally be found. Rarely, skull films show crescentic linear calcifications in the larger malformations.

The natural history of AVMs has been studied by Ondra and colleagues, who have presented data on a large and comprehensive series of untreated malformations in Finland over a 30-year period, and another similar series has been reported by Crawford and co-workers in Great Britain. In the latter study, comprising 343 patients, 217 were managed without surgery and observed for many years (mean, 10.4 years). Hemorrhage occurred in 42 percent and seizures in 18 percent. By 20 years after diagnosis, 29 percent had died and 27 percent of the survivors had a neurologic handicap. Although the lesion is present from birth, onset of symptoms is most common between 10 and 30 years of age; occasionally it is delayed to age 50 or even beyond. In almost half of patients, the first clinical manifestation is a cerebral subarachnoid hemorrhage; in 30 percent, a seizure is the first and only manifestation; and in 20 percent, the only symptom is headache. Progressive hemiparesis or other focal neurologic deficit is present in about 10 percent of patients. In a series of 1000 patients referred mainly for proton beam radiation of an AVM and studied by our colleague R. D. Adams, 464 had a hemorrhage as the first manifestation and 218 had a seizure (mainly with frontal and frontoparietal lesions). In 139, the lesion came to attention as a result of a progressive neurologic deficit; most of these were situated in the posterior fossa or axially in the cerebrum. Headaches were an early symptom in 212, but only 59 of these patients had a subsequent hemorrhage. The combination of a prolonged history of headaches, seizures, and a progressive deficit almost always indicated a large malformation.

Fully 95 percent of AVMs are disclosed by CT scans if enhanced and an even larger number by MRI (Fig. 34-25). Magnetic susceptibility MRI shows small areas of previous bleeding around AVMs. Arteriography is usually necessary to establish the diagnosis with certainty and will demonstrate AVMs larger than 5 mm in diameter (Fig. 34-26); MRI may fail to reveal smaller lesions. Small ones may be obscured by hemorrhage; even at autopsy, a careful search under the dissecting microscope may be necessary to find them.

Treatment The preferred approach in most centers is surgical excision. Some 20 to 40 percent of AVMs are amenable to block dissection, with an operative mortality rate of 2 to 5 percent and a morbidity of 5 to 25 percent (see Fleetwood and Steinberg for a

summary of reported surgical results up to 2002). In the others, which are inaccessible, attempts have been made to obliterate the malformed vessels by ligation of feeding arteries or by the use of endovascular embolization with liquid adhesives or particulate ma-

terial that are injected via a balloon catheter that has been navigated into a feeding vessel. Complete obliteration of large AVMs is usually not possible by these methods but, they are highly effective in reducing the size of the AVM prior to surgery.

Kjellberg and Chapman pioneered the treatment of AVMs at the Massachusetts General Hospital using a single dose of subnecrotizing stereotactically directed proton radiation. The technique of radiosurgery has been adopted by others using photon radiation sources, such as a linear accelerator, gamma knife, and other modes of focused x-ray radiation, as an accepted alternative to operative treatment of lesions situated in deep regions, including the brainstem, or in “eloquent” areas of the cortex. Generally, malformations smaller than 3 cm diameter are treatable in this way. Radiosurgical obliteration of AVMs occurs in a delayed manner, usually with a latency of at least 18 to 24 months after treatment. During this early period the patient is unprotected from rebleeding.

The likelihood of successful treatment and the nature of the risks depend on the location and size of the AVM and the radiation dose delivered. After 2 years, 75 to 80 percent of AVMs smaller than 2.5 cm in diameter have been obliterated. Even for those AVMs that have not been totally eliminated, the radiation effect appears to confer some long-term protection from bleeding. Of the larger ones, a majority are shrunken or appear less dense. The rest have shown no change at this low dose level, but even in this group, the morbidity and mortality are lower than in the untreated group. However, a proportion of larger AVMs that are obliterated will recanalize, and many of these will subsequently bleed. Among more than 250 patients whose AVMs disappeared following proton beam therapy, there has been no recurrence of hemorrhage for up to 10 years; in larger AVMs (approximately the last 1000

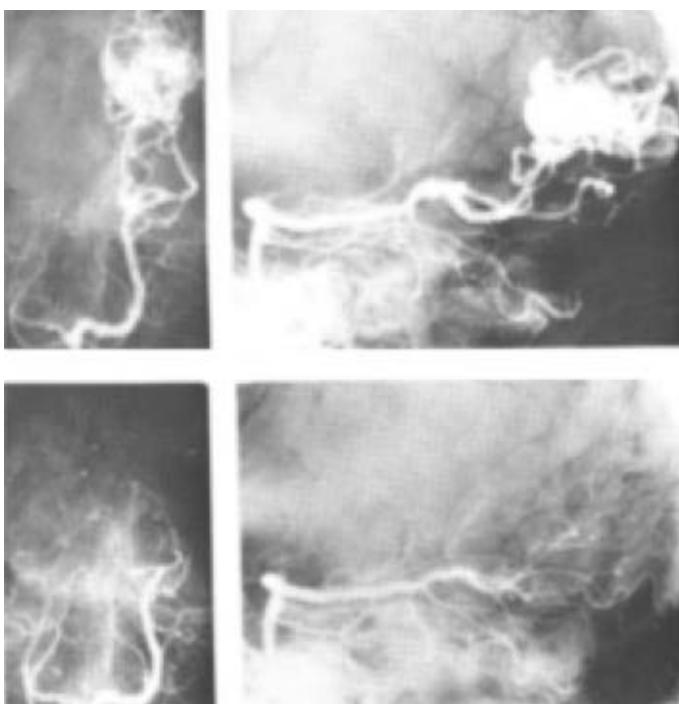

Figure 34-26. *Top:* Angiogram of a large parieto-occipital AVM prior to treatment showing the malformation and greatly enlarged draining veins. *Bottom:* Obliteration of the malformation 2 years after proton beam treatment.

cases) treated in this way, the frequency and severity of hemorrhage have been significantly reduced. The results of treatment with focused gamma radiation have been about the same. In one study, the risk of hemorrhage was reduced by 54 percent between the time of radiation and obliteration of the malformation and by 88 percent thereafter (Maruyama et al).

Two types of complications of radiation occur at a combined rate of approximately 2 to 4 percent. The first is delayed radiation necrosis, which is predictable based on the radiation dose, and the second is a venous congestion that occurs several weeks or months after treatment. The latter is indicative of the desired effect of thrombosis of the malformation. Both cause local symptoms for weeks or months. Radiation necrosis may be reduced by the administration of corticosteroids but the vascular problem generally is not helped.

The treatment of AVMs by endovascular techniques is increasingly popular but has not been fully evaluated. Nearly every AVM has several feeding arteries, some not reachable by catheter, and some part of the AVM remains after treatment. In most series, 25 percent or more of AVMs, mostly of small and medium size, could be completely obliterated, with a mortality rate below 3 percent and morbidity of 5 to 7 percent, which compares favorably with surgical outcomes. These techniques are also particularly well adapted to lesions of a combined AVM and an aneurysm on the feeding vessel.

Most recently, combined therapy that begins with endovascular reduction of the lesion and is followed by either surgery or radiation has been viewed most favorably. In series of patients using this approach, over 90 percent of lesions could be obliterated with a very low rebleeding rate over several years. What is clear is that the plan for each patient must be individualized based on the size, location, nature of feeding vessels, the presence of other vascular lesions (aneurysm or additional AVM), and the age of the patient. Even then, there will be differences of opinion based on local resources and experience.

Finally, if the primary problem is recurrent seizure, successful treatment with reduction or cessation of seizures is achieved in a very high proportion of cases. The results are comparable to those from surgery and radiation, even if the AVM is not entirely obliterated.

Dural Arteriovenous Fistulas

These curious vascular abnormalities, occurring in both the cranial and spinal dura, have different presentations at each site; the latter form is discussed with other diseases of the spinal cord in Chap. 46. The cranial type is being detected with increasing frequency as refinements continue to be made in imaging of the cerebral vessels, but its true incidence and pathogenesis are not fully known. The defining features are radiologic—a nidus of abnormal arteries and veins with arteriovenous shunting contained entirely within the leaflets of the dura. The lesion is fed by dural arterial vessels derived from the internal cranial circulation and often, more prolifically, from the external cranial circulation (external carotid artery and muscular branches of the vertebral artery). The venous drainage is complex and is largely into the dural venous sinuses (Fig. 34-27). The rapid transit of injected angiographic dye through these fistulas accounts for the early opacification of the draining venous structures; in the case of high-flow connections, this may not be seen unless images are taken almost immediately after the injection. A number of potential feeding vessels must be injected to demonstrate all the conduits into the lesion. On CT scanning and MRI, the fistula is sometimes detected as a thickening or enhancement of a region

Figure 34-27. Cerebral angiogram of a cerebral dural arteriovenous malformation. The nidus is located at the cerebral convexity (arrow). There is rapid filling of the cerebral venous system after injection of dye into one internal carotid artery.

of dura, generally close to a large dural venous sinus. In other cases, the dilated draining vessels may be seen only with the injection of dye or gadolinium. Probably, many are not detected by these techniques.

The origin of these vascular lesions has not been settled—several mechanisms may be involved. Most evidence suggests that some of these lesions, unlike conventional cerebral AVMs and aneurysms, are not developmental in origin. The best-defined examples are those that arise adjacent to a venous sinus thrombosis or in association with a vascular atresia, most often in the transverse sigmoid sinus or adjacent to the cavernous sinus. However, it is not clear whether the abnormality of the dural sinus is the cause or the result of the dural fistula. In a number of cases, a dural fistula has appeared after a forceful head injury, often in a region remote from the site of impact. A small group is associated with the Klippel-Trenaunay or Osler-Weber-Rendu syndromes, diseases in which a frequent conjunction with AVMs is well known. Usually, all of these causes can be excluded and the largest group remains idiopathic.

A major obstacle to our understanding of the dural AVM has been the varied and confusing ways in which this lesion presents clinically. Subdural hemorrhage is an infrequent mode of presentation, sometimes creating a large and fatal clot; another syndrome is a cerebral-subarachnoid hemorrhage, although this occurs with not nearly the frequency or severity as bleeding from brain AVMs. However, our knowledge of the risk of bleeding from dural fistulas and the evolution of the lesions is far less precise than it is for cerebral AVMs. It appears that the dural lesions most at risk of bleeding are those located in the anterior cranial fossa and at the tentorial incisura. Seizures are distinctly uncommon. A special syndrome linked to dural AVMs, although it may occur also with high-flow cerebral malformations, is of headache, vomiting, and papilledema—namely, *pseudotumor cerebri* (Chap. 30). A cranial bruit is infrequent. In small children, the high-flow lesions may shunt so much blood as to cause congestive heart failure, similar to malformations of the vein of Galen.

Treatment is by surgical extirpation or endovascular embolization, a painstaking procedure because of the multitude of poten-

tial feeding vessels. Surgery seems preferable for the smaller lesions and embolization for larger and inaccessible ones. The issue of anticoagulation, when there is slowed flow in a venous sinus draining a malformation, is unsettled.

Dural fistulas of the spine, which are as common as the cerebral ones, represent a special problem, discussed on page 1070.

Cavernous Malformations

Vascular malformations composed mainly of clusters of thin-walled veins without important arterial feeders and with little or no intervening nervous tissue make up a significant group, some 7 to 8 percent of our series of AVMs. Conventional subdivisions of this group into cavernous, venous, and telangiectatic types have not proven useful. We have, therefore, roughly designated them all as *cavernous*. They have several attributes that set them apart. Their tendency to bleed is probably no less than that of the more common AVMs, but far more often the hemorrhages are small and clinically silent. The exact incidence of bleeding is uncertain but is estimated to be less than 1 percent per year per lesion. Often there are multiple lesions. They are generally not seen in arteriograms. The diagnosis is based on their clinical manifestations and MRI, which discloses a cluster of vessels surrounded by a zone of hypodense ferritin in the T1-weighted images (Fig. 34-28), the product of previous small episodes of bleeding. A small but uncertain number are associated with adjacent venous malformations, visualized by imaging studies. The lack of formation of a mass over a long period of time separates this lesion from a malignant tumor that has bled. About one-half of all cavernous angiomas lie in the brainstem, and in the past (before the availability of MRI), many of them were misdiagnosed as multiple sclerosis because of a stepwise accumulation of neurologic deficits with each hemorrhage.

About 10 percent of these lesions are multiple and 5 percent are familial. In one of the families we have followed of Italian-American origin, there were 29 affected members in three generations. The inheritance followed an autosomal dominant pattern; Marchuk and coworkers have localized the abnormal gene in other kindreds to the long arm of chromosome 7. One interesting characteristic of this group, as pointed out by Labauge and colleagues, is the appearance over time of new lesions in one-third of patients. The follow-up of some of our patients has documented this.

Treatment Cavernous angiomas on the surface of the brain, within reach of the neurosurgeon, even those in the brainstem, can be plucked out, like clusters of grapes, with low morbidity and mortality. Kjellberg and colleagues have treated 89 deeply situated cavernous angiomas with low-dose proton radiation. Our impression is that these vascular malformations, like the hemangioblastoma, respond poorly to radiation and are not amenable to treatment by endovascular techniques.

Lesions that cause recurrent bleeding and are surgically accessible with little risk are often removed, but incidentally discovered angiomas and those that are inaccessible may be left alone. Although this is the approach usually taken, there is not adequate data on the rate and risk of bleeding to determine the proper approach.

Other Causes of Intracranial Bleeding

Next to hypertension, *anticoagulant therapy* is currently the most common cause of cerebral hemorrhage. The hemorrhages that develop, though sometimes situated in the sites of predilection of

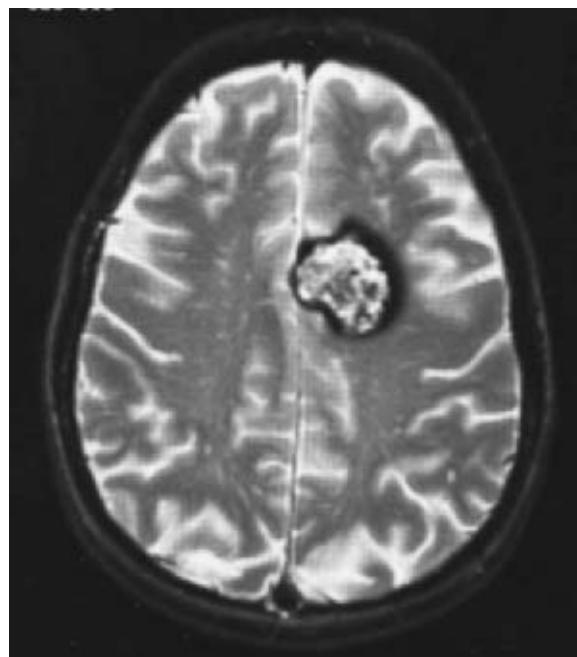

Figure 34-28. Large cavernous vascular malformation. MRI in the sagittal (above) and axial (below) planes demonstrates a medial left frontal lesion with a prominent rim of hemosiderin-laden macrophages and no associated edema. Most cavernous angiomas are much smaller and sometimes multiple but have the same signal characteristics.

hypertensive hemorrhage, are more likely to occur elsewhere, mainly in the lobes of the brain. When the bleeding is precipitated by warfarin therapy, treatment with fresh-frozen plasma and vitamin K is recommended; when bleeding is associated with aspirin therapy or other agents that affect platelet function, fresh platelet infusion, often in massive amounts, is required to control the hemorrhage. The use of *thrombolytics* in the treatment of stroke is complicated by intracranial hemorrhage in 6 to 20 percent of cases, depending on the dose and timing of drug administration after the onset of symptoms, as discussed on page 694.

In the elderly, *amyloid angiopathy* appears to be a major cause of lobar hemorrhages, especially if they appear in succession or are multiple. Several of our patients have had minor head injuries in

the weeks before hemorrhage. In our own material, only severe impregnation of vessels with amyloid and fibrinoid change in the vessel wall were associated with hemorrhage (Vonsattel et al.). Greenberg and colleagues have found that apolipoprotein E4, the same marker that is overrepresented in Alzheimer disease, is associated with severe amyloid angiopathy and intracerebral hemorrhage, but others have found an association with the E2 allele. Contrary to previous notions, there is probably no greater risk in evacuating these clots surgically than in the case of other cerebral hemorrhages, but most of them are of a size that allows conservative management.

Several *primary hematologic disorders* are also complicated by hemorrhage into the brain. The most frequent of these are leukemia, aplastic anemia, and thrombocytopenic purpura. Often they give rise to multiple intracranial hemorrhages, some in the subdural and subarachnoid spaces. As a rule, this complication signals a fatal issue. Other, less common causes of intracerebral bleeding are advanced *liver disease*, uremia being treated with dialysis, and lymphoma. Usually several factors are operative in these hematologic cases: reduction in prothrombin or other clotting elements (fibrinogen, factor V), bone marrow suppression by antineoplastic drugs, and disseminated intravascular coagulation. Any part of the brain may be involved, and the hemorrhagic lesions are usually multiple. Frequently there is also evidence of abnormal bleeding elsewhere (skin, mucous membranes, kidney) by the time cerebral hemorrhage occurs. Plasma exchange, used in the treatment of myasthenia gravis and Guillain-Barré disease, also lowers the serum fibrinogen to a marked degree, but we have not observed a single instance of intracerebral hemorrhage in more than 500 patients treated in this way.

Acute extradural and subdural hemorrhage, typically traumatic in origin, must also be considered in the patient who, under unknown circumstances, has rather abruptly developed a neurologic deficit such as hemiparesis or confusion, with or without bloody CSF. The use of anticoagulant drugs and intrinsic coagulopathies of all types are risks for these extracerebral hemorrhages. In *chronic subdural hemorrhage*, which can occur without remembered trauma, the indefinite picture of drowsiness, headache, confusion, and mild hemiparesis may erroneously be attributed to a stroke, especially in elderly persons. There should be no hesitation in subjecting patients to CT scanning whenever the diagnosis of subdural hemorrhage cannot readily be excluded on clinical grounds. In the patient who falls and strikes his head at the onset of a stroke, it may be difficult or impossible to decide whether blood in the CSF is due to the stroke or to cerebral contusion. These disorders are discussed more fully in the next chapter.

Occasionally the origin of intracranial hemorrhage cannot be determined clinically or pathologically. In some postmortem cases, a careful search under the dissecting microscope discloses a small arteriovenous malformation; this is the basis for suspecting that an overlooked lesion of this type may be the cause of cerebral hemorrhage in other cases. *Primary intraventricular hemorrhage*, a rare event in adults, can sometimes be traced to a vascular malformation or neoplasm of the choroid plexus; more often, such a hemorrhage is the result of periventricular bleeding, in which blood enters the ventricle without producing a visible parenchymal clot.

Hemorrhage into primary and secondary brain tumors is not rare; when this is the first clinical manifestation of the neoplasm, diagnosis may be difficult. Choriocarcinoma, melanoma, renal cell and bronchogenic carcinoma, pituitary adenoma, thyroid cancer, glioblastoma multiforme, intravascular lymphoma, and medullo-

blastoma may present in this way. Careful inquiry will usually disclose that neurologic symptoms compatible with intracranial tumor growth had preceded the onset of hemorrhage. Needless to say, a thorough search should be made in these circumstances for evidence of intracranial tumor or of secondary tumor deposits in other organs, particularly the lungs.

The term *mycotic aneurysm* designates an aneurysm caused by a localized bacterial or fungal inflammation of an artery (Osler introduced the term *mycotic* to describe endocarditis, but its proper current use is to describe fungal infection). With the introduction of antibiotics, mycotic aneurysms have become less frequent, but they are still being seen in patients with bacterial endocarditis and in intravenous drug abusers. Peripheral arteries are involved more often than intracranial ones; about two-thirds of the latter are associated with subacute bacterial endocarditis due to streptococcal infections. In recent years, the number of mycotic aneurysms due to staphylococcal infections and acute endocarditis appears to have increased. The usual pathogenic sequence is an embolic occlusion of a small artery, which may announce itself clinically by an ischemic stroke, with cells in the CSF. Later, or as the first manifestation, the weakened vessel wall gives way and causes a subarachnoid or brain hemorrhage. The mycotic aneurysm may appear on only one artery or several arteries, and the hemorrhage may recur. A consensus regarding the treatment of mycotic aneurysm has not been reached. The underlying endocarditis or septicemia mandates appropriate antibiotic therapy and, in at least 30 percent of cases, healing of the aneurysm can be observed in successive arteriograms with this approach alone. Treatment should continue for at least 6 weeks. Some neurosurgeons believe in excising an accessible aneurysm if it is solitary and the systemic infection is under control. Some mycotic aneurysms do not bleed, and in our view medical therapy takes precedence over surgical therapy.

The pathologic entity called *brain purpura* (pericapillary encephalorrhagia), incorrectly referred to as "hemorrhagic encephalitis," consists of multiple petechial hemorrhages scattered throughout the white matter of the brain. The clinical picture is that of a diffuse encephalopathy, but diagnosis is essentially pathologic. Blood does not appear in the CSF, and the condition should not be confused with a stroke. It is virtually impossible to establish the diagnosis during life, but the pathologic appearance is unique and highly characteristic. The lesions in brain purpura are always small, 0.1 to 2.0 mm in diameter, and are confined to the white matter, particularly the corpus callosum, centrum ovale, and middle cerebellar peduncles. Each lesion is situated around a small blood vessel, usually a capillary. In this para-adventitial area, both the myelin and axis cylinders are destroyed, and the lesion is usually though not always hemorrhagic. Fibrin exudation, perivascular and meningeal infiltrates of inflammatory cells, and widespread necrosis of tissue are not observed. In these respects brain purpura differs fundamentally from acute necrotizing hemorrhagic leukoencephalitis. Usually the patient becomes stuporous and comatose without focal neurologic signs, and the CSF is normal. The etiology of brain purpura is quite obscure. It may complicate viral pneumonia, uremia, arsenical intoxication, and, rarely, metabolic encephalopathy and sepsis, or there may be no associated disease.

A degree of hemorrhage is to be expected in acute hemorrhagic leukoencephalitis (Hurst type), which represents an extreme form of acute disseminated encephalomyelitis (Chap. 36), and in herpes encephalitis (Chap. 33).

Inflammatory diseases of arteries and veins, especially polyarteritis nodosa, lupus erythematosus, and moyamoya disease, are

occasionally associated with cerebral hemorrhage. Rupture of a vessel in these circumstances may be on the basis of hypertension or local vascular disease, and bleeding nearly always occurs into brain tissue rather than into the subarachnoid space. Rarely, intracranial dissection of an artery (usually the vertebral) may allow some blood to escape into the subarachnoid space.

The other rare types of hemorrhage, listed in Table 34-9, are self-explanatory.

Hemorrhages of *intraspinal* origin, all of them rare, may be the result of trauma, AVM (the usual cause of nontraumatic hematomyelia), anterior spinal artery aneurysms, or bleeding into tumors. Spinal subarachnoid hemorrhage from an AVM may simulate an intracranial subarachnoid hemorrhage, causing a stiff neck, headache, and even subhyaloid hemorrhages. Subarachnoid hemorrhage in which interscapular or neck pain predominates should raise the suspicion of an aneurysm of the anterior spinal artery or of a spinal AVM or cavernous angioma. Angiographic study of the radicular spinal vessels and the origins of the anterior spinal arteries from the vertebral arteries may disclose the source of bleeding. Extradural and subdural spinal extravasations may be *spontaneous* (sometimes in relation to rheumatoid arthritis) but are far more often due to trauma, anticoagulants, or both. Extradural spinal hemorrhage causes the rapid evolution of paraplegia or quadriplegia; diagnosis must be prompt if function is to be salvaged by surgical drainage of the hematoma. These are discussed further in Chap. 44.

HYPERTENSIVE ENCEPHALOPATHY AND ECLAMPSIA

Clinical Features

Hypertensive encephalopathy is the term applied to a relatively rapidly evolving syndrome of severe hypertension in association with headache, nausea and vomiting, visual disturbances, confusion, and—in advanced cases—stupor and coma. Multiple seizures are frequent and may be more marked on one side of the body than the other. These symptoms of diffuse cerebral disturbance may be accompanied by focal or lateralizing neurologic signs, either transitory or lasting, which should always suggest cerebral hemorrhage or infarction, i.e., the more common cerebrovascular complications of severe chronic hypertension. A clustering of multiple microinfarcts and petechial hemorrhages (the basic neuropathologic changes in hypertensive encephalopathy) in one region may rarely result in a mild hemiparesis, aphasic disorder, or rapid failure of vision. By the time the neurologic manifestations appear, the hypertension has usually reached the malignant stage, with diastolic pressures above 125 mmHg, retinal hemorrhages, exudates, papilledema (*hypertensive retinopathy* grade IV), and evidence of renal and cardiac disease. However, instances of encephalopathy at lower pressures are common, especially if the hypertension has been abrupt in onset (see below). The term *hypertensive encephalopathy* should be reserved for the above syndrome and should not be used to refer to chronic recurrent headaches, dizziness, epileptic seizures, TIAs, or strokes, which often occur in association with high blood pressure.

Hypertensive encephalopathy may complicate hypertension from any cause (chronic renal disease, renal artery stenosis, acute glomerulonephritis, acute toxemia, pheochromocytoma, Cushing syndrome), cocaine, or administration of drugs such as amino-

phylline or phenylephrine, but it occurs most often in patients with rapidly worsening “essential” hypertension.

In *eclampsia*, which may be considered a special form of hypertensive encephalopathy, and in *acute renal disease*, particularly in children, encephalopathic symptoms may develop at blood pressure levels considerably lower than those of hypertensive encephalopathy of “essential” type. In eclampsia, the retinal and cerebral lesions are the same as those that complicate malignant nephrosclerosis; in both there is also failure of autoregulation of the cerebral arterioles. In the pathogenesis of pre-eclampsia, inhibition of an endothelium-derived relaxing factor by hemoglobin has been postulated by Sarrel and colleagues. See page 291 for a discussion of eclamptic seizures.

Laboratory Features Hypertensive encephalopathy is marked by characteristic changes on CT scanning and MRI. The radiologic findings are often misinterpreted as large areas of infarction or demyelination, but their tendency to normalize over several weeks is remarkable. As summarized by Hauser and coworkers, the main finding is a bilateral increase in T2 signal intensity in the white matter on MRI and a corresponding reduced density (edema) on CT, usually concentrated in the posterior part of the hemispheres (Fig. 34-29). This condition is one of the causes of reversible posterior leukoencephalopathy. These imaging characteristics are due to an accumulation of fluid, but—unlike the edema in trauma, neoplasm, or stroke—there is little or no mass effect and the water does not tend to course along white matter tracts such as the corpus callosum. In addition, scattered cortical lesions occur in a watershed distribution and probably correspond to small infarctions. These same findings in the white matter and cortex occur in eclampsia (Fig. 34-30) and have been seen in cases of diffuse vasospasm due to sympathomimetic and serotoninergic drugs, discussed further on.

Finally, it should be mentioned that hypertensive encephalopathy and eclampsia have at times caused subarachnoid hemorrhage. Most such cases are not due to the rupture of an intracranial aneurysm and are not as overwhelming as in the latter case; indeed, the headache associated with this form of hemorrhage tends to be much milder than with aneurysmal rupture and it may even be absent. Most often the bleeding is mainly a feature of the radiologic examination of the brain as described by Shah. The mechanism is obscure.

In many but not all the cases, the CSF pressure and protein values are elevated, the latter to more than 100 mg/dL in some instances, but there is no cellular reaction.

Pathophysiology Neuropathologic examination reveals a rather normal-looking brain, but in some cases cerebral swelling, hemorrhages of various sizes, or both will be found. In extreme cases, a cerebellar pressure cone reflects an increased volume of tissue and increased pressure in the posterior fossa; in rare instances lumbar puncture appears to have precipitated fatalities. Microscopically there are widespread minute infarcts in the brain (with a predilection for the basis pontis), the result of fibrinoid necrosis of the walls of arterioles and capillaries and occlusion of their lumens by fibrin thrombi (Chester et al). This is often associated with zones of cerebral edema. Similar vascular changes are found in other organs, particularly in the retinae and kidneys.

Volhard originally attributed the symptoms of hypertensive encephalopathy to vasospasm. This notion was reinforced by Byrom, who demonstrated, in rats, a segmental constriction and dil-

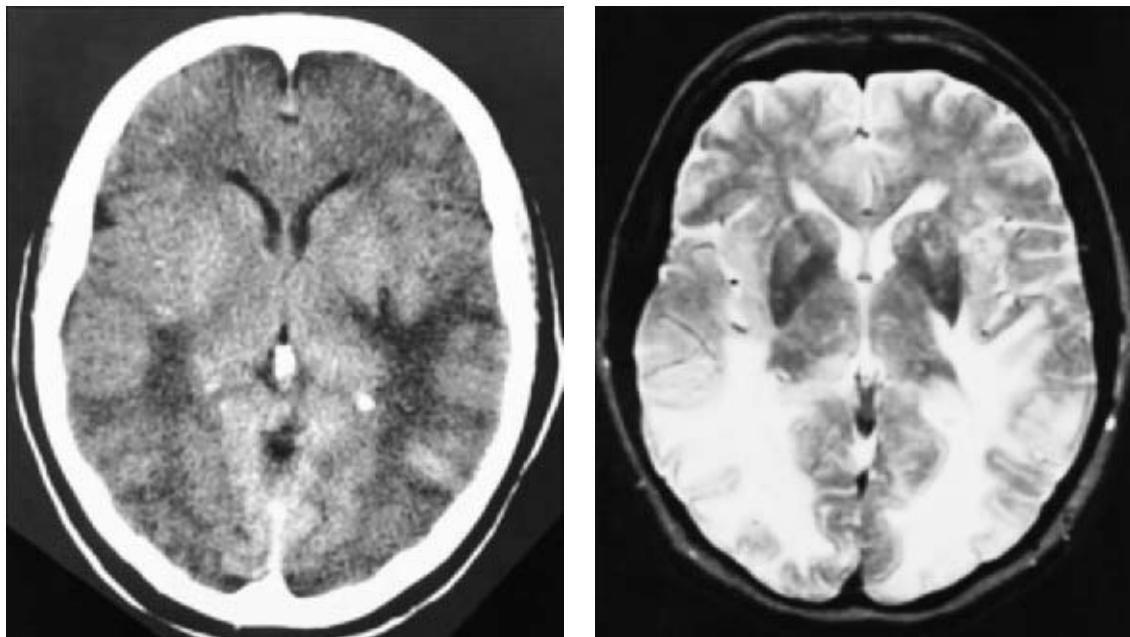

Figure 34-29. Hypertensive encephalopathy in a 55-year-old woman with headache and a single seizure. The characteristic changes of excess water in large regions of the white matter are seen on the CT scan (*left panel*) and in a T2-weighted MRI (*right panel*). The areas of signal change are associated with little mass effect and tend to be concentrated in the posterior regions of the brain. Other small cortical and subcortical lesions are common in watershed areas. There may be associated heterogeneous infarctions in the cerebral cortex, as shown in the following figure. The same changes in the occipital white matter may occur in eclampsia and from other causes of “posterior leukoencephalopathy” (see also page 1040).

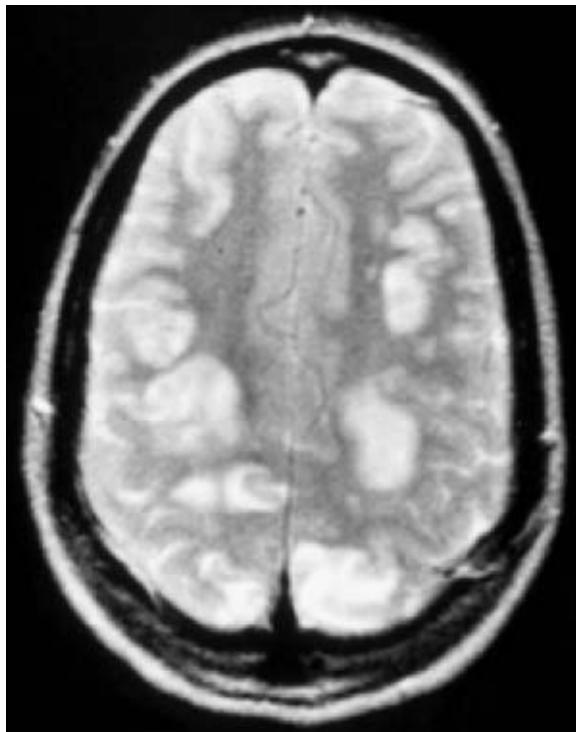

Figure 34-30. MRI T2 signal changes in eclampsia. Most of the vascular changes and edema are situated in the cortical watershed distributions between the middle and an anterior cerebral arteries. These imaging findings were transient, as was mild signal change in the occipital subcortical regions, the latter being typical of hypertensive encephalopathy, as in Fig. 34-29.

atation of cerebral and retinal arterioles in response to severe hypertension. However, the observations of Byrom and of others indicate that overdistention of the arterioles (which have lost their adaptive capacity), rather than excessive constriction, may be responsible for the necrosis of the vessel wall (see reviews of Auer and of Chester et al). The brain edema is the result of active exocytosis of water rather than simply a passive leak from vessels subjected to high pressures.

A few eclamptic women will develop hemolysis, hepatic failure and thrombocytopenia—hemolysis, elevated liver enzymes, low platelet count (HELLP syndrome)—an illness that has similarities to disseminated intravascular coagulation (DIC). The interplay between eclampsia and HELLP in relation to cerebral lesions is complex and not fully understood (see further on).

Treatment Lowering of the blood pressure with antihypertensive drugs may reverse the picture in a day or two. In the past, when effective antihypertensive drugs were not available, the outcome was often fatal. The BUN is only slightly elevated except in cases of renal failure, and the usual patient is not uremic. The same can be accomplished by administering magnesium sulfate in the eclamptic woman. Treatment consists of measures that promptly reduce arterial blood pressure, but antihypertensive drugs must be used cautiously; a safe target is a pressure of 150/100 mmHg. One may use intravenous sodium nitroprusside, 0.5 to 0.8 mg/kg/min; a calcium channel blocker such as nifedipine, 10 to 20 mg sublingually; or intravenous beta-adrenergic blockers (labetalol, 20 to 40 mg intravenously followed by an infusion at 2 mg/min, or esmolol are favored). These must be followed by longer-acting antihypertensive agents such as ACE inhibitors or calcium channel blockers.

If there is already evidence of brain edema and increased intracranial pressure, dexamethasone, 4 to 6 mg every 6 h, is usually added, but its effect, and the use of hyperosmolar therapy, have not been studied systematically; our clinical impression is that they have little effect.

Diffuse and Focal Cerebral Vasospasm

A focal reduction in the caliber of the basal vessels and their proximal branches is a well-known complication of subarachnoid hemorrhage, as described on page 718. Vasospasm has also been implicated in migraine and migrainous stroke and as an explanation for TIAs, but with little supportive evidence. Some degree of attenuation of large cerebral vessels is observed in hypertensive encephalopathy, in eclampsia, and with adrenergic drug use (e.g., phenylpropanolamine, cocaine, “tripan” drugs used for the treatment of migraine), but the role of the vascular changes in causing strokes has never been clear. A related condition of cerebral vasculitis caused by sympathomimetic drugs is discussed further on, with other vasculitides. The problem of stroke with migraine, which has a complex and uncertain relationship to vasospasm, is discussed on page 151.

In addition to these disorders of known causation, Call and colleagues have described a striking idiopathic widespread segmental vasospasm of cerebral vessels characterized by severe headache and fluctuating TIA-like episodes (all cases drawn from our hospital services; termed Call-Fleming syndrome in some publications). The middle cerebral artery and its branches are mainly affected; the angiographic appearance may be mistaken for arteritis. A number of similar cases have been described, and we have seen several that resulted in a small stroke. There may be a posterior leukoencephalopathy that is similar to the imaging appearance in hypertensive encephalopathy. Sometimes the headache is minimal. The nature of this condition of idiopathic diffuse vasospasm is unknown. A relationship to hypertensive encephalopathy or to delayed postpartum eclampsia has been suggested, because of the aforementioned white matter changes and the observation of widespread vasospasm in eclamptic women. The patients we have seen with this process, after several weeks of dramatically fluctuating focal neurologic symptoms and disabling headache, have recovered completely or nearly so. In all likelihood, several disorders cause this type of vasculopathy. Calcium channel blockers or corticosteroids have been prescribed, but their effectiveness cannot be determined. There are clinical similarities to the syndrome of migraine, transient focal deficits, and CSF pleocytosis described on page 152; the spinal fluid in the vasospasm cases is, however, normal.

It has recently been brought to attention—by Singhal and colleagues and others—that the use of serotonergic drugs may produce a similar syndrome of reversible multifocal vasospasm, severe headache, and stroke. One of their three patients was using the antimigraine medicine sumatriptan; the other two were using serotonin reuptake inhibitor antidepressants and, in addition, had taken over-the-counter cold remedies that included pseudophedrine and dextromethorphan; we are aware of other similar cases. These authors proposed that in these cases a “serotonin syndrome” had occurred, similar to what has been seen with overdoses of this class of antidepressants.

It has been suspected that the same sort of vasculopathy is produced by sympathomimetic drugs alone, such as ephedra in health food supplements, phenylpropanolamine, pseudophedrine,

and cocaine, but there are few well-studied cases. These are discussed below, under “Arteritis Symptomatic of Underlying Systemic Disease and Sympathomimetic Drug Reactions.” In all cases, including those noted above, the treatment is cessation of the offending drugs; nitroglycerin, nitroprusside, or beta-adrenergic infusions have been tried with uncertain effect.

INFLAMMATORY DISEASES OF BRAIN ARTERIES

Infectious Vasculitis

Inflammatory diseases of the blood vessels of infectious origin and their effects upon the nervous system have been considered in detail in Chap. 32. There it was pointed out that meningovascular syphilis, tuberculous meningitis, fungal meningitis, and the subacute (untreated or partially treated) forms of bacterial meningitis may be accompanied by inflammatory changes and occlusion of the cerebral arteries or veins. Occasionally, in syphilitic, cryptococcal, and tuberculous meningitis, a stroke may be the first clinical sign of meningitis, but more often it develops well after the meningeal symptoms are established. The nature of the cerebral vasculitis that may rarely accompany AIDS is unknown.

Typhus, schistosomiasis, mucormycosis, malaria, and trichinosis are rare causes of inflammatory arterial disease, which, unlike the above, is not secondary to meningeal infections. In *typhus and other rickettsial diseases*, capillary and arteriolar changes and perivascular inflammatory cells are found in the brain; presumably they are responsible for the seizures, acute psychoses, cerebellar syndromes, and coma characterizing the neurologic disorder in these diseases. The internal carotid artery may be occluded in diabetic patients as part of the orbital and cavernous sinus infections with *mucormycosis*. In *trichinosis*, the cause of the cerebral symptoms has not been established. Parasites have been found in the brain; in one of our patients the cerebral lesions were produced by bland emboli arising in the heart and related to a severe myocarditis. In *cerebral malaria*, convulsions, coma, and sometimes focal symptoms appear to be due to the blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles. Schistosomiasis may implicate cerebral or spinal arteries. These diseases are discussed further in Chap. 32.

Noninfectious Inflammatory Diseases of Cranial Arteries

Included under this heading is a diverse group of arteritides that have little in common except their tendency to involve the cerebral vasculature. One subgroup includes the *giant-cell arteritides*—extracranial (temporal) arteritis; granulomatous arteritis of the brain; and aortic branch arteritis, one form of which is known as Takayasu disease. All are discussed on the following pages.

A second group includes polyarteritis nodosa, the Churg-Strauss type of arteritis, Wegener granulomatosis, systemic lupus erythematosus, Behcet disease, post-zoster arteritis, and AIDS-related arteritis. Immunologic studies have shown that in most of these diseases there is an abnormal deposit of complement-fixing immune complex on the endothelium, leading to inflammation, vascular occlusion, or rupture with hemorrhage. The initial event is thought in some cases to be evoked by a virus, bacterium, or drug. It is postulated by some immunologists that in the *granulomatous arteritides*, a different mechanism is operative—that an

exogenous antigen induces antibodies that attach to the primary target (the vessel wall) as immune complexes, damage it, and attract lymphocytes and mononuclear cells. The giant cells form around remnants of the vessel wall (elastic tissue, etc.). An acute necrotizing cerebral angiitis—which may be idiopathic, sometimes complicates ulcerative colitis, and responds to treatment with prednisone and cyclophosphamide—may also belong in this category. The special case of intravascular lymphoma, which simulates a cerebral vasculitis, is discussed in Chap. 31.

Temporal Arteritis (Giant-Cell Arteritis, Cranial Arteritis; See also page 159) In this disease, not uncommon among elderly persons, arteries of the external carotid system, particularly the temporal branches, are the sites of a subacute granulomatous inflammatory exudate consisting of lymphocytes and other mononuclear cells, neutrophilic leukocytes, and giant cells. The most severely affected parts of the artery usually become thrombosed. The sedimentation rate is characteristically elevated above 80 mm/h and sometimes exceeds 120 mm/h, but a small number of cases occur with values below 50 mm/h.

Headache or head pain is the chief complaint, and there may be severe pain, aching, and stiffness in the proximal muscles of the limbs associated with the markedly elevated sedimentation rate. Thus the clinical picture overlaps that of *polymyalgia rheumatica* as discussed in Chap. 10. Other less frequent systemic manifestations include fever, anorexia and loss of weight, malaise, anemia, and a mild leukocytosis. Instances of dementia, depression, and other neurologic illnesses that have been described in the literature in patients with temporal arteritis seem to us coincidental.

Occlusion of branches of the ophthalmic artery, resulting in blindness in one or both eyes, is the main complication, occurring in over 25 percent of patients. In the most extreme form, the optic nerve head can be seen to be infarcted, with papilledema and visual loss. This is a form of anterior ischemic optic neuropathy discussed in Chap. 10. In a few cases blindness is preceded by transient visual loss simulating a TIA. Occasionally the arteries of the oculomotor nerves are also involved, causing an ophthalmoplegia. Rarely, an arteritis of the aorta and its major branches—including the carotid, subclavian, coronary, and femoral arteries—is found at postmortem examination.

Significant inflammatory involvement of *intracranial arteries* from temporal arteritis is uncommon, perhaps because of a relative lack of elastic tissue, but in a few cases strokes have occurred on the basis of occlusion of the internal carotid or vertebral arteries.

The diagnosis should be suspected in elderly patients who develop severe, persistent headache and elevation of the sedimentation rate; it depends on finding a tender, thrombosed, or thickened cranial artery and demonstration of the lesion in a biopsy. The procedure is innocuous and the diagnosis may require that both sides be sampled because of the patchy distribution of granulomatous lesions. Schmidt and colleagues have reported that the diagnosis can often be made with duplex ultrasonography. In 22 of 30 cases, a dark halo, probably reflecting edema, surrounded the affected temporal artery; 6 cases showed either occlusion or stenosis of the artery; there were no false-positive tests. A considerable length of the temporal artery can be insonated by this technique, a particularly useful feature in a process that affects the vessel segmentally. From our limited experience, these findings have proven difficult to detect. The arteritic changes may also be revealed by arteriography of the external carotid arteries.

The administration of prednisone, 50 to 75 mg/day, provides

striking relief of the headache and polymyalgic symptoms within days and sometimes within hours and also prevents blindness. The medication must be given in very gradually diminishing doses for at least several months or longer, guided by the symptoms and the sedimentation rate. The latter begins to drop within days but seldom falls below 25 mm/h.

Intracranial Granulomatous Arteritis Scattered examples of a small-vessel giant-cell arteritis of undetermined etiology in which only brain vessels are affected have come to medical attention over the years. The clinical state has taken diverse forms, sometimes presenting as a low-grade, nonfebrile meningitis with sterile CSF, followed by infarction of one or several parts of the cerebrum or cerebellum. In other cases it has masqueraded as a cerebral tumor, evolving over a period of weeks, or as a viral encephalitis or an unusual dementia. Headaches (variable in our experience but sometimes severe), focal cerebral or cerebellar signs of gradual (seldom stroke-like) evolution, confusion with memory loss, pleocytosis and elevated CSF protein, and papilledema as a result of increased intracranial pressure (in about half the cases) constitute the most frequently encountered syndrome. The symptoms usually persist for several months. In contrast to temporal arteritis, the sedimentation rate is generally normal or only slightly elevated.

In only about half the patients can the diagnosis be made by angiography, which demonstrates an irregular narrowing and in some cases blunt ending of small cerebral arteries (Fig. 34-31). CT scanning and MRI show multiple irregular white matter and cortical changes and small cortical lesions; often these cannot be differentiated from a tumor or infectious process. Occasionally the white matter abnormalities become confluent and the radiologic appearance simulates Binswanger disease or hypertensive encephalopathy. The diagnosis is made most often by a brain biopsy, which includes a sample of the meninges, but even with tissue sampling, only about half of suspected cases show the typical histopathologic changes; often, however, patients with normal angi-

Figure 34-31. Granulomatous angiitis of the brain. Carotid angiogram, lateral projection, demonstrating numerous areas of irregular narrowing (arrows) and, in some areas, contiguous slight dilation ("beading"), particularly in the anterior cerebral artery.

ograms will have the typical findings on biopsy. As pointed out by Alrawi and colleagues, many patients prove to have an alternative condition, mainly an infectious encephalitis and brain or intravascular lymphoma, abscess, or Creutzfeldt-Jakob disease. Tissue excised during an operation (or brain biopsy) for a suspected brain tumor, lymphoma, or white matter disease has revealed the characteristic vasculitis in some cases; in others the diagnosis has been made only at autopsy, the findings coming as a distinct surprise.

The affected vessels are in the 100- to 500-mm range and are surrounded and infiltrated by lymphocytes, plasma cells, and other mononuclear cells; giant cells are distributed in small numbers in the media, adventitia, or perivascular connective tissue. Infarction of brain tissue can be traced to thrombosis. The meninges are variably infiltrated with inflammatory cells. Sometimes only a part of the brain has been affected—in one of our cases the cerebellum, in another, one frontal lobe and the opposite parietal lobe.

Among the most important considerations is the cerebral arteritis caused by varicella zoster virus, which can simulate in radiographic appearance granulomatous arteritis and giant cell arteritis (page 643). The viral form of arteritis follows or evolves in association with herpes zoster ophthalmicus. On occasion, intravascular lymphoma may present a similar picture.

The clinical and radiologic appearance of brain arteritis also raises the question of sarcoidosis, which is sometimes limited to the nervous system, of brain lymphoma or intravascular lymphoma, of CADASIL, multiple sclerosis, or of the polyarteritis (allergic granulomatous angiitis) described by Churg and Strauss. Unlike some of these diseases, however, the lungs and other organs are spared; there is no eosinophilia, increase in sedimentation rate or antineutrophil cytoplasmic antibodies (ANCA), or anemia. As mentioned, brain lymphoma of the intravascular type and multiple sclerosis are diagnostic considerations from both a clinical and a radiologic perspective.

Some patients with isolated central nervous system angiitis (those presenting as an aseptic meningitis with multiple infarcts) have responded to corticosteroid and cyclophosphamide therapy (Moore).

Takayasu Disease (Aortic Branch Disease, Occlusive Thromboangiopathy) This is a nonspecific arteritis involving mainly the aorta and the large arteries arising from its arch. It is similar in many ways to giant-cell arteritis except for its propensity to involve the proximal rather than the distal branches of the aorta. Most of the patients have been young Asian women, but there are scattered reports of similar cases from the United States, Latin America, and eastern Europe. The exact etiology has never been ascertained, but an autoimmune mechanism is suspected.

Constitutional symptoms such as malaise, fever, anorexia, weight loss, and night sweats usually introduce the disease. The erythrocyte sedimentation rate is elevated in the early and active stages. Later there is evidence of occlusion of the innominate, subclavian, carotid, vertebral, and other arteries. The affected arteries no longer pulsate, hence the descriptive term *pulseless disease*. However, it should be noted that in non-Asian individuals, the disease is usually due to atherosclerosis. When renal arteries are involved, hypertension may result, and there may be coronary occlusion, which is often fatal. Involvement of the pulmonary artery may lead to pulmonary hypertension. Coolness of the hands and weak radial pulses are common indicators of the disease and headaches are frequent. Blurring of vision, especially upon physical activity, dizziness, and hemiparetic and hemisensory syndromes are the usual neurologic manifestations (Lupi-Herrera et al). Several au-

thors have emphasized the frequency of posturally induced neurologic symptoms as well as the relative infrequency of major strokes, despite multiple TIA-like spells. The inflamed vessels in the thorax are well demonstrated in radionuclide scans using gallium.

Pathologic studies disclose a periarteritis, often with giant cells and reparative fibrosis. Many of the patients die in 3 to 5 years. According to Ishikawa and colleagues, the administration of corticosteroids in the acute inflammatory stage of the disease improves the prognosis. Reconstructive vascular surgery has helped some of the patients in the later stages of the disease.

Polyarteritis (Periarteritis) Nodosa In this disorder there is an inflammatory necrosis of arteries and arterioles throughout the body. The lungs are usually spared, however, which is the basis of distinguishing this form of vasculitis from the allergic granulomatous angiitis of Churg and Strauss, mentioned above. The vasa nervorum are frequently involved by the lesions of polyarteritis, giving rise to a mononeuropathy multiplex or to a symmetrical axonal type of polyneuropathy (see page 1137). Involvement of the CNS is unusual (occurring in fewer than 5 percent of cases) and takes the form of widespread microinfarcts; macroscopic infarction is a rarity. The clinical manifestations vary: included are headache, confusion and fluctuating cognitive disorders, convulsions, hemiplegia, and brainstem signs. We have also observed acute spinal cord lesions. The CNS lesions and brain hemorrhage are rare and usually occur in a setting of renal hypertension.

Wegener Granulomatosis This is a rare disease of unknown cause, affecting adults as a rule and favoring males slightly. A subacutely evolving vasculitis with necrotizing granulomas of the upper and lower respiratory tracts followed by necrotizing glomerulonephritis are its main features. Neurologic complications come later in one-third to one-half of cases and take two forms: (1) a peripheral neuropathy either in a pattern of polyneuropathy or, far more frequently, in a pattern of mononeuropathy multiplex (page 1138) and (2) multiple cranial neuropathies as a result of direct extension of the nasal and sinus granulomas into adjacent upper cranial nerves and from adjacent to pharyngeal lesions to the lower cranial nerves (see also page 1188). The basilar parts of the skull may be eroded, with spread of granuloma to the cranial cavity and more remote parts. Cerebrovascular events, seizures, and cerebritis are less common neurologic complications. Spastic paraparesis, temporal arteritis, Horner syndrome, and papilledema have been observed but are rare (see Nishino et al). The orbits are involved in 20 percent of patients, and lesions here simulate the clinical and radiologic appearance of orbital pseudotumor, cellulitis, or lymphoma. Pulmonary granulomas, usually asymptomatic but evident on a chest film, are also common. The vasculitis implicates both small arteries and veins. There is a fibrinoid necrosis of their walls and an infiltration by neutrophils and histiocytes. The sedimentation rate is elevated, as are the rheumatoid and antiglobulin factors. The presence in the blood of antineutrophil cytoplasmic antibodies (c-ANCA) has been found to be relatively specific and sensitive for Wegener disease but it may also be present in intravascular lymphoma.

A degree of therapeutic success in this formerly fatal disease has been achieved by the use of cyclophosphamide, chlorambucil, or azathioprine. Cyclophosphamide in oral doses of 1 to 2 mg/kg per day has cured 90 to 95 percent of the cases. In acute cases, rapidly acting steroids—prednisone, 50 to 75 mg/day—should be given in conjunction with the immunosuppressant drug(s).

Systemic Lupus Erythematosus Involvement of the nervous system is an important aspect of this disease. In the pathologic and clinical series reported by Johnson and Richardson, the CNS was affected in 75 percent of cases, but our recent experience has suggested a far lower frequency of clinical manifestations. Disturbances of mental function—including alteration of consciousness, seizures, and signs referable to cranial nerves—are the usual neurologic manifestations; most often they develop in the late stages of the disease, but they may occur early and may be mild and transient. Hemiparesis, paraparesis, aphasia, homonymous hemianopia, movement disorders (chorea), and derangements of hypothalamic function occur but have been infrequent in our experience. Larger infarcts are usually traceable to emboli from Libman-Sacks (nonbacterial thrombotic, marantic) endocarditis. In some instances the CNS manifestations resemble multiple sclerosis, especially when there is an optic neuritis and myelopathy. The presence of serum antinuclear antibodies is of help in the differentiation of lupus erythematosus but in itself does not establish the diagnosis. The CSF is entirely normal or shows only a mild lymphocytic pleocytosis and increase in protein content, although in some patients—primarily those with peripheral neuropathy and myelopathy—the protein content may be greatly increased.

Most of the neurologic manifestations can be accounted for by widespread microinfarcts in the cerebral cortex and brainstem; these, in turn, are related to destructive and proliferative changes in arterioles and capillaries. The acute lesion is subtle; it is not a typical fibrinoid necrosis of the vessel wall, like that in hypertensive encephalopathy, and there is no cellular infiltration. Attachment of immune complexes to the endothelium is the postulated mechanism of vascular injury. Thus, the changes do not represent a vasculitis in the strict sense of the word. Other neurologic manifestations are related to hypertension, which frequently accompanies the disease and may precipitate cerebral hemorrhage; to endocarditis, which may give rise to cerebral embolism; to thrombotic thrombocytopenic purpura, which commonly complicates the terminal phase of the disease (Devinsky et al); and to treatment with corticosteroids, which may precipitate or accentuate muscle weakness, seizures, and psychosis. In other cases, steroids appear to improve these neurologic manifestations. A similar set of neurologic problems arises in relation to the anti-phospholipid antibody syndrome, which may be a feature of lupus or arise independently (see page 735). It is not been entirely clear to us what proportion of the cerebrovascular features of lupus might be explained on the basis of the coagulation disorder.

Arteritis Symptomatic of Underlying Systemic Disease and Sympathomimetic Drug Reactions Both AIDS and drug abuse (mainly cocaine) have been associated with a cerebral vasculitis that is similar to polyarteritis nodosa. With respect to the former, if deep infarctions have occurred, a basal meningitis due to tuberculosis, cryptococcosis, or syphilis with occlusion of penetrating vessels must always be entertained. Drug-induced vasculitis is difficult to distinguish from a more common state of focal vasospasm that may also be induced by these same agents, as discussed earlier (page 730). Finally, a true cerebral or spinal cord vasculitis can rarely be found in association with systemic lymphoma, particularly with Hodgkin disease. The nature of this process is indeterminate but may be related to the deposition of circulating immune complexes in the walls of cerebral vessels.

The cerebrovascular problems consequent to cocaine use are quite varied. Seizures and death may occur as a result of a syn-

drome of delirium and extreme hyperthermia. More interesting are the strokes that arise during and just after cocaine use. Here, as emphasized by Levine and colleagues (1991), a clear distinction should be made between the complications of cocaine hydrochloride (the usual form of ingestible cocaine) and the alkaloid form, or “crack cocaine.” The former, when injected intravenously more so than when used intranasally, is prone to cause cerebral hemorrhage as a result of acute hypertension, similar to the bleeding that may be precipitated by other sympathomimetic drugs such as amphetamine and phenylpropanolamine. Both subarachnoid and intracerebral hemorrhage may result. Or, the features of hypertensive encephalopathy are precipitated, including changes in the posterior white matter of the cerebral hemispheres that are so striking on imaging studies. The strokes with crack cocaine, however, are more often ischemic, typically involving the territory of a large vessel. Some ambiguity attends the vasculopathy induced by crack cocaine, less often by cocaine hydrochloride, and by the amphetamines. There are undoubtedly instances of a true cerebral inflammatory vasculitis, perhaps of a hypersensitivity type such as those reported with biopsy verification by Krendel and colleagues and by Merkel and associates and others. What is confusing about these cases is the normal angiographic appearance in many instances and large-vessel occlusions in others, in contrast to the pathologic changes, which are concentrated in small cortical vessels. Furthermore, many cases seem to be of an entirely different type, displaying long segments of vascular attenuation in the angiogram and no evidence of an inflammatory process in biopsy or autopsy material. The correct treatment, aside from lowering the blood pressure, is uncertain.

Crack cocaine may also cause a choreiform disorder (“crack dancing”), not unlike that associated with antiphospholipid antibody but generalized rather than focal (see further on); usually there are small infarctions in the basal ganglia, but an immune mechanism has also been suggested.

Another type of small-vessel arteritis occurs as a hypersensitivity phenomenon. Often it is associated with an allergic skin lesion (Stevens-Johnson vasculopathy or a leukocytoclastic vasculitis). The clinical picture does not resemble that of polyarteritis nodosa, but the central or peripheral nervous system is affected in rare instances. The response to corticosteroids is excellent.

Yet another ill-defined form of vasculitis has been described by Susac and colleagues (Susac syndrome). This is a microangiopathy affecting mainly the brain and retina. Psychiatric symptoms, dementia, sensorineural deafness, and impairments of vision are the clinical manifestations. Funduscopic (multiple retinal artery branch occlusions) and arteriography manifest evidence of the vasculopathy. The patients seem to respond to steroid therapy. Only biopsy material has been examined.

Mixed essential cryoglobulinemia, a vasculitic disorder that more often affects the peripheral than the central nervous system, may nonetheless produce an encephalopathy.

Behget Disease This disorder may suitably be considered here, since it is essentially a chronic, recurrent vasculitis, involving small vessels, with prominent neurologic manifestations. It is most common in Turkey, where it was first described, in other Near Eastern countries, and in Japan, but it occurs throughout Europe and North America, affecting men more often than women. The disease was originally distinguished by the triad of relapsing iridocyclitis and recurrent oral and genital ulcers, but it is now recognized to be a systemic disease with a much wider range of symptoms, including

erythema nodosum, thrombophlebitis, polyarthritis, ulcerative colitis, and a number of neurologic manifestations, some of them encephalitic or meningitic in nature. The most reliable diagnostic criteria, according to the International Study Group that assembled data on 914 cases from 12 medical centers in 7 countries, were recurrent aphthous or herpetiform oral ulceration, recurrent genital ulceration, anterior or posterior uveitis, cells in the vitreous or retinal vasculitis, and erythema nodosum or papulopustular lesions.

The nervous system is affected in about 30 percent of patients with Behçet disease (Chajek and Fainaru); the manifestations are: recurrent meningoencephalitis, cranial nerve (particularly abducens) palsies, cerebellar ataxia, and corticospinal tract signs. There may be episodes of diencephalic and brainstem dysfunction resembling minor strokes. A few postmortem examinations have related these small foci of necrosis to a vasculitis, including perivascular and meningeal infiltration of lymphocytes. There may also be cerebral venous thrombosis. The neurologic symptoms usually have an abrupt onset and are accompanied by a brisk spinal fluid pleocytosis (lymphocytes or neutrophils may predominate), along with elevated protein but normal glucose values (in one of our patients, 3000 neutrophils per cubic millimeter were found at the onset of an acute meningitis). As a rule, neurologic symptoms clear completely in several weeks, but they have a tendency to recur, and some patients are left with persistent neurologic deficits. Rarely, the clinical picture is that of a progressive confusional state or dementia (see the reviews of Alema and of Lehner and Barnes for detailed accounts).

The cause of Behçet disease is unknown. We have been unable to detect virus particles in the margins of an ulcerative mouth lesion. A pathergy skin test—the formation of a sterile pustule at the site of a needle prick—is listed as an important diagnostic test by the International Study Group, but on the basis of admittedly limited U.S. experience, we and our colleagues have found it to be of questionable value. Administration of corticosteroids has been the usual treatment, on the assumption of an autoimmune etiology. Since the episodes of disease naturally subside and recur, evaluation of treatment is difficult.

THROMBOSIS OF CEREBRAL VEINS AND VENOUS SINUSES

Thrombosis of the cerebral venous sinuses, particularly of the superior sagittal or lateral sinus and the tributary cortical and deep veins, gives rise to a number of important neurologic syndromes. Cerebral vein thrombosis may develop in relation to infections of the adjacent ear and paranasal sinuses or to bacterial meningitis, as described in Chap. 32. More common is noninfectious venous occlusion resulting from one of the many hypercoagulable states discussed below.

Occlusion of cortical veins that are the tributaries of the dural sinuses takes the form of a venous infarctive stroke. The diagnosis is difficult except in certain clinical settings known to favor the occurrence of venous thrombosis, such as the taking of birth control pills or postpartum and postoperative states, which are often characterized by thrombocytosis and hyperfibrinogenemia. Hypercoagulable conditions also occur in cancer (particularly of the pancreas and other abdominal organs), cyanotic congenital heart disease; cachexia in infants; sickle cell disease; antiphospholipid antibody syndrome, the aforementioned Behçet disease, factor V Leiden mutation, protein S or C deficiency, antithrombin III deficiency, resistance to activated protein C; primary or secondary

polycythemia and thrombocythemia; and paroxysmal nocturnal hemoglobinuria. The study by Martinelli and colleagues, mentioned earlier in the chapter, attributed 35 percent of cases of cerebral vein thrombosis to a mutation in the factor V or the prothrombin gene. Averback, who reported seven cases of venous thrombosis in young adults, has emphasized the diversity of the clinical causes. Two of his patients had carcinoma of the breast and one had ulcerative colitis. A few cases will follow head injury or remain unexplained.

A stroke in a patient suffering from any one of these systemic conditions should suggest venous thrombosis, though in some instances—e.g., postpartum strokes—arteries are occluded as often as veins. The somewhat slower evolution of the clinical stroke syndrome, the presence of multiple cerebral lesions not in typical arterial territories, and its greater epileptogenic and hemorrhagic tendency favor venous over arterial thrombosis.

Superficial Thrombosis of Cortical Veins Certain syndromes occur with sufficient regularity that they suggest thrombosis of a particular vein or sinus. The signature features of isolated *thrombosis of superficial cortical veins* are the presence of large superficial (cortex and subjacent white matter) hemorrhagic infarctions and a marked tendency to partial seizures. Hemiparesis, incomplete hemianopia, and aphasia, any of which may fluctuate over days, are also characteristic according to Jacobs and colleagues. These variable syndromes reflect the inconstant location of the main surface veins. Thrombosis of the vein of Labbé causes infarction of the underlying superior temporal lobe, and occlusion of the vein of Trolard implicates the parietal cortex. Quite often, in our experience, the focal deficit worsens immediately after a partial seizure. The intracranial pressure is not elevated, as it is when the dural venous sinuses are occluded. The diagnosis is now made by careful examination of the MR venogram or by the venous phase of the conventional angiogram. Cortical vein thrombosis should be suspected in the situation of multiple hemorrhagic infarctions in one hemisphere without a source of embolism or atherothrombosis.

Dural Sinus Thrombosis

Sagittal and Lateral Sinus Thrombosis In the case of *sagittal sinus thrombosis*, intracranial hypertension with headache, vomiting, and papilledema may constitute the entire syndrome (this is the main consideration in the differential diagnosis of pseudotumor cerebri, Chap. 30) or it may be conjoined with hemorrhagic infarction. Paraparesis, hemiparesis, fluctuating unilateral or bilateral sensory symptoms, or aphasia result only if the thrombosis propagates to surface veins. Focal or odd sensory or motor seizures occur on the same basis but are not as common as with cortical vein thrombosis.

The common radiologic picture that results from occlusion of the superior sagittal sinus is of bilateral superficial paramedian parietal or frontal hemorrhagic infarction or edematous venous congestion. In the case of CT scan with contrast infusion, a lack of dye opacification in the posterior sagittal sinus can be observed with careful adjustment of the viewing window ("empty delta sign"). The spinal fluid pressure is increased and the fluid may be slightly sanguinous. Lateral sinus thrombosis causes hemorrhagic infarction of the temporal lobe convexity, usually with considerable vasogenic edema. The enhanced CT scan, arteriography (venous phase), and MR venography greatly facilitate diagnosis by directly visualizing the venous occlusion. Once a venous thrombosis be-

comes established, the tributary surface veins take on a “corkscrew” appearance that is appreciated on the venous phase of an angiogram.

Cavernous Sinus Thrombosis As pointed out in Chaps. 13 and 14, in cases of *anterior cavernous sinus thrombosis* there is marked chemosis and proptosis—with disorders referable to cranial nerves III, IV, VI, and the ophthalmic division of V (Fig. 34-32). *Posterior cavernous sinus thrombosis*, spreading to the inferior petrosal sinus, may cause palsies of cranial nerves VI, IX, X, and XI without proptosis, and involvement of the *superior petrosal sinus* may be accompanied by a fifth nerve palsy. Increased intracranial pressure without ventricular dilatation occurs with thrombosis of the superior sagittal sinus, the main jugular vein, and the lateral sinus or torcula.

Thrombosis of the venous sinuses in neonates presents special problems in diagnosis. In the series of deVeber et al, various perinatal complications, including systemic illness such as severe dehydration or infection, were the common precedents; the outcome was poor. In young children the risk factors differed in that connective tissue and prothrombotic disorders and head and neck infections were more common.

Deep Cerebral Vein Thrombosis Occlusion of the vein of Galen and of the internal cerebral veins is the rarest and clinically most obscure of the venous syndromes. From the few cases that have been studied, a picture of bithalamic infarction emerges, often reversible, and consisting mainly of inattention, spatial neglect, and amnesia in the case reported by Benabdeljili and colleagues and of akinetic mutism and apathy in the case of Gladstone and associates. In most reports of this condition, it is the neuropsychological aspects that are emphasized. The MRI is striking, with a large bicircular region of signal change that encompasses the thalamus. Much of the signal change probably represents reversible edema and venous congestion, since substantial clinical improvement may occur.

Treatment of Cerebral Venous Thrombosis Anticoagulant therapy beginning with heparin for several days, followed by warfarin, and combined with antibiotics if the venous occlusion is infectious (it rarely is in recent times) has been lifesaving in some cases. Nonetheless, the overall mortality rate remains high, with large hemorrhagic venous infarctions found in 10 to 20 percent of cases. The clinical trial conducted by Einhaupl and colleagues has settled the question of therapy in favor of aggressive anticoagulation.

Thrombolytic therapy by local venous or systemic infusion has also been successful in small series of cases, such as the 5 patients treated with urokinase and heparin by DiRocco and colleagues. However, this approach has not been subjected to a systematic study. We have reserved thrombolysis for extreme cases of dural sinus thrombosis with stupor or coma and greatly raised CSF pressure. This subject is reviewed by Benamer and Bone, who conclude that warfarin anticoagulation should be reserved for patients who deteriorate despite treatment with heparin. Most treated patients do well, but it may take weeks for the headaches to remit. Coma and multiple cerebral hemorrhages, on the other hand, are usually fatal.

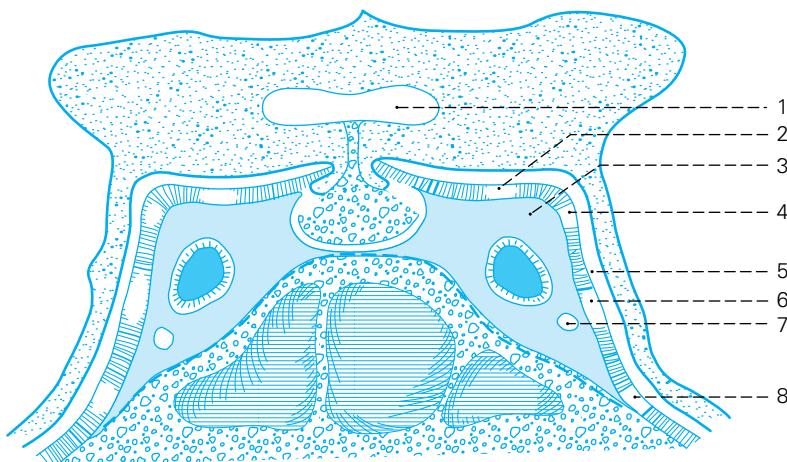

Figure 34-32. Diagram of the cavernous sinus: (1) optic chiasm; (2) oculomotor nerve; (3) cavernous sinus; (4) trochlear nerve; (5) internal carotid artery; (6) ophthalmic nerve; (7) abducens nerve; (8) maxillary nerve. (Reproduced by permission from Krayenbühl and Yasargil.)

Nonbacterial Thrombotic (Marantic) Endocarditis and Cerebral Embolism

Sterile vegetations, referred to also as *nonbacterial thrombotic endocarditis*, consist of fibrin and platelets and are loosely attached to the mitral and aortic valves and contiguous endocardium. They are a common source of cerebral embolism (almost 10 percent of all instances of cerebral embolism according to Barron et al, but lower in the experience of others). In almost half the patients, the vegetations are associated with a malignant neoplasm; the remainder occurs in patients debilitated by other diseases (Biller et al). Except for the setting in which it occurs, marantic embolism has no distinctive clinical features that permit differentiation from cerebral embolism of other types other than that it is often the cause of sequential strokes over days or weeks. The apoplectic nature of marantic embolism distinguishes it from the usual forms of tumor metastases. The hazards of using anticoagulants in gravely ill patients with widespread malignant disease probably outweigh the benefits from this treatment, but drugs that prevent platelet aggregation, while possibly helpful, have not been studied systematically for this condition.

The lesions of small cerebral arteries formerly observed in patients with rheumatic heart disease and referred to as *rheumatic arteritis* have not been well characterized clinically or pathologically. The vascular lesions and the microinfarcts that accompany them are probably manifestations of diffuse cerebral embolism. There is probably no relationship to the lesion of Sydenham chorea.

Stroke as a Complication of Hematologic Disease

The brain is involved in the course of many hematologic disorders, some of which have already been mentioned. A number of the better-characterized ones are discussed here.

Antiphospholipid Antibody Syndrome This condition, in which TIAs, or stroke, migraine, and thrombocytopenia in various combinations, occurs in young adults, has already been mentioned under “*Strokes in Children and Young Adults*.” The related term

lupus anticoagulant is not ideal, since most patients with the anticoagulant do not have lupus and the antibody has a procoagulant, not anticoagulant, property *in vivo*. Nonetheless, the main laboratory feature of the illness is a prolonged partial thromboplastin time. Further testing for antiphospholipid antibody consists of detection of both lupus anticoagulant and anticardiolipin antibody; there is a partial overlap between these—80 percent of patients with lupus anticoagulant have anticardiolipin antibody but fewer than 50 percent of those with anticardiolipin antibody have lupus anticoagulant. The principal antigen involved is in fact not phospholipid but β_2 -glycoprotein 1, a protein that binds to phospholipid. The titer of antibody correlates with the risk of thrombosis and smoking; pregnancy and the use of oral contraceptives raise the risk further. There may be an increased incidence of migraine but this has been disputed.

The most frequent neurologic abnormality is a TIA, usually taking the form of amaurosis fugax (transient monocular blindness), with or without retinal arteriolar or venous occlusion (Digre et al). Stroke-like phenomena are more frequent in patients who also have migraine, hyperlipidemia, and antinuclear antibodies and in those who smoke or take birth control pills. Almost one-third of the 48 patients reported by Levine and associates had thrombocytopenia and 23 percent had a false-positive VDRL test. Some of the phospholipids with which the antibodies react are shared with clotting factors, particularly prothrombin and annexin, as well as with the “lupus anticoagulant” (a cardiolipin-glycoprotein complex). These antibodies are circulating serum polyclonal immunoglobulins (IgG, IgM, IgA). The vascular lesions are mainly in the cerebral white matter and are infarcts, seen well with MRI. Angiography reveals occlusions of arteries at unusual sites (Brey et al). The mechanism of stroke is not entirely clear and may derive from emboli originating on mitral valve leaflets similar to nonbacterial thrombotic endocarditis; alternatively, and more likely in our view, there is a noninflammatory *in situ* thrombosis of medium-sized cerebral vessels, as suggested by the limited pathologic material studied by Briley and colleagues.

These circulating antibodies may also cause a syndrome of transient bilateral choreal or hemichorea; some patients have an additional slight hemiparesis or other subtle focal signs. Almost all of the affected patients we have seen have been women with thrombocytopenia, some of whom probably had systemic lupus, at least on the grounds of laboratory studies (see Cevera et al). A direct connection of the choreic syndrome to the antibodies, comparable to what is proposed in Sydenham chorea, may be valid but at the moment is unproven. Some cases display microinfarctions in the basal ganglia, perhaps on the basis of valvular vegetations. The syndrome may be precipitated in these patients by the introduction of estrogen-containing birth control pills and is improved, usually promptly, by corticosteroids or antiplatelet agents.

The *Sneddon syndrome* consists of deep blue-red lesions of livedo reticularis and livedo racemosa in association with multiple strokes; 126 cases had been reported up to 1992. Most but not all patients have high titers of antiphospholipid antibodies. Although the skin lesions show a noninflammatory vasculopathy with intimal thickening, the pathology of the occlusive disease has not been adequately studied. In a report of 17 such patients by Stockhammer and coworkers, 8 had strokes and MRI showed lesions in 16 of 17 patients. The age of patients with strokes was 30 to 35 years, hence this condition must always be considered in young adults with cerebrovascular disease. Many of the lesions on MRI were small, deep, and multiple. Although there is a tendency for strokes to recur,

many of the patients have remained well for years after a single stroke. Skin biopsy aids in diagnosis.

There are instances in which the radiologic changes caused by recurrent small infarctions are difficult to distinguish from multiple sclerosis, as discussed in several parts of Chap. 36, on demyelinating diseases. Associations of the syndrome with transverse myelitis, Guillain-Barré syndrome, hearing loss, and a number of other processes has been suspected but not proven.

Treatment Warfarin has been used with some benefit in the above conditions. Khamashta and colleagues have found that the INR must be maintained close to 3 for effective prevention of stroke. According to the study conducted by Crowther and colleagues, an INR of 2 to 3 conferred the same degree of protection from thrombosis as did higher levels, but the number of thrombotic events was low in both groups and there was only one stroke in 114 patients over a period of about 3 years. Patients with severe thrombocytopenia and with other intrinsic coagulopathies should be treated with warfarin very cautiously. Although the INR is used as a gauge of the level of anticoagulation, it may be altered by the antibodies; no ideal method for monitoring treatment has been devised. Aspirin, on uncertain grounds, is thought not to confer protection for stroke, but in only a few small series has its effect been analyzed. In “catastrophic” cases, intravenous immunoglobulin and plasma exchange have been used with some effect.

It is most important to eliminate smoking and estrogen-containing compounds, since these greatly raise the risk of stroke. Plasma exchange may be useful in fulminant cases. Aspirin and heparin are favored in women with recurrent fetal loss related to antiphospholipid antibody (Lockshin and Sammaritano).

Thrombotic Thrombocytopenic Purpura (TTP, Moschcowitz Syndrome) This is yet another uncommon but serious disease of the small blood vessels, observed mainly in young adults. It is characterized pathologically by widespread occlusions of arterioles and capillaries involving practically all organs of the body, including the brain, as described by Adams and colleagues (1948). The nature of the occluding material has not been completely defined. Fibrin components have been identified by immunofluorescent techniques; some investigators have demonstrated disseminated intravascular platelet aggregation rather than fibrin thrombi. TTP is caused by an acquired circulating IgG inhibitor of von Willebrand factor—cleaving protease; a rarer familial form is caused by a constitutional deficiency of the protease.

Clinically, the main features of this disease are fever, anemia, symptoms of renal and hepatic disease, and thrombocytopenia—the latter giving rise to the common hemorrhagic manifestations (petechiae and ecchymoses of the skin, retinal hemorrhages, hematuria, gastrointestinal bleeding, etc.). Neurologic symptoms are practically always present and are the initial manifestation of the disease in about half the cases. Confusion, delirium, seizures, and hemiparesis—sometimes remittent or fluctuating in nature—are the usual manifestations of the nervous system disorder and are readily explained by the widespread microscopic ischemic lesions in the brain. Garrett and colleagues have emphasized the presentation of nonconvulsive status epilepticus in TTP, and we have encountered two such cases. Gross infarction was not observed. In most patients who survive, recovery of the focal neurologic deficits can be expected unless there is an identifiable infarction on CT or MRI. The CSF is normal except for elevated protein in some cases. To our knowledge, a mononeuritis multiplex does not occur. The recommended treatment is plasma exchange or plasma infusion.

Thrombocytosis and Thrombocythemia These terms refer to an increase of platelets above 800,000/mm³. The condition is generally considered to be a form of myeloproliferative disease. In some patients there is an enlarged spleen, polycythemia, chronic myelogenous leukemia, or myelosclerosis. In several of our patients no explanation of the thrombocytosis was found. They presented with recurrent cerebral and systemic thrombotic episodes, often of minor degree and transient. Cytopheresis, to reduce the platelets, and antimitotic drugs (hydroxyurea) to suppress megakaryocyte formation, are helpful in ameliorating the neurologic symptoms. In one of the cases we have followed, several small lesions, presumably infarctions, were situated in the white matter and simulated multiple sclerosis.

Polycythemia Vera This is another myeloproliferative disorder of unknown cause, characterized by a marked increase in RBC mass and in blood volume and often by an increase in WBCs and platelets as well. This condition must be distinguished from the many secondary or symptomatic forms of polycythemia (erythrocytosis), in which the platelets and white cells remain normal. The slightly increased incidence of thrombosis in primary polycythemia is attributed to the high blood viscosity, engorgement of vessels, and reduced rate of blood flow. The majority of patients with cerebrovascular manifestations have TIAs and small strokes, but we have seen one case of sagittal sinus thrombosis. With very high hematocrit, sludging of red cells may be seen in the retinal vessels. The cause of cerebral hemorrhage in this disease is less clear, although a number of abnormalities of platelet function and of coagulation have been described (see Davies-Jones et al).

A wide variety of bleeding disorders—such as *leukemia*, *aplastic anemia*, *thrombocytopenic purpura*, and *hemophilia*—may also give rise to cerebral hemorrhage. Many rare forms of bleeding disease may be complicated by hemorrhagic manifestations; these have been reviewed by Davies-Jones and colleagues.

Sickle Cell Disease This inherited disease is related to the presence of the abnormal hemoglobin S in the red corpuscles. Clinical abnormalities occur only in patients with sickle cell disease—i.e., with the homozygous state, and not in those with the sickle cell trait, which represents the heterozygous state. The disease, which is practically limited to persons of central African and certain Mediterranean origins, begins early in life and is characterized by “crises” of infection (particularly pneumococcal meningitis), pain in the limbs and abdomen, chronic leg ulcers, and infarctions of bones and visceral organs. Ischemic lesions of the brain, both large and small, are the most common neurologic complications, but cerebral, subarachnoid, and subdural hemorrhage may also occur and the vascular occlusions may be either arterial or venous.

Disseminated Intravascular Coagulation (DIC) This is perhaps the commonest and most serious disorder of coagulation affecting the nervous system. The basic process depends on the release of thromboplastin substances from damaged tissue, resulting in the activation of the coagulation process and the formation of fibrin, in the course of which clotting factors and platelets are consumed. Virtually any mechanism that produces tissue damage can result in the release of tissue thromboplastins into the circulation. Thus, DIC complicates a wide variety of clinical conditions—overwhelming sepsis, massive trauma, cardiothoracic surgery, heat stroke, burns, incompatible blood transfusions and other immune complex disorders, diabetic ketoacidosis, leukemia, obstetric com-

plications, cyanotic congenital heart disease, and shock from many causes.

The essential pathologic change in DIC is the occurrence of widespread fibrin thrombi in small vessels, resulting in numerous small infarctions of many organs, including the brain. Sometimes DIC is manifest by a hemorrhagic diathesis in which petechial hemorrhages are situated around small penetrating vessels. In some cases cerebral hemorrhage is quite extensive, similar to a primary hypertensive hemorrhage. The main reason for the hemorrhage is the consumption of platelets and various clotting factors that occurs during fibrin formation; in addition, fibrin degradation products have anticoagulant properties of their own.

The diffuse nature of the neurologic damage may suggest a metabolic rather than a vascular disorder of the brain. In the absence of a clear metabolic, infective, or neoplastic cause of an encephalopathy, the onset of acute and fluctuating focal neurologic abnormalities or a generalized and sometimes terminal neurologic deterioration during the course of a severe illness should arouse suspicion of DIC, and coagulation factors and fibrin split products should be measured. Platelet counts are invariably depressed and there is evidence of consumption of fibrinogen and other clotting factors, indicated by prolonged prothrombin and partial thromboplastin times.

In the related illness abbreviated as HELLP mentioned previously, women with eclampsia develop liver failure and thrombocytopenia; the contribution of this limited form of DIC to the eclamptic effects on the nervous system have not been established (see earlier discussion of eclampsia).

DIFFERENTIATION OF VASCULAR DISEASE FROM OTHER NEUROLOGIC ILLNESSES

The diagnosis of a vascular lesion rests essentially on recognition of the stroke syndrome; without evidence of this, the diagnosis must always be in doubt. The three criteria by which the stroke is identified should be re-emphasized: (1) the temporal profile of the clinical syndrome, (2) evidence of focal brain disease, and (3) the clinical setting. Definition of the temporal profile requires a clear history of the premonitory phenomena, the mode of onset, and the evolution of the neurologic disturbance in relation to the patient's medical status. Here, an inadequate history is the most frequent cause of diagnostic error. If these data are lacking, the stroke profile may still be determined by extending the period of observation for a few days or weeks, thus invoking the clinical rule that the physician's best diagnostic tool is a second and third examination.

There are few categories of neurologic disease whose temporal profile mimics that of the cerebrovascular disorders. Migraine may do so, but the history usually provides the diagnosis. A seizure may be followed by a prolonged focal deficit (Todd's paralysis) but is rarely the initial event in a stroke; the setting in which these symptoms occur and their subsequent course clarify the clinical situation. Stroke-like episodes appear in the course of certain hereditary metabolic disorders (Fabry disease, homocystinuria, mitochondrial disease). Differentiation is not difficult because of the associated myopathic and neurologic signs and characteristic metabolic defects. Tumor, infection, inflammation, degeneration, and nutritional deficiency are not likely to manifest themselves precipitously, although rarely a brain metastasis produces a focal deficit of abrupt onset (see below). Trauma, of course,

occurs abruptly but usually offers no problem in diagnosis. In multiple sclerosis and other demyelinative diseases, there may be an abrupt onset or exacerbation of symptoms, but for the most part they occur in a different age group and clinical setting. Conversely, a stroke-like onset of cerebral symptoms in a young adult should always raise a suspicion of demyelinative disease. A stroke developing over a period of several days usually progresses in a stepwise fashion, increments of deficit being added abruptly from time to time. A slow, gradual, downhill course over a period of 2 weeks or more indicates that the lesion is probably not vascular but rather neoplastic, demyelinative, infectious (abscess) or granulomatous, or a subdural hematoma.

In regard to the *focal neurologic deficits* of cerebrovascular disease, many of the nonvascular diseases may produce symptoms that are much the same, and the diagnosis cannot rest solely on this aspect of the clinical picture. Nonetheless, certain combinations of neurologic signs, if they conform to a neurovascular pattern—e.g., the lateral medullary syndrome—mark the disease as vascular-occlusive in nature.

Many thrombotic strokes are preceded by TIAs, which, if recognized, are diagnostic of this form of vascular disease. It is essential that TIAs be differentiated from seizures, syncope, panic attacks, neurologic migraine, and attacks of labyrinthine vertigo, since a failure to do so may result in unnecessary arteriographic studies and even a surgical operation.

With very few exceptions, the presence of *blood in the CSF* points to a cerebrovascular (rarely spinal vascular) lesion provided that trauma and a *traumatic tap* can be excluded. *Headache* is common in cerebrovascular disease; it occurs not only with hemorrhage but also with thrombosis, arterial dissections, and rarely with embolism. Seizures are almost never the premonitory, first, or only manifestation of a stroke but can rarely occur in the first few hours after infarction or intracranial bleeding. *Brief unconsciousness* (5 to 10 min) is rare in stroke, being seen only with basilar artery insufficiency and as an initial event in ruptured aneurysm or primary intracerebral hemorrhage. In the latter case, a depression in the state of consciousness soon reasserts itself and is then progressive. Certain neurologic disturbances are hardly ever attributable to stroke—e.g., diabetes insipidus, fever, bitemporal hemianopia, parkinsonism, generalized myoclonus, repeated falls, and isolated cranial nerve palsies—and their presence may be of help in excluding vascular disease.

Finally, the diagnosis of cerebrovascular disease should always be made on positive data, not by exclusion.

A few conditions are so often confused with cerebrovascular diseases that they merit further consideration. When a history of trauma is absent, the headache, drowsiness, mild confusion, and hemiparesis of subdural hematoma may be ascribed to a “small stroke,” and the patient may fail to receive immediate surgical therapy. In subdural hematoma, the symptoms and signs usually develop gradually over a period of days or weeks. The degree of headache, obtundation, and confusion is disproportionately greater than the focal neurologic deficit, which tends to be indefinite and variable until late in the evolution of the hematoma. If the patient has fallen and injured his head at the onset of the stroke, it may be impossible to rule out a complicating subdural hematoma on clinical grounds alone, in which case CT scanning and MRI are usually diagnostic. The reverse diagnostic error will not be made if one remembers that patients with subdural hematoma rarely exhibit a total hemiplegia, monoplegia, hemianesthesia, homonymous hemianopia, or aphasia. If such focal signs are present and particularly

if they developed suddenly, subdural hematoma is not likely to be the explanation.

A brain tumor, especially a rapidly growing glioblastoma multiforme or lymphoma, may produce a severe hemiplegia within a week or two. Also, the neurologic deficit due to carcinoma metastatic to the cerebrum may evolve rapidly, almost at a stroke-like pace. Moreover, in rare cases, the hemiplegia may be preceded by transitory episodes of neurologic deficit, indistinguishable from TIAs. However, in both conditions, a detailed history will indicate that the evolution of symptoms was gradual; if it was saltatory, seizures will usually have occurred. The chest film frequently discloses a primary or secondary tumor, and an increased blood sedimentation rate suggests that a concealed systemic disease process is at hand. A lack of detailed history may also be responsible for the opposite diagnostic error, i.e., mistaking a relatively slowly evolving stroke (usually due to internal carotid artery or basilar occlusion) for a tumor. Again, CT scanning and MRI will usually settle the problem. A brain abscess or inflammatory necrotic lesion—e.g., herpes encephalitis or toxoplasmosis—may also develop rapidly.

Dementia of the Alzheimer type is often ascribed, on insufficient and conceptually incorrect grounds, to the occurrence of multiple small strokes. If vascular lesions are responsible, evidence of an apoplectic episode or episodes and of focal neurologic deficit to account for at least part of the syndrome will almost invariably be disclosed by history and examination. In the absence of a history of episodic development or of focal neurologic signs, it is unwarranted to attribute senile dementia to cerebrovascular disease—in particular to small strokes in silent areas. *Cerebral arteriosclerosis* is another term that has often been used carelessly to explain such mental changes, the implication (incorrect) being that arteriosclerosis itself causes ischemic damage to the nervous system, producing loss of intellectual function but no other neurologic deficit. If cerebral arteriosclerosis (atherosclerosis) is actually responsible, there should be evidence of it in the form of strokes at some time in the course of the illness and often in the heart (myocardial infarction, angina pectoris) or legs (intermittent claudication, loss of pulses). Frequently the lesions of both vascular and Alzheimer disease are present, in which case there may be difficulty in determining to what extent each of them is responsible for the neurologic deficit. Several studies have shown an increased incidence or an acceleration of Alzheimer dementia if there are concurrent vascular lesions, but further studies are needed to confirm this notion.

Recurrent seizures as the result of a previous stroke occur in up to 10 percent of cases (*postinfarction epilepsy*, page 740). When evidence, by history or examination, of the original stroke is lacking, as it often is, or if the seizures are not observed or leave behind a temporary increase in the neurologic deficit (Todd's paralysis), the diagnosis of another stroke or a tumor may be made in error.

Miscellaneous conditions occasionally taken to be a stroke are Bell's palsy; Stokes-Adams attacks; a severe attack of labyrinthine vertigo; diabetic ophthalmoplegia; acute ulnar, radial, or peroneal palsy; embolism to a limb; and temporal arteritis associated with blindness.

Contrariwise, certain manifestations of stroke may be incorrectly interpreted as evidence of some other neurologic disorder. In lateral medullary infarction, *dysphagia* may be the outstanding feature; if the syndrome is not kept in mind, a fruitless radiologic search for a local esophageal or pharyngeal cause may be undertaken. Similarly, *facial pain or a burning sensation* due to involvement of the trigeminal spinal nucleus in lateral medullary stroke may be misattributed to sinus disease. *Headache*, at times severe,

often occurs as a prodrome of a thrombotic stroke or subarachnoid hemorrhage; unless this is appreciated, a diagnosis of migraine may be made. *Dizzy spells, vertigo, vomiting, or brief intermittent lapses of equilibrium due to vascular disease of the brainstem* may be ascribed to vestibular neuritis, Ménière disease, Stokes-Adams syncope, or gastroenteritis. A detailed account of the attack will usually avert this error. A strikingly focal monoplegia of cerebral origin, causing only weakness of the hand or arm or foot drop, is not infrequently misdiagnosed as a peripheral neuropathy.

In the presence of coma, the differentiation of vascular from other neurologic diseases offers special problems. If the patient is comatose when first seen and an adequate history is not available, cerebrovascular lesions must be differentiated from all the other causes of coma described in Chap. 17 and commented on below.

COMMON CLINICAL PROBLEMS IN CEREBROVASCULAR DISEASE

Inevitably, most patients are seen first by clinicians who may not be expert in all the fine points of cerebrovascular disease. Situations arise in which critical decisions must be made regarding anticoagulation, further laboratory investigation, and the advice and prognosis to be given to the family. The following are some of the situations encountered by the authors that may be of value to students and residents and to nonspecialists in the field.

The Patient with a History of an Ischemic Attack or Small Stroke in the Past The patient may be functioning normally when examined, but it has been ascertained by the history or radiologic procedures that a stroke or TIA occurred in the past. The problem is what measures should be taken to reduce the risk of further strokes. This is particularly problematic if a surgical procedure is planned. A brief focal TIA, several minutes or less in duration, or many stereotyped spells usually represent severe stenosis of the internal carotid artery on the side of the affected cerebral hemisphere. If the symptoms have occurred recently, these may be forerunners of complete occlusion. If the TIA was far in the past—more than several weeks previously—the immediate risks of occlusion are reduced. The initial approach is to establish the patency of the carotid arteries by ultrasound or MRA. If there is a reduction in diameter of greater than 70 percent when compared with an adjacent normal segment of vessel, and probably if there is a severely ulcerated but not critically stenotic plaque, carotid surgery (or angioplasty) is advisable. If a single TIA lasted more than an hour or the neurologic examination discloses minor signs referable to the region of the hemisphere affected by the TIA, a search for a source of embolus is indicated. Appropriate diagnostic studies include ECG, a transesophageal echocardiogram, monitoring for cardiac arrhythmia, ultrasound of the carotid arteries, and a CT scan or MRI if it has not already been performed. Preventive anticoagulation (warfarin) is instituted if a source of clot within the cardiac chambers is found or if there is atrial fibrillation. Aspirin is appropriate but not imperative if no abnormality is found. Control of elevated blood pressure and addressing high cholesterol levels are ancillary steps. The mistake is to ignore the potential significance of a small stroke or TIA.

The Patient with Atrial Fibrillation In patients with this arrhythmia who are over age 65 and in those of any age with valvular disease, anticoagulation with warfarin is virtually mandated unless

there is excessive risk due to falling or hematologic disease. Patients below approximately age 65 who are “lone fibrillators” (have no other cardiac or systemic disease) need not receive anticoagulation unless there has been a previous embolism. Whether younger patients who have additional vascular risk factors, such as diabetes or hypertension, benefit from anticoagulation is not known. If warfarin is to be discontinued for a necessary surgical procedure, it should be reinstated as soon as the surgeon deems it safe, since this is a time of increased stroke vulnerability. It has been the sense of many cardiologists that intermittent atrial fibrillation and fibrillation-flutter tachycardias also represent a risk of cerebral embolism, but there are no adequate studies to confirm this.

The Patient with a Recent Stroke That May Not Be Complete

Here the basic problem is whether a thrombotic infarction (venous or arterial) will spread and involve more brain tissue; or if embolic, whether the ischemic tissue will become hemorrhagic or another embolus will occur; or if there is an arterial dissection, whether it will give rise to emboli. Therapies are controversial in most of these circumstances. In some centers it is the practice to try to prevent propagation of a thrombus by administering heparin (or low-molecular-weight heparin) followed by warfarin, as discussed earlier. Thrombolytic agents are an alternative if the stroke has occurred within the previous 2 or 3 h and is not too large. Except perhaps in cases of recent myocardial infarction, atrial fibrillation, or carotid disease, it is not imperative to begin heparin immediately while awaiting the effects of warfarin.

The Inevident or Misconstrued Syndromes of Cerebrovascular Disease Although hemiplegia is the classic type of stroke, cerebrovascular disease may manifest itself by signs that spare the motor pathways but have the same serious diagnostic and therapeutic implications. The following stroke syndromes tend to be overlooked.

Sometimes disregarded is a leaking aneurysm presenting as a sudden and intense generalized headache lasting hours or days and unlike any headache in the past. Examination may disclose no abnormality except for a slightly stiff neck and raised blood pressure. Failure to investigate such a case by imaging procedures and examination of the CSF may permit the occurrence of a later massive subarachnoid hemorrhage. Small cerebral hemorrhages, subdural hematomas, or brain tumors figure into the differential diagnosis, which is usually settled by a CT scan or MRI.

A second unobvious stroke is one caused by occlusion of the posterior cerebral artery, usually embolic. This may not be recognized unless the visual fields are routinely tested at the bedside. The patient himself may not be aware of the difficulty or will complain only of blurring of vision or the need for new glasses. Accompanying deficits are inability to name colors or recognize manipulable objects or faces, difficulty in reading, etc. MRI or CT scanning usually corroborates the clinical diagnosis, and therapy is directed against further emboli or extension of the thrombosis.

Another inapparent or confounding stroke that may be mistaken for psychiatric disease is an attack of paraphasic speech from embolic occlusion of a branch of the left middle cerebral artery. The patient talks in nonsensical phrases, appears confused, and does not fully comprehend what is said to him. He may perform satisfactorily at a superficial level and offer socially appropriate greetings and gestures. Only scrutiny of language function and behavior will lead to the correct diagnosis. Infarction (or trauma) of the dominant or nondominant temporal lobe and rarely of the cau-

date may produce an agitated delirium with few focal findings. This may be mistaken for a toxic or withdrawal state.

Parietal infarctions on either side (usually nondominant hemisphere) are often missed because the patient is entirely unaware of the problem or the symptoms create only a subtle confusional state, drowsiness, or only subtle problems with calculation, dialing a phone, reaching accurately for objects, or loss of ability to write. Extinction of bilaterally presented visual or tactile stimuli gives a clue; marked asymmetry of the optokinetic nystagmus response is sometimes the only definite sign.

A cerebellar hemorrhage may at first be difficult to recognize as a stroke. An occipital headache and complaint of dizziness with vomiting may be interpreted as a labyrinthine disorder, gastroenteritis, or myocardial infarction. A slight ataxia of the limbs, inability to sit or stand, and mild gaze paresis may not have been properly tested or have been overlooked. Early intervention by surgery may be lifesaving; but once the syndrome has progressed to the point of coma with pupillary abnormalities with bilateral Babinski signs, surgery is most often useless.

Periventricular white matter changes (leukoareosis) correlate poorly with cerebrovascular disease and may be misinterpreted. We prefer to ignore them unless they are extensive and obscure a new lacunar stroke.

The Comatose Stroke Patient The most common causes of vascular coma are intracranial hemorrhage—usually deep in the hemisphere, less often in the cerebellum or brainstem, extensive subarachnoid hemorrhage, and basilar artery occlusion. After several days, brain edema surrounding a large infarction in the territory of the middle cerebral artery or adjacent to a hemorrhage may compress the midbrain and produce the same effect. Certain remedial surgical measures are still available in these circumstances: drain-

age of blood from the ventricles, shunting of the ventricles in cases of secondary hydrocephalus due to obstruction of the third ventricle or aqueduct, evacuation of a cerebral hemorrhage in cases of recent decline into stupor and coma, and hemicraniectomy in the case of massive stroke edema. Also, thrombolytic therapy and anticoagulants are sometimes successful in reversing the progression of basilar artery thrombosis. These procedures are best carried out in centers with experience in cerebrovascular intensive care. If coma persists or is deep and sudden, only supportive treatment is possible.

Seizures Following Stroke With the exception of infarction due to cerebral venous occlusion, epileptic seizures following stroke are not a great problem. As mentioned earlier and in other chapters of the book, seizures are quite infrequent as the initial manifestation of an ischemic stroke, and when they do occur in this fashion, an embolus is usually the causative mechanism. In the data presented by Lamy and colleagues (who were studying stroke in young patients with patent foramen ovale), when seizures occurred not at the outset but within the first week after stroke, as they did in 2 to 4 percent of their cases, about half had another seizure, usually single, during the next several years. However, the same was true for those with a first seizure after 1 week. No satisfactory study has been conducted to determine if these patients benefit from anticonvulsant therapy to prevent the second or subsequent seizures. Following the practice of most other neurologists, we prescribe phenytoin or an equivalent drug only if there has been a seizure and continue it for about 18 months. If the EEG continues to show focal sharp waves or other epileptic activity at that time, we continue the drug; if not, we may discontinue the medication. It is also clear that prophylactic anticonvulsant treatment of all stroke patients is not necessary.

CHAPTER 35

CRANIOCEREBRAL TRAUMA

Among the vast array of neurologic diseases, cerebral trauma ranks high in order of frequency and gravity. In the United States, in persons under 45 years of age, trauma is the leading cause of death, and more than half of these deaths are due to head injuries. Each year, according to the American Trauma Society, an estimated 500,000 Americans are admitted to hospitals following cerebral trauma; of these, 75,000 to 90,000 die and even larger numbers, most of them young and otherwise healthy, are left permanently disabled.

The basic problem in craniocerebral trauma is at once both simple and complex: simple because there is usually no difficulty in determining causation—namely, a blow to the head—complex because of a number of delayed effects that may complicate the injury. As for the trauma itself, nothing medical can be done, for it is finished before the physician arrives on the scene. At most there can be an assessment of the full extent of the immediate cerebral injury, an evaluation of factors conducive to complications and further lesions, and the institution of measures to avoid such additional problems. But of the disastrous intracranial phenomena that can be initiated by head injury, several fall within the purview of the neurologist, for they are secondary effects that evolve during the period of medical observation, offering possibilities of treatment. No doubt, new techniques of cellular biology will expose phenomena that are set in motion by traumatic injury of nerve cells and glia. Some of these changes may be reversible, but at the moment, such knowledge is limited.

It is a common misconception that craniocerebral injuries are matters that concern only the neurosurgeon and not the general physician or neurologist. Actually, some 80 percent of head injuries are first seen by a general physician in an emergency department, and probably fewer than 20 percent ever require neurosurgical intervention of any kind—even this number is decreasing. Often the neurologist must take charge of the head-injured patient, or his opinion is sought in consultation. To enact his role effectively, he must be familiar with the clinical manifestations and the natural course of primary brain injury and its complications and have a sound grasp of the underlying physiologic mechanisms. Such knowledge must be up to date and immediately applicable, particularly as it relates to the interpretation of computed tomography (CT) and magnetic resonance imaging (MRI), both of which have greatly enhanced our ability to deal with head trauma and its complications. The present chapter reviews the salient facts concerning craniocerebral injuries and outlines a clinical approach that the authors have found useful over the years. Matters pertaining to spinal injury are considered in Chap. 44.

DEFINITIONS AND MECHANISMS

The very language that one uses to discuss certain types of head injury divulges a number of misconceptions inherited from previous generations of physicians. Certain words have crept into the medical vocabulary and have often been retained long after the ideas for which they stood have been refuted—attesting to the disadvantage of premature adoption of explanatory terms rather than descriptive ones. The word *concussion*, for example, implies

a violent shaking or jarring of the brain and a resulting transient functional impairment. Yet despite numerous postulates of physical changes within nerve cells, axons, or myelin sheaths (vibration effects, formation of intracellular vacuoles, etc.), little convincing confirmation of their existence has been possible in humans or in experimental animals. Similarly the word *contusion*, meaning a bruising of cerebral tissue without interruption of its architecture, is applied rather indiscriminately to a variety of clinical states, some of which could not depend on a pathologic change of this type, e.g., “minor contusion state or syndrome”—an expression introduced by Wilfred Trotter, who was himself critical of words that “embalm a fallacious theory.”

In all attempts to analyze the mechanisms of *closed*, or *blunt (nonpenetrating)*, head injury, one fact stands pre-eminent—that there must be the sudden application of a physical force of considerable magnitude to the head. Unless the head is struck, the brain suffers no injury—except in the rare instances of violent flexion-extension (whiplash) of the neck and somewhat controversial cases of crush injury to the chest or explosive injury with a sudden extreme increase of intrapulmonary pressure. The factors of particular importance in brain injury are the differential mobility of the head and brain, the tethering of the upper brainstem while allowing movement of the cerebral hemispheres, and the relationship of injured parts of the brain to dural septa and bony prominences. As to concussive injuries, it is useful to point out that all concussions involve a physical force that imparts motion to the stationary head or a hard surface that arrests the motion of a moving head, i.e., concussion does not occur if the head is stationary. This is the basis of most civilian head injuries, and they are notable in two respects: (1) they frequently induce at least a temporary loss of consciousness and (2) even though the skull is not penetrated, the brain may suffer gross damage, i.e., contusion, laceration, hemorrhage, and swelling. A theory that would bring into plausible form these physical and gross neuropathologic changes and their relation to transient loss of consciousness (concussion) or prolonged coma has been formulated only in relatively recent years.

By contrast, high-velocity missiles may penetrate the skull and cranial cavity or, rarely, the skull may be compressed between two converging forces that crush the brain without causing significant displacement of the head or the brain. In these circumstances the patient may suffer severe and even fatal injury without immediate loss of consciousness. Hemorrhage, destruction of brain tissue, and, if the patient survives for a time, meningitis or abscess are the principal pathologic changes created by injuries of these types. They offer little difficulty to our understanding. These various types of head injuries are illustrated in Fig. 35-1.

The relation of *skull fracture* to brain injury has been viewed in changing perspective throughout the history of this subject. In the first half of the century, fractures dominated the thinking of the medical profession, and cerebral lesions were regarded as secondary. Later, it became known that the skull, though rigid, is still flexible enough to yield to a blow that could injure the brain without causing fracture. Therefore the presence of a fracture, although a rough measure of the force to which the brain has been exposed, is no longer considered an infallible index of the presence of ce-

rebral injury. Even in fatal head injuries, autopsy reveals an intact skull in some 20 to 30 percent of cases (see also page 754). Contrariwise, many patients suffer skull fractures without serious or prolonged disorder of cerebral function, largely because the energy of a blow is dissipated in the fracture.

The modern trend is to be concerned primarily with the presence or absence of brain injury rather than with the fracture of the skull itself. Nevertheless, fractures cannot be dismissed without further comment for several reasons. The presence of a fracture always warns of the possibility of underlying cerebral injury. Overall, brain injury is estimated to be 5 to 10 times more frequent with skull fractures than without them and perhaps 20 times more frequent with severe and multiple fractures. Moreover, fractures assume importance by indicating the site and possible severity of brain damage, in providing an explanation for certain cranial nerve palsies, and in creating potential pathways for the ingress of bacteria and air or the egress of cerebrospinal fluid (CSF). In all these respects, fractures through the base of the skull are of special significance, more so than those of the cranial vault, and are considered below.

Basal Skull Fractures and Cranial Nerve Injuries

Some of the major sites and directions of basilar skull fractures are indicated in Fig. 35-2. One can readily perceive the possibilities of

injury to cranial nerves in relation to such fractures. Fractures of the base are often difficult to detect in plain skull films, but their presence should always be suspected if any one of a number of characteristic clinical signs is in evidence. Fracture of the petrous pyramid often deforms the external auditory canal or tears the tympanic membrane, with resultant leakage of CSF (otorrhea); or, blood may collect behind an intact tympanic membrane and discolor it. If the fracture extends more posteriorly, damaging the sigmoid sinus, the tissue behind the ear and over the mastoid process becomes boggy and discolored (Battle sign). Basal fracture of the anterior skull may also cause blood to leak into the periorbital tissues, imparting a characteristic “raccoon” or “panda bear” appearance. The presence of any of these signs calls for CT scanning of the skull base using bone window settings to detect a fracture.

The existence of a basal fracture is commonly indicated by signs of cranial nerve damage. The olfactory, facial, and auditory nerves are the ones most liable to injury, but any one, including the twelfth, may be damaged. *Anosmia and an apparent loss of taste* (actually a loss of perception of aromatic flavors, since the elementary modalities of taste are unimpaired) are frequent sequelae of head injury, especially with falls on the back of the head. In the majority of cases the anosmia is permanent. If unilateral, it will not be noticed by the patient. The mechanism of these disturbances is thought to be a displacement of the brain and tearing of the olfactory nerve filaments in or near the cribriform plate, through which they course.

A fracture in or near the sella may tear the stalk of the pituitary gland, with resulting *diabetes insipidus*. Rarely such a fracture may cause bleeding from

a pre-existing pituitary adenoma and produce the syndrome of pituitary apoplexy (page 577). A fracture of the sphenoid bone may lacerate the optic nerve, with blindness from the beginning. The pupil is unreactive to a direct light stimulus but still reacts to a light stimulus to the opposite eye (consensual reflex). The optic disc becomes pale, i.e., atrophic, after an interval of several weeks. Partial injuries of the optic nerve result in scotomas and a troublesome blurring of vision.

Complete *oculomotor nerve injury* is characterized by ptosis, a divergence of the globes with the affected eye resting in an abducted and slightly depressed position, loss of medial and most of the vertical movements of the eye with diplopia, and a fixed, dilated pupil, as described in Chap. 13. Diplopia that is worse on looking down, and compensatory tilting of the head suggest *trochlear nerve* injury. In a series of 60 patients with head injury, Lepore found that fourth nerve palsy was the commonest cause of diplopia, occurring unilaterally twice as often as bilaterally, followed in frequency by damage to one or both third nerves, then, least often, a unilateral or bilateral sixth nerve palsy. Five of his patients had palsies that reflected damage to more than one nerve, and seven had supranuclear disorders of convergence. The long subarachnoid course of the fourth nerve is usually given as the explanation for its frequent injury, but this mechanism has never been validated. These optic and ocular motor nerve disorders must be distinguished from those due to displacement of the globe as a result of direct injury to the orbit and the oculomotor muscles.

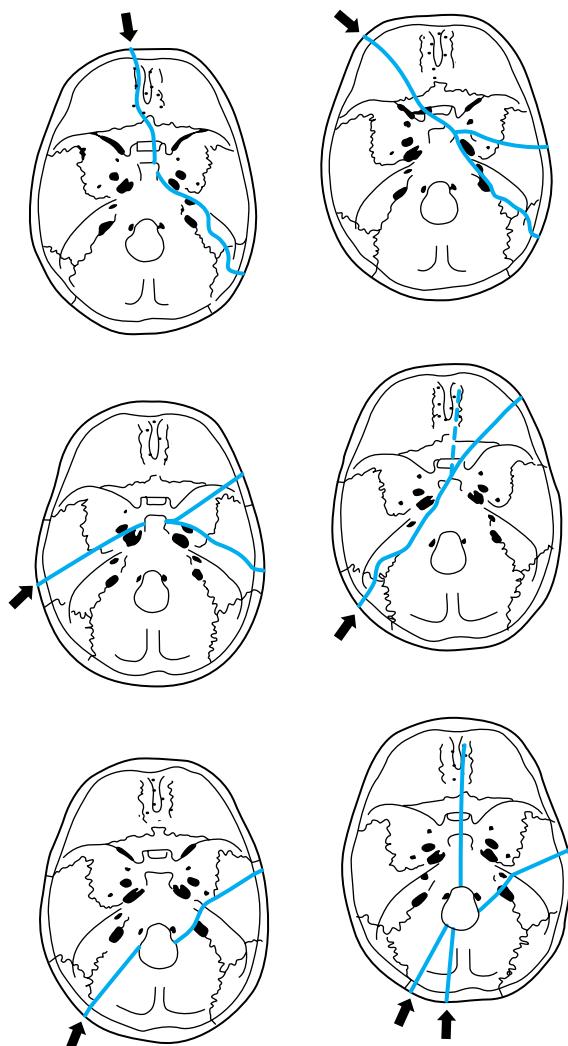

Figure 35-2. The course of fracture lines through the base of the skull. Arrows indicate point of application and direction of force. (Reproduced by permission from Courville.)

Injury to the *ophthalmic and maxillary divisions of the trigeminal nerve* may be the result of either a basal fracture across the middle cranial fossa or a direct extracranial injury to the branches of the nerves. Numbness and paresthesias of the skin supplied by the nerve(s) or a neuralgia can be troublesome sequelae of these injuries.

The *facial nerve* may be involved in one of two ways. In the first type of injury, associated with transverse fractures through the petrous bone, there is an immediate facial palsy, probably due to contusion or transection of the nerve. Surgical anastomosis has sometimes been successful in this circumstance. The second, more common type, is associated with longitudinal fractures of the petrous bone, the facial palsy then often being delayed for several days—a sequence that may be misinterpreted as progression of the intracranial traumatic lesion. This latter type is usually transitory, and its mechanism is not known.

Injury to the *eighth cranial nerve* due to petrous fractures results in a loss of hearing or in postural vertigo and nystagmus coming on immediately after the trauma. Deafness due to nerve injury must be distinguished from the high-tone hearing loss due to *cochlear* injury and from deafness caused by bleeding into the

middle ear and disruption of the ossicular chain (conduction deafness). Also, vertigo must be distinguished from the very common symptom of posttraumatic giddiness discussed in a later section. A fracture through the hypoglossal canal causes weakness of one side of the tongue. It should be kept in mind that blows to the upper neck may also cause lower cranial nerve palsies, either by direct injury to their peripheral extensions or as a result of *carotid artery dissection*, either of its cervical or intracranial segment.

Carotid-Cavernous Fistula

A basal fracture through the sphenoid bone may lacerate the internal carotid artery or one of its intracavernous branches where it lies in the cavernous sinus. Within hours or a day or two, a disfiguring pulsating exophthalmos develops as arterial blood enters the sinus and distends the superior and inferior ophthalmic veins that empty into the sinus. The orbit feels tight and painful, and the eye may become partially or completely immobile because of pressure on the ocular nerves traversing the sinus (Fig. 14-4). The sixth nerve is affected most often and the third and fourth nerves less frequently. Also, there may be a loss of vision due to ischemia of the optic nerve and retina; congestion of the retinal veins and glaucoma are additional factors in the visual failure. Some 5 to 10 percent of fistulas resolve spontaneously, but the remainder must be obliterated by interventional radiologic means (by a detachable balloon inserted into the carotid artery via a transfemoral catheter) or by a direct surgical repair of the fistula (see Stern).

Not all carotid-cavernous fistulas are traumatic. They may occasionally occur with rupture of an intracavernous saccular aneurysm or in Ehlers-Danlos disease, where the connective tissue is defective; or the cause may be unexplained.

Pneumocephalus, Aerocele, and Rhinorrhea (Cerebrospinal Fluid Leak)

If the skin over a skull fracture is lacerated and the underlying meninges are torn, or if the fracture passes through the inner wall of a paranasal sinus, bacteria may enter the cranial cavity, with resulting meningitis or abscess formation. Also, CSF that leaks into the sinus present as a watery discharge from the nose (*CSF rhinorrhea*). The nasal discharge can be identified as CSF by testing it for glucose with diabetic test tape (mucus has no glucose) or by the presence of fluorescein or iodinated water-soluble dye that is injected into the lumbar subarachnoid space and then absorbed by pledgets placed in the nasal cavity. Most cases of acute CSF rhinorrhea heal by themselves. If the condition is persistent or is complicated by an episode of meningitis, repair of the torn dura mater is indicated. The prophylactic use of antibiotics to prevent meningitis from a nasal CSF leak is currently not favored, but many neurosurgeons continue this practice, particularly in children (see page 599).

A collection of air in the cranial cavity (aerocele) is a common occurrence following skull fracture or following an extended neurosurgical procedure. It is usually found (by CT scan) in the epidural or subdural space over the cerebral convexities or between the hemispheres and serves only to warn of a potential route for the entry of bacteria into the cranium. Small collections of air are usually absorbed without incident, but a large collection of air may act as a mass and cause clinical deterioration after injury (tension pneumocranum; Fig. 35-3). Inhalation of 100% oxygen has a salutary effect, but needle aspiration of the air is required if it is causing clinical signs (Fig. 35-3).

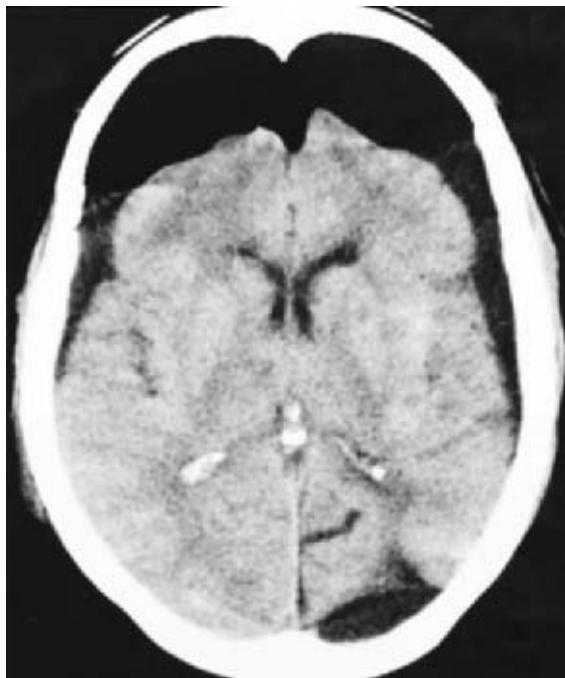

Figure 35-3. CT of postoperative tension pneumocranum (aerocele) that caused progressive drowsiness and required removal by aspiration. The air is apparent as a very low density collection that compresses the frontal lobes.

Depressed (“derby hat”) fractures are of significance only if the underlying dura is lacerated or the brain is compressed by indentation of bone. They should then be surgically repaired, preferably within the first 24 to 48 h.

Cerebral Concussion

Mechanisms of Concussion Much has been written about the mechanisms of concussion and coma in closed, or blunt, head injury. Certain facts concerning these conditions stand out: (1) Concussion, meaning a *reversible traumatic paralysis of nervous function*, is always immediate (not delayed even by seconds). (2) The effects of concussion on brain function may last for a variable time (seconds, minutes, hours, or longer). To set arbitrary limits on the duration of loss of consciousness—i.e., to consider a brief loss as indicative of concussion and a prolonged loss as indicative of concussion or other traumatic cerebral lesion, as proposed in some older medical writings—is illogical and unsound physiologically. As pointed out by Symonds, any such difference is quantitative, not qualitative. Admittedly, in the more prolonged states of coma, there is a greater chance of finding hemorrhage and contusion, which undoubtedly contribute to the persistence of coma and the likelihood of irreversible change. (3) The optimal condition for the production of concussion, demonstrated originally by Denny-Brown and Russell, is a sudden change in the momentum of the head; i.e., either movement is imparted to the stationary head by a blow or movement of the head is arrested by a hard, unyielding surface. These two types of blunt (nonpenetrating) head injury are called *accelerative* and *decelerative*, respectively.

The mechanism of concussive “cerebral paralysis” has been interpreted in various ways throughout medical history in light of the state of scientific knowledge at a particular period of time. The

favored hypotheses for the better part of a century were “vasoparalysis” (suggested by Fischer in 1870) or an arrest of circulation by an instantaneous rise in intracranial pressure (proposed by Strohmeyer in 1864 and popularized by Trotter in 1932). Jefferson, in his essay on the nature of concussion (1944), convincingly refuted these vascular hypotheses. Later, Shatsky and coworkers, by the use of high-speed cineangiography, showed displacement of vessels but no arrest of circulation immediately after impact.

Beginning with the work of Denny-Brown and Russell in 1941, the physical factors involved in head and brain injury have been subjected to careful analysis. These investigators demonstrated, in the monkey and cat, that concussion resulted when the freely moving head was struck by a heavy mass. If the head was prevented from moving at the moment of impact, the same degree of force invariably failed to produce concussion. More recently, the importance of head motion per se was verified by Gennarelli and colleagues, who were able to induce concussion in primates by rapid acceleration of the head without impact, a condition that rarely occurs in humans.

Holbourn, a Cambridge physicist, from a study of gelatin models under conditions simulating head trauma, deduced that when the head is struck, movement of the partly tethered but suspended brain always lags (due to inertia); but inevitably the brain moves also, and when it does it must rotate, for it occupies a round skull whose motions (because of attachment to the neck) usually describe an arc. Pudenz and Sheldon and later Ommaya and coworkers (1974) proved the correctness of this assumption by photographing the brain through a transparent (Lucite) calvarium at the moment of impact. The brain is thus subjected to shearing stresses set up by rotational forces mainly in the sagittal plane centered at its point of tethering in the high midbrain and subthalamus. The torque at the level of the upper reticular formation would explain the immediate loss of consciousness, as described below. Also, these rotational movements of the brain provide a reasonable explanation for the occurrence of surface injuries in certain places, i.e., where the swirling brain comes into contact with bony prominences on the inner surface of the skull (petrous and orbital ridges, sphenoid wings), and of injuries to the corpus callosum, which is flung against the falx.

These views on the site and mechanism of concussion have been supported by a number of additional physiologic observations. Foltz and Schmidt, in 1956, suggested that the reticular formation of the upper brainstem was the anatomic site of concussive injury. They showed that in the concussed monkey, lemniscal sensory transmission through the brainstem was unaltered, but its effect in activating the high reticular formation was blocked. They also demonstrated that the electrical activity of the medial reticular formation was depressed for a longer time and more severely than that of the cerebral cortex.

In 1956 and again in 1961, Strich described the neuropathologic findings in patients who died months after severe closed head injuries that had caused immediate and protracted coma. In all of her cases—in which there were no signs of skull fracture, raised intracranial pressure, or gross subarachnoid hemorrhage—she observed an uneven but diffuse degeneration of the cerebral white matter. In cases of shorter survival (up to 6 weeks), she observed ballooning and interruption of axis cylinders. These findings were subsequently confirmed by Nevin, by J. H. Adams and colleagues, and by Gennarelli and coworkers, the last of these groups working with monkeys. It is noteworthy that in most of these cases, and subsequent ones reported by Jellinger and Seitelberger, there were

also lesions in the region of the reticular activating system and small hemorrhagic softenings in the corpus callosum, superior cerebellar peduncles, and dorsolateral tegmentum of the midbrain. Strich interpreted the extensive white matter lesions, both in the hemispheres and in the brainstem, to represent a degeneration of nerve fibers that had been stretched or torn by the shear stresses set up during rotational acceleration of the head (*diffuse axonal injury*), as had been postulated earlier by Holbourn. She suggested that if nerve fibers are stretched rather than torn, the lesions may be reversible and may play a part in the mechanism of concussion. Symonds elaborated this view and saw in the shearing stresses—which are maximal at the point where the cerebral hemispheres rotate on the relatively fixed brainstem (i.e., at the midbrain-subthalamic level)—the explanation of concussion. The extension of this idea, namely that diffuse axonal injury throughout the cerebral white matter is the main cause of persistent unconsciousness, has been widely adopted but—as we discuss further on—is open to dispute. Indeed, even the proponents of diffuse axonal injury as an important effect of severe brain damage have found that thalamic lesions are almost always present in cases of prolonged coma or the persistent vegetative state (Adams et al 2000).

Clinical Manifestations of Concussion The immediate abolition of consciousness, suppression of reflexes (falling to the ground if standing), transient arrest of respiration, a brief period of bradycardia, and fall in blood pressure following a momentary rise at the time of impact are the characteristic clinical signs of concussive injury. Rarely, if these abnormalities are sufficiently intense, death may occur at the moment of impact, presumably from respiratory arrest. Usually the vital signs return to normal and stabilize within a few seconds while the patient remains unconscious. Brief tonic extension of the limbs, clonic convulsive movements lasting up to about 20 seconds and other peculiar movements may occur immediately after the loss of consciousness (see McCrory et al). These “concussive convulsions” are probably of little significance and have not been shown to confer an increased risk of future seizures. McCrory and colleagues noted an association between motor and convulsive movements and facial impact, and we have seen this feature twice in teenagers who collided while pursuing a ball. The plantar reflexes are transiently extensor. Then, after a variable period of time, the patient begins to stir and opens his eyes but is unseeing. Corneal, pharyngeal, and cutaneous reflexes, originally depressed, return, and the limbs are withdrawn from painful stimuli. Gradually contact is made with the environment, and the patient begins to obey simple commands and respond slowly and inadequately to simple questions. Memories are not formed during this period; the patient may even carry on a conversation which, later on, he cannot recall. Finally there is full recovery, corresponding to the time when the patient can form consecutive memories of current experiences.

The time required for the patient to pass through these stages of recovery may be only a few seconds or minutes, several hours, or possibly days; but again, between these extremes there are only quantitative differences, varying with the intensity of the process. To the observer, such patients are comatose only from the moment of injury until they open their eyes and begin to speak; however, for the patient, the period of unconsciousness extends from a point before the injury occurred (*retrograde amnesia*) until the time when he is able to form consecutive memories—at the end of the period of anterograde amnesia. The duration of the amnesic period, particularly of *anterograde amnesia*, is the most reliable index of

the severity of the concussive injury. If there is no disturbance or loss of consciousness, none of the lesions described below are likely to be found. More recently, the notion has been introduced that momentary “stunning” represents the mildest degree of concussion. This state has found its way into various guidelines for the management of sports injuries, but there is no reason at the moment to presume it shares the same mechanism as concussion.

Pathologic Changes Associated with Severe Head Injury

In fatal cases of head injury, the brain is often bruised, swollen, and lacerated and there may be hemorrhages, either meningeal or intracerebral, and hypoxic-ischemic lesions. The prominence of these pathologic findings was responsible for the long-prevailing view that cerebral injuries are largely a matter of bruises (*contusions*), hemorrhages, and the need for urgent operations. That this can hardly be the case is indicated by the fact that some patients survive and make an excellent recovery from head injuries that are clinically as severe or almost as severe as the fatal ones. One can only conclude, therefore, that most of the immediate symptoms of severe head injury depend on histologically invisible and highly reversible functional changes, including those underlying concussion.

The effects of bruises, lacerations, hemorrhages, localized swellings, white matter necroses, and herniations of tissue should not be minimized, since they are probably responsible for or contribute to many of the fatalities that occur 12 to 72 h or more after the injury. As pointed out by Jennett, a majority of patients who remain in coma for more than 24 h after a head injury are found to have intracerebral hematomas. Of these lesions, the most important are contusions of the surface of the brain beneath the point of impact (*coup lesion*) and the more extensive lacerations and contusions on the side opposite the site of impact (*contre coup lesion*), as shown in Fig. 35-4. Blows to the front of the head produce mainly coup lesions, whereas blows to the back of the head cause mainly contre coup lesions. Blows to the side of the head produce either coup or contre coup lesions or both. Irrespective of the site of the impact, the common sites of cerebral contusions are in the frontal and temporal lobes, as illustrated in Figs. 34-4 and 35-5. The inertia of the malleable brain—which causes it to be flung against the side of the skull that was struck, to be pulled away from the contralateral side, and to be impelled against bony prominences within the cranial cavity—explains these coup-contre coup patterns. As noted, the experimental studies of Ommaya and others indicate that the effects of linear acceleration of the head are much less significant than are those due to rotation. Relative sparing of the occipital lobes in coup-contre coup injury is explained by the smooth inner surface of the occipital bones and subadjacent tentorium as pointed out by Courville.

The contused cortex is diffusely swollen and hemorrhagic, most of the blood being found around parenchymal vessels. On CT scanning, the contusions appear as edematous regions of cortex and subcortical white matter admixed with areas of increased density representing leaked blood (Fig. 35-6). The bleeding points may coalesce and give the appearance of a clot in the cortex and immediately adjacent white matter. The predilection of these lesions for the crowns of convolutions attests to their traumatic origin (being thrown against the overlying skull) and distinguishes them from cerebrovascular and other types of cerebral lesions.

In nearly all cases of severe head injury there is damage to the corpus callosum by impact with the falx; necrosis and hemor-

rhage are sometimes visible by CT scanning and can be seen to spread bilaterally to adjacent white matter (Fig. 35-7). Also, there may be scattered hemorrhages in the white matter along lines of force from the point of impact to the contralateral side. Areas of white matter degeneration of the type described by Strich may also be present. In the authors' pathologic material, these white matter lesions tend to be focal, some in regions near hemorrhages, contusions, and ischemic lesions and others at a distance, along transcallosal and ascending and descending tracts that had been interrupted by such lesions. As indicated earlier, the degeneration of white matter can be remarkably diffuse, with no apparent relationship to focal destructive lesions. This *diffuse axonal injury*, as it is now generally designated, and the callosal and midbrain injuries, are said to be the predominant abnormalities in many cases of severe head injury. Recent investigations using MRI, such as that of Kampl and colleagues, indicate that diffuse injury of this type may be the substrate of the persistent vegetative state. There was also a pattern of damage in the corpus callosum, corona radiata, and the dorsolateral midbrain tegmentum in their cases. We would point out that in almost all of our cases of severe cranial injury and protracted coma the major sites of injury were adjacent to zones of ischemia and old hemorrhages in the midbrain and subthalamus—i.e., in the zones subjected to the greatest torque—and we continue to favor these latter lesions as the critical ones in cases of persistent coma and vegetative state (Ropper and Miller). This was true also of the cases of persistent coma described by Jellinger and Seitelberger. Notable is the fact that these deep lesions coincide with the postulated locus of reversible concussive paralysis. In other words, the attribution of persistent coma and the vegetative state to diffuse axonal injury remains uncertain in our view and disruption of the caudal thalamic and rostral midbrain areas have been often present in our material.

Primary brainstem hemorrhages, are distinguished from the secondary hemorrhages resulting from the effects of downward displacement of the brainstem (transtentorial herniation). Duret originally emphasized the medullary location of these hemorrhages, but the term *Duret hemorrhage* has come to signify any secondary brainstem hemorrhage.

In addition to contusions and extradural, subdural, subarachnoid, and intracerebral hemorrhages, there are variable degrees of vasogenic edema that increases during the first 24 to 48 h, and zones of infarction due to vascular spasm caused by subarachnoid blood surrounding basal vessels. Marmarou et al have convincingly demonstrated that *brain swelling* after head injury is essentially the result of edema and not of an increase in cerebral blood volume, as has long been postulated. In children and in some cases in adults, the cerebral edema may be massive and lead to secondary brainstem compression.

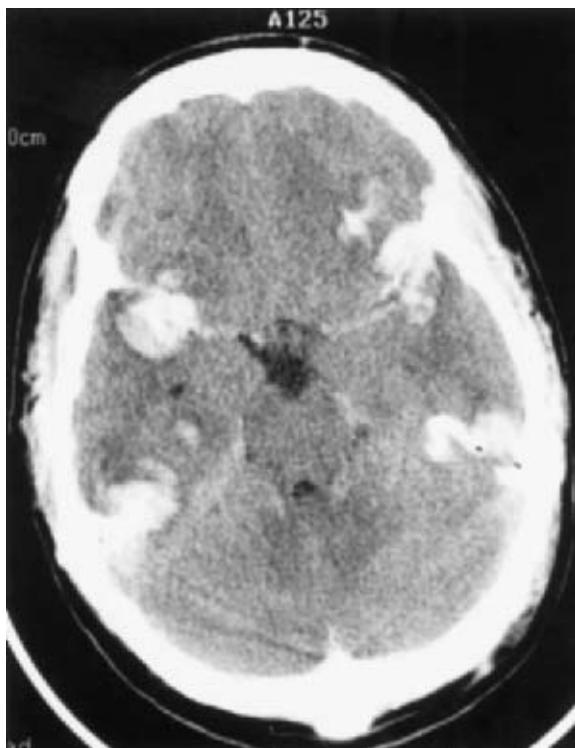

Figure 35-6. CT scan without contrast infusion showing areas of hemorrhagic contusion adjacent to bony prominences. There is also slight subarachnoid blood along the tentorium and in the insular cisterns, both typical of traumatic bleeding.

APPROACH TO THE PATIENT WITH HEAD INJURY

The physician first called on to attend a patient who has had a closed (blunt) head injury will generally find the patient in one of three clinical conditions, each of which must be dealt with differently. Usually it is possible to categorize the patient by assessing his mental and neurologic status when first seen and at intervals after the accident. In many emergency wards and intensive care units, the *Glasgow Coma Scale* is used as a rapid reference to accomplish this purpose (Table 35-1). It registers three aspects of neurologic function: eye opening, verbal response, and motor response to various stimuli. The scores provided by this scale have been found to correspond roughly with outcome of the head injury, as discussed further on. The scale uses a summed score with a maximum of 15; a score of 7 or less is considered to reflect severe trauma and a poor clinical state, 8 to 12, moderate injury, and higher scores, mild injury.

Patients Who Are Conscious or Are Rapidly Regaining Consciousness (Minor Head Injury)

This is the most frequently encountered clinical situation. Roughly, two degrees of disturbed function can be recognized within this category. In one, the patient was not unconscious at all but only stunned momentarily or "saw stars." This injury is insignificant when judged in terms of life or death and brain damage—though, as we point out further on, there is always the possibility of a skull fracture or the later development of an epidural or subdural hematoma. Moreover, the patient is still liable to a troublesome post-

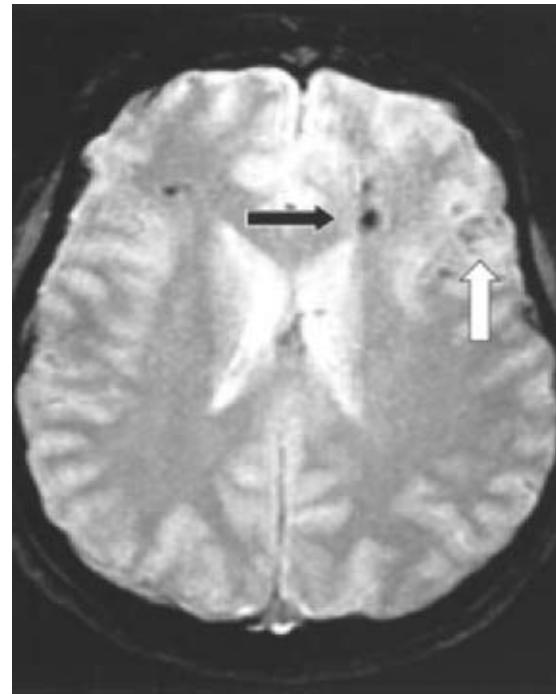

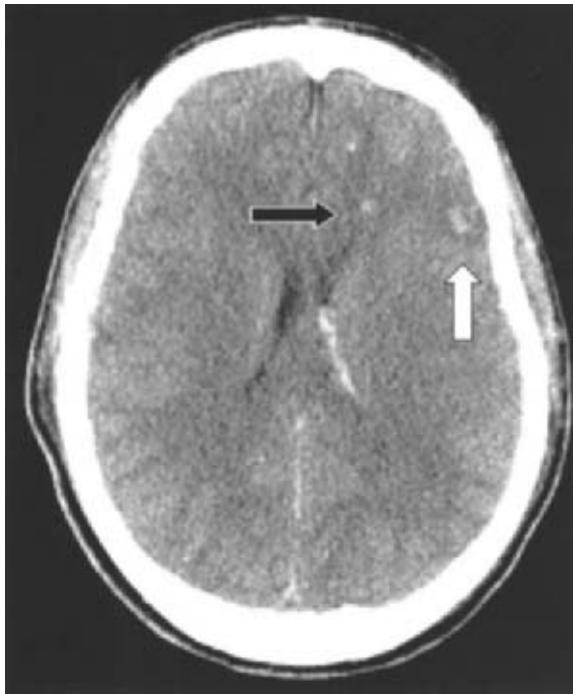

Figure 35-7. CT scan (left) and MRI (right) from a patient with diffuse axonal injury. There are multiple small hemorrhagic areas (one of which is shown by the dark arrow) in the cerebral white matter. The MRI highlights the small amount of blood in these lesions. Also shown are a contusion in the anterior temporal lobe (white arrow), which often accompanies the deep type of axonal injury, and blood in the ventricle.

traumatic syndrome—consisting of headache, giddiness, fatigability, insomnia, and nervousness—which may appear soon after or within a few days of the injury. In the second instance, consciousness was temporarily abolished for a few seconds or minutes, i.e., the patient was genuinely concussed. When such a patient is first seen, recovery may already be complete, or he may be in one of the stages of partial recovery described earlier, under “Clinical Manifestations of Concussion.” Even though mentally clear, the patient may have an amnesia for events immediately preceding and following the injury. Thereafter, headache and other symptoms of the posttraumatic syndrome or compensation neurosis may develop.

In most cases of this type, there is little need of a neurologic consultation, and hospitalization is not required provided that a responsible family member is available to report any change in the clinical state. In only a small group of these patients, mainly in those who are slow in regaining consciousness or have a skull fracture, is there significant risk of ongoing hemorrhage or other delayed complications.

Whether to obtain x-ray films of the head routinely in such patients is an unresolved problem. In our litigious society, the physician is inclined to do so. If there is no fracture and the patient is mentally clear, Jennett estimates that there is only one chance in a thousand of developing an intracranial (extradural) hemorrhage. He states that this increases to 1 in 30 in patients with a fracture; but most studies, such as the one by Lloyd and colleagues, have found that the presence of a skull fracture in children proves to be a relatively poor indicator of intracranial injury.

With a focus on cost-effective use of ancillary testing, there has also been considerable discussion of the criteria that justify obtaining a cranial CT following seemingly minor forms of head trauma. In our view, a CT should generally be obtained in a case of head injury associated with prolonged loss of consciousness, severe and persisting headache, nausea and vomiting, a confusional state, and any new, objective neurologic signs. The CT scan may

be particularly important in elderly patients with minor head trauma, in whom the presence of an intracranial lesion (mainly subdural hematoma) may not be predicted by clinical signs. However, in children, it may be advisable to perform the scans more liberally. This is underscored by the results of a study of 215 children with minor head trauma conducted by Simon and colleagues; 34 children with no known loss of consciousness and a Glasgow Coma Scale score of 15 nonetheless displayed intracranial lesions, although only 3 required surgery.

These minor and seemingly trivial head injuries may sometimes be followed by a number of puzzling and worrisome clinical phenomena, some insignificant, others serious and indicative of a pathologic process other than concussion. The latter are described below. When they occur, a neurologic or neurosurgical evaluation is indicated.

Delayed Fainting after Head Injury Following an accident, the injured person, after walking about and seeming to be normal, may turn pale and fall unconscious to the ground. Recovery occurs within a few seconds or minutes. This is a vasodepressor syncopal attack, possibly related to pain and emotional upset, and differs in no way from the fainting that follows pain and fright without injury. Such syncopal attacks also occur with injuries that spare the head, but with head injury they become more difficult to interpret.

Denny-Brown described a more severe type of delayed posttraumatic collapse that we have seen only rarely. Again, the patient appears to be recovering from a blow to the head, which may simply have dazed him or caused a brief period of unconsciousness, when suddenly, after a period of several minutes to hours, he collapses and becomes unresponsive for a brief time. The most disquieting feature of this clinical state is a marked bradycardia, which, coupled with the lucid interval, raises the specter of an evolving epidural hemorrhage (actually, bradycardia is a late and inconstant sign of epidural bleeding). However, intracranial pressure is not raised, the disorder fails to develop further, and—following a brief period of restlessness, vomiting, and headache—the patient recovers completely over a period of several days. Denny-Brown suggested that this form of delayed posttraumatic collapse was due to a contusion of the medulla, but how this explains the sequence of clinical events is not clear. The authors believe it possibly to be a severe form of vasodepressor syncope but have no firm explanation.

A more serious form of delayed collapse after head injury is described further on, under “Concussion Followed by a Lucid Interval.”

Drowsiness, Headache, and Confusion This syndrome occurs most often in children, who, after a concussive or nonconcussive head injury, seem not to be themselves. They lie down, are drowsy, complain of headache, and may vomit—symptoms that suggest the presence of an epidural or subdural hemorrhage. Mild focal edema near the point of impact may be seen on MRI. There is usually no skull fracture but, as Nee and colleagues point out, vomiting is associated with an increase in the incidence of skull fracture. The symptoms subside after a few hours, attesting to the benign nature of the condition.

Transient Traumatic Paraplegia, Blindness, and Migrainous Phenomena With falls or blows on top of the head, both legs may become temporarily weak and numb, with wavering bilateral Babinski signs and sometimes with sphincteric incontinence. Blows to the occiput may cause temporary blindness. The symptoms disappear after a few hours. It seems unlikely that these transient symptoms represent a direct localized concussive effect, caused either by indentation of the skull or by impact on these parts

Clinical and radiographic characteristics of the main traumatic brain lesions

	ACUTE EPIDURAL HEMATOMA	SUBDURAL HEMATOMA	CHRONIC SUBDURAL HEMATOMA	CONTUSION/ PARENCHYMAL HEMORRHAGE	VENTRICULAR HEMATOMA	SUBARACHNOID HEMORRHAGE	SUBDURAL HYCROMA	DIFFUSE AXONAL INJURY
Causative factor	Laceration of middle cerebral artery or dural sinus	Tearing of bridging pial veins and arteries	Trauma (may be absent or minimal) Risk factors: coagulopathy and severe brain atrophy	Shearing of parenchymal vessels. Risk factors: coagulopathy and amyloid vasculopathy	Shearing of parenchymal vessels; r/o vascular defects	Exclude underlying aneurysmal rupture	Arachnoid tear, following meningitis	Deceleration or rotational forces
Typical location	Lateral cerebral convexities	Lateral cerebral convexities	Lateral cerebral convexities, may be bilateral	Inferior frontal and temporal lobes	Lateral and third ventricles blood filled	Basilar cisterns	Lateral cerebral convexities	Deep white matter, corpus callosum, dorsolateral pons
Evolution	Hours	Many hours	Days to weeks	Expand over 12–48 hours	Rapid	Minutes to hours	Days to weeks	From time of injury
Clinical profile	Classically, lucid interval then coma, but more variable	Drowsiness, coma Pupillary dilation with contralateral then bilateral limb weakness; progressive stupor then coma	Headache, progressive alteration in mental status ± focal neurologic signs	Stupor → coma, dilated pupil, progressive hemiplegia, spasticity	Progressive signs of hydrocephalus	HA, meningismus, delayed manifestations, vasospasm	Mimics chronic subdural hematoma	Coma, posturing, normal ICP
Age at risk	Children, young adults	Any	Elderly	Any	Any	Any	Infants, children, adults	Any
Radiologic features	Acute bulging epidural clot bounded by cranial sutures; lenticular in shape	Acute blood rimming broad region of cerebral convexity	Hyper- or isodense, unilateral or bilateral	Multiple, confluent regions of edema intermixed with focal, acute blood	Focal, acute blood within ventricles; may layer with gravity	Acute blood lining cortex in subarachnoid space	Focal, CSF density, fluid collection	CT may be normal; MRI shows evolving small deep contusions
Surgical intervention	Urgent evacuation	Urgent evacuation if large enough to cause symptoms	Evacuation in some circumstances	Evacuate if large	Shunting	Generally not treated	Aspiration of fluid	None
						May cause secondary vasospasm		

of the brain against the inner table of the skull. A concussion of the cervical portion of the spinal cord is another suggested but improbable mechanism of transient paraplegia. The blindness and paraplegia are usually followed by a throbbing vascular type of headache. Transient migrainous visual phenomena, aphasia, or hemiparesis, followed by a headache, are observed sometimes after minimal concussion in athletes who participate in competitive contact sports. Possibly all of these phenomena are due to an attack of migraine or migraine equivalent induced by a blow to the head. This can be perplexing for a few hours, especially if it is the first such attack of migraine in a child. Another clinical possibility, particularly in cases of acute quadriplegia, is cartilaginous embolism of the cervical cord (page 1072).

Delayed Hemiplegia In our experience, most examples of these disorders have occurred in male adolescents or young adults who, some hours after a relatively minor athletic or more severe road injury, developed a massive hemiplegia, homonymous hemianopia, or aphasia (with left-sided lesions). Imaging or ultrasound may reveal a *dissection of the internal carotid artery*. The dissection may occur in the extracranial or the intracranial portion of the carotid artery and should be sought by MR angiography or arteriography if the hemiparesis has no other explanation. In other instances, particularly after a blow to the neck, a mural thrombus forms in the carotid, which, in turn, may shed an embolus to the anterior or middle cerebral artery. In yet other instances, the hemiplegia has no explanation other than the blow to the head, perhaps the result of the migraine phenomenon described above.

Other causes of delayed hemiplegia are a late evolving epidural or subdural hematoma and, in more severe injuries, an intracerebral hemorrhage (occasionally from a pre-existent arteriovenous malformation). Most of these are associated with a diminution in the level of consciousness.

Fat Embolism With fractures of large bones, there may be, after 24 to 72 h, an acute onset of pulmonary symptoms (dyspnea and hyperpnea) followed by coma with or without focal signs or seizures; this sequence is due to systemic fat embolism, first of the lungs and then of the brain. In some cases the onset of pulmonary symptoms is associated with a petechial rash over the thorax, and one in three cases is said to show fat globules in the urine. Respiratory distress is the most important and often the only feature of the fat embolism syndrome, evident in the chest film as fluffy infiltrates in both lungs. In the brain, the fat emboli cause widespread petechial hemorrhages, involving both white and gray matter and a few larger infarcts. Most patients with fat embolism recover spontaneously in 3 or 4 days, although a mortality rate of up to 10 percent is quoted, usually related to the underlying injuries. Treatment, aside from respiratory support, is controversial. Heparin, which had been used in the past, is not considered effective.

Patients Who Have Been Comatose from the Time of Head Injury

Here the central problem, so ably set forth by Symonds, is the relationship between concussion and contusion. Since consciousness is abolished at the moment of injury, one can hardly doubt the existence of concussion in such cases; but when hours and days pass without consciousness being regained, the second half of the usual definition of concussion—namely, that the paralysis of cerebral function be transitory—is not satisfied. Careful pathologic examination of such cases usually discloses evidence of increased intracranial pressure and of cerebral contusions, lacerations, subarachnoid hemorrhage, zones of infarction, and scattered intrace-

rebral hemorrhages—both at the point of injury (coup) and on the opposite side (contrecoup), in the corpus callosum, and between these points, along the line of force of the injury. In some patients, the diffuse axonal type of injury is a prominent abnormality; most often, there are separate but strategically placed ischemic and hemorrhagic lesions in the upper midbrain and lower thalamic region, as already mentioned. The tissue around the contusions is swollen, and in postmortem preparations the white matter in these regions appears pale in myelin stains. Varying amounts of blood in the subdural space are usually present. A major displacement of the thalamus and midbrain is frequently present, with compression of the opposite cerebral peduncle against the free margin of the tentorium as well as secondary midbrain hemorrhages and zones of necrosis; in some cases, there is frank transtentorial herniation.

It should be kept in mind that severe head injury is associated with an immediate arrest of respiration and sometimes with bradycardia and cardiac arrest. The effects on the brain of these systemic changes may in themselves be sufficiently profound to cause coma. Also, head injury often complicates alcohol and drug ingestion, so that the possibility of a toxic or metabolic encephalopathy as the cause (or a contributing cause) of stupor must always be considered.

Within this category of severe head injury and protracted coma, *three clinical subgroups can be recognized: one* in which cerebral and other bodily injuries are severe and may be incompatible with survival; *a second* in which improvement sets in within a few days or a week or two, followed by variable degrees of recovery but leaving the patient with residual neurologic signs; and *a third* and relatively small group in which the patients remain permanently comatose, stuporous, or profoundly reduced in their cerebral capacities, i.e., in the so-called vegetative and minimally conscious states (see Chap. 17). Of course there are many degrees of injury that fall between these three arbitrary subgroups. In all of these patients, following the initial period of stabilization, the matters of interest are the clinical and radiologic assessments, with the purpose of uncovering a surgically remediable lesion—namely a subdural or epidural hematoma—or a treatable intraparenchymal hematoma. In most cases, the discovery of such a mass lesion mandates surgical removal. But unless it is the only lesion, the procedure often proves to be insufficient and coma is likely to persist because of the associated cerebral damage. The recognition and management of these hematomas are described further on.

The *first subgroup* comprises patients who are so severely injured that their lives are obviously endangered. When first seen, such a patient may be in shock (possibly from rupture of a visceral organ or injury of the cervical cord), with hypotension, hypoxia, hypothermia, a fast thready pulse, and pale, moist skin. If this state persists along with deep coma, widely dilated fixed pupils, absent eye movements and corneal and pharyngeal reflexes, flaccid limbs, stertorous and irregular respirations or respiratory failure, death usually follows in a short time. Once respiration ceases and the electroencephalogram (EEG) becomes isoelectric, the clinical state corresponds to brain death, as described on page 306. However, the diagnosis of brain death should not be made immediately after injury, in order to allow time to exclude the effects of anoxia, drug or alcohol intoxication, and hypotension. In some of these patients, the blood pressure and respirations stabilize; the degree of cerebral injury can then be evaluated over a period of hours by observing the depth of coma and the temperature, pulse, and blood pressure. Deep coma with subnormal temperature and rising pulse rate are grave prognostic signs, as are a rapidly rising temperature and pulse rate with rapid, irregular respirations. In some fatal cases, the tem-

perature continues to rise until the end, when there is circulatory collapse.

In this category of severe cerebral injury, where the patients survive for only a few hours or days, postmortem examination commonly discloses cerebral contusion and focal hemorrhage, necrosis of tissue, and brain swelling. In the Traumatic Coma Data Bank, which included 1030 gravely injured patients with Glasgow Coma Scale scores of 8 or less, 21 percent had subdural hematomas, 11 percent had intracerebral clots, and 5 percent had epidural hematomas. Notable, however, is the fact that half the patients had no mass lesions on the CT scan. On the basis of CT criteria, these patients were thought to have diffuse axonal injury. However, in 50 consecutive autopsies of severely injured patients, summarized in an earlier era by Rowbotham, all but two showed macroscopic changes, indicating the relative unreliability of CT analysis. The lesions in these cases consisted of surface contusions (48 percent), lacerations of the cerebral cortex (28 percent), subarachnoid hemorrhage (72 percent), subdural hematoma (15 percent), extradural hemorrhage (20 percent), and skull fractures (72 percent). As these figures indicate, several of these changes were found in the same patient. Moreover, trauma of extracranial organs and tissues is frequent and obviously contributes to the fatal outcome.

Among patients who survived and remained vegetative until death, Adams and colleagues (2000) found that 80 percent had thalamic damage and 71 percent had findings of diffuse axonal injury, as discussed earlier. This leaves in somewhat ambiguous status the proximate cause of the persistent vegetative state after blunt head injury, but it does emphasize the frequency of bilateral thalamic damage in cases of the vegetative state from all causes.

In respect to the second subgroup, i.e., the relatively less severe and seldom fatal head injuries, all gradations in tempo and degree of recovery can be observed. In the least severely injured of this group, recovery of consciousness begins in a few hours, although there may be a relapse within the first day or two as a result of swelling of the contused brain tissue, enlargement of a subdural hematoma, brain hemorrhage, or infarction, the last provoked by arterial spasm in relation to subarachnoid hemorrhage. The CSF is usually bloody. Eventually, recovery may be nearly complete, but the period of traumatic amnesia covers a span of several days or even weeks.

In this second subgroup, the sequence of clinical events is the same as that described in relation to concussion except that their duration is more protracted. Stupor gives way to a confusional state that may last for weeks, and it may for a variable period be associated with aggressive behavior and uncooperativeness (traumatic delirium). The period of traumatic amnesia is proportionately longer than in the less severely injured. It is during the period of recovery of consciousness that focal neurologic signs (hemiparesis, aphasia, abulia, etc.) become more obvious, though some unilateral signs may have been detected during the comatose period. Once the patient improves to the point of being able to converse, he is demonstrably slow in thinking, with few mental associations; unstable in emotional reactions; and faulty in judgment—a state sometimes referred to as “traumatic dementia.”

Finally there is that relatively small, distressing group of severely brain-injured patients in whom the vital signs become normal but who *never regain full consciousness*. As the weeks pass, the prospects become more bleak. Such a patient, especially if a child, may still emerge from coma after 6 to 12 weeks and make a surprisingly good though usually incomplete recovery, but such instances are decidedly rare. Some of those who survive for long periods open their eyes and move their heads and eyes from side

to side but betray no evidence of seeing or recognizing even the closest members of their families. They do not speak and are capable of only primitive postural or reflex withdrawal movements. Jennett and Plum referred to this as the “persistent vegetative state” (see page 305). Fourteen percent of the patients in the Traumatic Coma Data Bank remained in this state. Hemiplegia or quadriplegia with varying degrees of decerebrate or decorticate posturing is usually demonstrable. Life is mercifully terminated after several months or years by some medical complication. Our colleague R. D. Adams has examined the brains of 14 patients who remained in coma and in vegetative states from one to 14 years. All showed extensive zones of necrosis and hemorrhage in the upper brainstem.

In generalizing about this category of head injury, i.e., patients who are and have been comatose from the time of injury, the effects of contusion, hemorrhage, and brain swelling often become evident within 18 to 36 h after the injury and then may progress for several days. If the patients survive this period, their chances of dying from complications of these effects—such as increased intracranial pressure, herniations of the temporal lobe, subdural hemorrhage, hypoxia, and pneumonia—are greatly reduced. The mortality rate of those who reach the hospital in coma is about 20 percent, and most of the deaths occur in the first 12 to 24 h as a result of direct injury to the brain in combination with other nonneurologic injuries. Of those alive at 24 h, the overall mortality falls to 7 to 8 percent; after 48 h, only 1 to 2 percent succumb. There is some evidence that transfer of such patients to an intensive care unit, where they can be monitored by personnel experienced in the handling of head injury, improves the chances for survival (see further on).

Concussion Followed by a Lucid Interval and Serious Cerebral Damage

This group is smaller than the other two but is of great importance because it includes a disproportionate number of patients who are in urgent need of surgical treatment. The initial coma may have lasted only a few minutes or, exceptionally, there may have been none at all—in which instance one might wrongly conclude that since there was no concussion, there is no possibility of traumatic hemorrhage or other type of brain injury. Patients who display this sequence of events, referred to as “talk and die” by Marshall and associates, deteriorate because of the delayed expansion of a small subdural hematoma, worsening brain edema, or occasionally the late appearance of an epidural clot. Among 34 such patients in the Traumatic Coma Data Bank, the majority showed substantial degrees of midline shift on the initial CT scan, reflecting the presence of early brain edema and contusion (Marshall et al). A similar condition of delayed intracerebral hematoma, discussed further on (*Spätapoplexie*), is a feature of a more severe initial head injury that engenders coma from the onset.

SPECIFIC TRAUMATIC CRANIAL LESIONS (Table 35-2)

The following conditions must be considered in all cases of these delayed types but occur as often with serious initial injury.

Acute Epidural Hemorrhage

As a rule, this arises with a temporal or parietal fracture and laceration of the middle meningeal artery or vein. Less often, there is a tear in a dural venous sinus. The injury, even when it fractures the skull, may not have produced coma initially, or it may be part

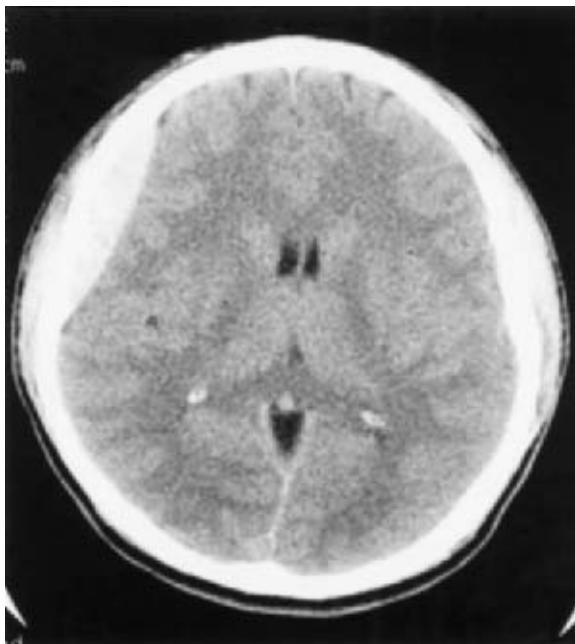

Figure 35-8. Acute epidural hematoma; unenhanced CT scan showing a typical lens-shaped frontal epidural clot.

of a devastating craniocerebral injury. A typical example is that of a child who has fallen from a bicycle or swing or has suffered some other hard blow to the head and was unconscious only momentarily. A few hours or a day later (exceptionally, with venous bleeding the interval may be several days or a week), headache of increasing severity develops, with vomiting, drowsiness, confusion, aphasia, seizures (which may be one-sided), hemiparesis with slightly increased tendon reflexes, and a Babinski sign. As coma develops, the hemiparesis may give way to bilateral spasticity of the limbs and Babinski signs. The pulse is often slow (below 60 beats per minute) and bounding, with a concomitant rise in systolic blood pressure (Cushing effect). The pupil may dilate on the side of the hematoma. Physicians need not be reminded that lumbar puncture is contraindicated in this setting, particularly now that CT and MRI are available. Death, which is almost invariable if the clot is not removed surgically, comes at the end of a comatose period and is due to respiratory arrest. The visualization of a fracture line across the groove of the middle meningeal artery and knowledge of which side of the head was struck (the clot is usually on that side) are of aid in diagnosis and lateralization of the lesion. However, meningeal vessels may occasionally be torn without fracture. The CT scan reveals a lens-shaped clot with a smooth inner margin (Fig. 35-8). The surgical procedure consists of placement of burr holes in an emergency situation or, preferably, a craniotomy, drainage of the hematoma, and identification and ligation of the bleeding vessel. The operative results are excellent except in cases with extended fractures and laceration of the dural venous sinuses, in which the epidural hematoma may be bilateral rather than unilateral. If coma, bilateral Babinski signs, spasticity, or decerebrate rigidity supervene before operation, it usually means that displacement of central structures and crushing of the midbrain have already occurred; prognosis is then poor. Small epidural hemorrhages, followed by serial CT scanning, will be seen to enlarge gradually for a week or two and then be absorbed. There is always controversy about removing these in a patient who has no symptoms;

if the clot is small and there is careful surveillance, they can be left alone.

Acute and Chronic Subdural Hematomas

The problems created by acute and chronic subdural hematomas are so different that they must be discussed separately. In *acute subdural hematoma*, which may be unilateral or bilateral, there may be a brief lucid interval between the blow to the head and the advent of coma. Or, more often, the patient is comatose from the time of the injury and the coma deepens progressively. Frequently the acute subdural hematoma is combined with epidural hemorrhage, cerebral contusion, or laceration. The clinical effects of these several lesions are difficult to distinguish; there are some patients in whom it is impossible to state before operation whether the clot is epidural or subdural in location. Subdural clots more than 5 mm thick can be accurately visualized by the CT scan in more than 90 percent of cases (Fig. 35-9). A large acute clot causes a pineal shift as well as marked compression of one lateral ventricle; but if the clots are bilateral, there may be no shift and the ventricles appear symmetrical.

Acute, rapidly evolving subdural hematomas are due to tearing of bridging veins, and symptoms are caused by compression of the brain by an expanding clot of fresh blood. Unlike epidural arterial hemorrhage, which is steadily progressive, venous bleeding is usually arrested by the rising intracranial pressure.

Exceptionally, *the subdural hematoma forms in the posterior fossa* and gives rise to headache, vomiting, pupillary inequality, dysphagia, cranial nerve palsies, and, rarely, stiff neck and ataxia of the trunk and gait if the patient is well enough to be tested for these functions. Because of their apposition to bone or their axial orientation along the tentorial dura, posterior fossa clots are more likely than clots over the cerebral convexities to be missed in CT scans.

In *chronic subdural hematoma*, the traumatic etiology is often

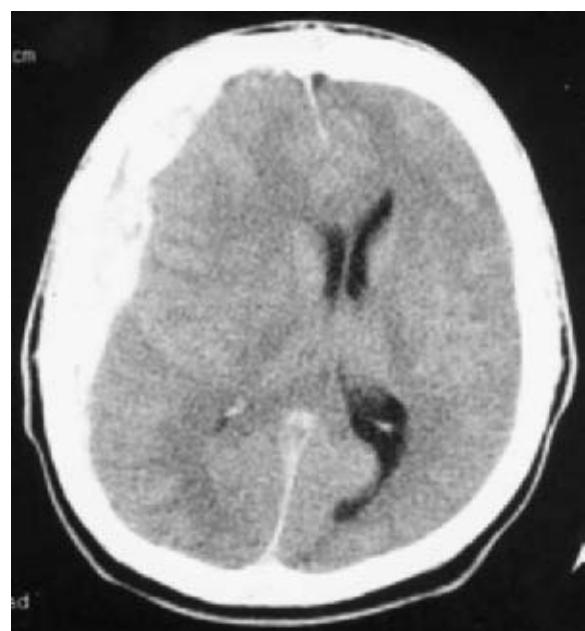

Figure 35-9. Acute subdural hematoma over the right convexity, with substantial mass effect (displacement) of brain tissue but little edema.

less clear. The head injury, especially in elderly persons and in those taking anticoagulant drugs, may have been trivial and may even have been forgotten. A period of weeks then follows when headaches (not invariable), light-headedness, slowness in thinking, apathy and drowsiness, unsteady gait, and occasionally a seizure or two are the main symptoms. The initial impression may be that the patient has a vascular lesion or brain tumor or is suffering from drug intoxication, a depressive illness, or Alzheimer disease. A gradual expansion of the hematoma is believed to cause the progression of symptoms. As with acute subdural hematoma, the disturbances of mentation and consciousness (drowsiness, inattentiveness, incoherence of thinking, and confusion) are more prominent than focal or lateralizing signs, and they may fluctuate. The focal signs usually consist of hemiparesis and rarely of an aphasic disturbance. Homonymous hemianopia is seldom observed, probably because the geniculocalcarine pathway is deep and not easily compressed; similarly, hemiplegia, i.e., complete paralysis of one arm and leg, is usually indicative of a lesion within the cerebral hemisphere rather than a compressive lesion on its surface. An important feature of the hemiparesis from subdural hematoma, when it occurs, is that it may sometimes be ipsilateral to the clot, as a result of compression of the contralateral cerebral peduncle against the free edge of the tentorium by horizontal displacement of the mid-brain (Kernohan-Woltman false localizing sign; see page 310). If the condition progresses, the patient becomes stuporous or comatose, but this course is often interrupted by striking fluctuations of awareness.

With both large acute and chronic hematomas, dilatation of the ipsilateral pupil is a fairly reliable indicator of the side of the hematoma, though this sign may be misleading (occurring on the opposite side in 10 percent of cases, according to Pevehouse and co-workers). Convulsions are seen occasionally, most often in alcoholics or in patients with cerebral contusions, but they cannot be regarded as a cardinal sign of subdural hematoma. Rare cases of internuclear ophthalmoplegia and of chorea have been reported but have not occurred in our material. Presumably they are a result of distortion of deep structures. Also, transient disturbances of neurologic function simulating transient ischemic attacks (TIAs) may occur. In infants and children, enlargement of the head, vomiting, and convulsions are prominent manifestations of subdural hematoma.

CT scanning with contrast infusion and MRI are the most reliable diagnostic procedures. On CT scans, the acute clot is initially hyperdense but becomes isodense after a period of time (Fig. 35-10), during which it may be difficult to detect except by the tissue shifts it causes. It then becomes progressively hypodense (with respect to the cortex) over 2 to 6 weeks. The evolution of signal changes in the MRI is similar to the sequential imaging changes found with parenchymal hematomas. The acute clot is hypointense on T2-weighted images, reflecting the presence of deoxyhemoglobin. Over the subsequent weeks, all image sequences show it as hyperintense as a result of methemoglobin formation. Eventually the chronic clot again becomes hypointense on the T1-weighted images. With contrast infusion, both imaging procedures usually reveal the vascular and reactive border surrounding the clot. Usually, by the fourth week, sometimes later, the hematoma becomes hypodense, typical of a chronic subdural hygroma.

Other formerly used investigative measures are seldom necessary but are mentioned here for completeness and in the event that the diagnosis is made in the course of evaluating some other neurologic problem. Skull films are helpful when there is calcification surrounding a chronic hematoma, a calcified pineal that is

Figure 35-10. Subacute subdural hematoma on the left (reader's right). CT scans after administration of intravenous contrast material. The lesion is isodense to the adjacent brain tissue, but its margin can be appreciated with contrast enhancement. Note displacement of cerebral structures.

shifted to one side, or an unexpected fracture line is found. The EEG is usually abnormal bilaterally, sometimes with reduced voltage over the hematoma and high-voltage slow waves over the opposite side. In an arteriogram, the cortical branches of the middle cerebral artery are separated from the inner surface of the skull, and the anterior cerebral artery may be displaced contralaterally. The CSF may be clear and acellular but more often is bloody or xanthochromic depending on the presence or absence of recent or old contusions and subarachnoid hemorrhage; the pressure may be elevated or normal. A xanthochromic fluid with relatively low protein content should always raise the suspicion of chronic subdural hematoma.

The chronic subdural hematoma becomes gradually encysted by fibrous membranes (pseudomembranes) that grow from the dura. Some hematomas—probably those in which the initial bleeding was slight (see below)—resorb spontaneously. Others expand slowly and act as space-occupying masses (Fig. 35-11). Gardner, in 1932, first postulated that the gradual enlargement of the hematoma was due to the accession of fluid, particularly CSF, which was drawn into the hemorrhagic cyst by its increasing osmotic tension as red blood cells (RBCs) hemolyzed and protein was liberated. This hypothesis, which came to be widely accepted, is not supported by the available data. Rabe and colleagues demonstrated that the breakdown of RBCs contributes little if at all to the accumulation of fluid in the subdural space. According to the latter authors, the most important factor in the accumulation of subdural fluid is a pathologic permeability of the developing capillaries in the outer pseudomembrane of the hematoma. The CSF plays no discernible role in this process, contrary to the original view of Munro and Merritt. In any event, as the hematoma enlarges, the compressive effects increase gradually. Severe cerebral compression and displacement with temporal lobe–tentorial herniation are the usual causes of death.

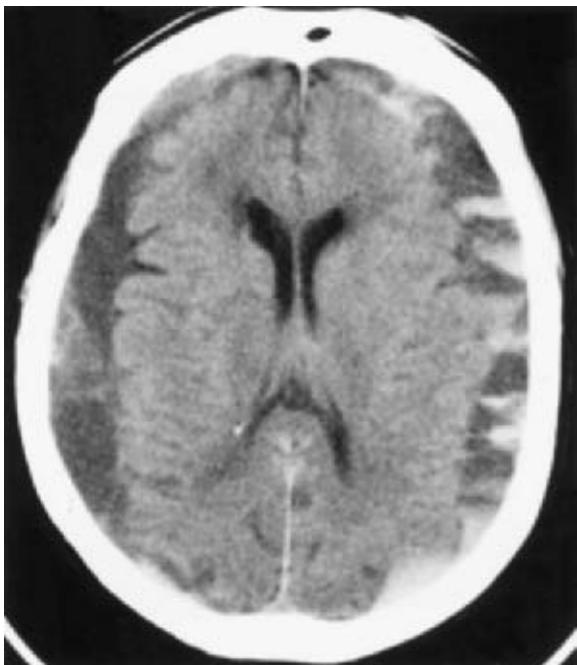

Figure 35-11. Chronic subdural hematomas over both cerebral hemispheres, without shift of the ventricular system. Chronicity results in hypodense appearance of the clots. Some old blood can still be seen on the right side. The bilaterally balanced masses result in an absence of horizontal displacement, but they may compress the upper brainstem.

Why somewhat less than one-half of all subdural hematomas remain solid and nonenlarging and the remainder liquefy and then enlarge is not known. The experimental observations of Labadie and Glover suggest that the volume of the original clot is a critical factor: the larger its initial size, the more likely it will be to enlarge. An inflammatory reaction, triggered by the breakdown products of blood elements in the clot, appears to be an additional stimulus for growth as well as for neomembrane formation and its vascularization.

Treatment of Subdural Hematoma In most cases of acute hematoma, it is sufficient to place burr holes and evacuate the clot before deep coma has developed. Treatment of larger hematomas, particularly after several hours have passed and the blood has clotted, consists of wide craniotomy to permit control of the bleeding and removal of the clot. As one would expect, the interval between loss of consciousness and the surgical drainage of the clot is perhaps the most important determinant of outcome in serious cases. Thin, crescentic clots can be observed and followed over several weeks and surgery undertaken only if focal signs or indications of increasing intracranial pressure arise (headache, vomiting, and bradycardia). Small subdural hematomas causing no symptoms and followed by CT scans will self-absorb, leaving only a deep yellow, sometimes calcified membrane attached to the inner dural surface. If the acute clot is too small to explain the coma or other symptoms, there is probably extensive contusion and laceration of the cerebrum.

To remove the more chronic hematomas, a craniotomy must be performed and an attempt made to strip the membranes that surround the clot. This diminishes the likelihood of reaccumulation of fluid but it is not always successful. Other causes of operative failure are swelling of the compressed hemisphere or failure of the

hemisphere to expand after removal of a large clot. The difficulty of managing these patients surgically should not be underestimated. Elderly patients may be slow to recover after removal of the chronic hematoma or may have a prolonged period of confusion. Postoperative expansion of the brain can be followed by serial CT scans and may take weeks. Small, asymptomatic chronic collections are usually left alone and followed serially by clinical and CT examination, first at weekly and then monthly and yearly intervals.

Although no longer a common practice, the administration of corticosteroids is an alternative to surgical removal of subacute and chronic subdural hematomas in patients with minor symptoms or with some contraindication to surgery. Headache and other symptoms, such as gait difficulty or limb clumsiness, may resolve satisfactorily after several weeks of medication and may remain abated when the steroids are slowly reduced.

Subdural Hygroma

This encapsulated collection of clear or xanthochromic fluid in the subdural space may form after an injury as well as after meningitis (in an infant or young child). More often subdural hygromas appear without infection, presumably due to a ball-valve effect of an arachnoidal tear that allows cerebrospinal fluid to collect in the space between the arachnoid and the dura; brain atrophy is conducive to this process. Occasionally a hygroma originates from a tear in an arachnoidal cyst. It may be difficult to differentiate a long-standing subdural hematoma from hygroma, and some chronic subdural hematomas are probably the result of repeated small hemorrhages that arise from the membranes of hygromas. Shrinkage of the hydrocephalic brain after ventriculoperitoneal shunting is also conducive to the formation of a subdural hematoma or hygroma, in which case drowsiness, confusion, irritability, and low-grade fever are relieved when the subdural fluid is aspirated or drained. In adults, hygromas are usually asymptomatic and do not require treatment.

Cerebral Contusion

Severe closed head injury is almost universally accompanied by cortical contusions and surrounding edema. The mass effect of contusional swelling, if sufficiently large, is a major factor in the genesis of tissue shifts and raised intracranial pressure. The CT appearance of contusion has already been described (page 751; see also Figs. 35-4 and 35-5). In the first few hours after injury, the bleeding points in the contused area may appear small and innocuous. The main concern, however, is the tendency for a contused area to swell or to develop into a hematoma. This may give rise to clinical deterioration hours to days after the injury, sometimes abrupt in onset and concurrent with the appearance of swelling of the damaged region on the CT scan. It has been claimed, on uncertain grounds, that the swelling in the region of an acute contusion is precipitated by excessive administration of intravenous fluids (fluid management is considered further on in this chapter). Craniotomy and decompression of the swollen brain is usually of little benefit.

Traumatic Intracerebral Hemorrhage

One or several intracerebral hemorrhages may be apparent immediately after head injury, or hemorrhage may be infrequently delayed in its development by several days (*Spätapoplexie*). The bleeding is in the subcortical white matter of one lobe of the brain

or in deeper structures, such as the basal ganglia or thalamus. The injury is nearly always severe; blood vessels as well as cortical tissue are torn.

The clinical picture of traumatic intracerebral hemorrhage is similar to that of hypertensive brain hemorrhage (deepening coma with hemiplegia, a dilating pupil, bilateral Babinski signs, stertorous and irregular respirations). It may be manifest by an abrupt rise in blood pressure and in intracranial pressure. In elderly patients, it is sometimes difficult to determine whether a fall had been the cause or the result of an intracerebral hemorrhage. Craniotomy with evacuation of the clot has given a successful result in a few cases, but the advisability of surgery is governed by several factors, including the level of consciousness, the time from the initial injury, and the associated damage (contusions, subdural and epidural bleeding) shown by imaging studies. The wider application of intracranial pressure monitoring and of CT scans at intervals after the injury should facilitate diagnosis and perhaps help to elucidate the pathogenesis of delayed hemorrhages. Boto and colleagues determined that basal ganglia hemorrhages were prone to enlarge in the day or two after closed head injury and that those over 25 mL in volume were fatal in 9 of 10 cases.

It should be mentioned again that subarachnoid blood of some degree is very common after serious head injury. A problem that sometimes arises in cases that display both contusions and substantial subarachnoid blood is the possibility that a ruptured aneurysm was the initial event and that a resultant fall caused the contusions. In cases where the subarachnoid blood is concentrated around one of the major vessels of the circle of Willis, an angiogram may be justified to exclude the latter possibility. This subject is addressed in Chap. 34.

Acute Brain Swelling in Children

This condition is seen in the first hours after injury and may prove rapidly fatal. The CT scan shows enlargement of both hemispheres and compression of the basal cisterns and ventricles. There is usually no papilledema in the early stages, during which the child hyperventilates, vomits, and shows extensor posturing. The assumption has been that this represents a loss of regulation of cerebral blood flow and a massive increase in the blood volume of the brain. The administration of excessive water in intravenous fluids may contribute to the problem and should be avoided. Inappropriate secretion of antidiuretic hormone (ADH) also exaggerates the swelling in some children. We have not observed this complication in adults.

“Shaken Baby” Syndrome

This form of craniocerebral trauma in infants is well known in large emergency practices but can be missed if not specifically considered. As the name implies, the inciting trauma is typically violent shaking of the body or head of an infant, resulting in rapid acceleration and deceleration of the cranium combined with cervical whiplash. The presence of this type of injury must often be inferred from the combination of lesions on imaging studies or autopsy examination, but precision in examination is paramount because of its forensic and legal implications. The diagnosis is suspected from the combination of subdural hematomas and retinal hemorrhages, as summarized by Bonnier and colleagues. Sometimes there are occult skull fractures, but more often, there is little or no direct cranial trauma. Additional lesions may be evident on diffusion-

weighted MRI, particularly in the white matter of the corpus callosum and the temporo-occipito-parietal region. This syndrome confers a high risk for slowing of development; there may be acquired microcephaly reflecting brain atrophy consequent to both contusions and infarctions. A low initial Glasgow Coma Scale score, severe retinal hemorrhages, and skull fractures are associated with poor outcomes. Old and recent fractures in other parts of the body should arouse suspicion of this syndrome.

Penetrating Wounds of the Head

Missiles and Fragments The descriptions in the preceding pages apply to blunt, nonpenetrating injuries of the skull and their effects on the brain. The disorders included in this section are more the concern of the neurosurgeon than the neurologist. In the past, the care of penetrating craniocerebral injuries was mainly the preoccupation of the military surgeon, but—with the increasing amount of violent crime in society—such cases have become commonplace on the emergency wards of general hospitals.

In civilian life, *missile injuries* are essentially caused by bullets fired from rifles or handguns at high velocities. Air is compressed in front of the bullet so that it has an explosive effect on entering tissue and causes damage for a considerable distance around the missile track. *Missile fragments*, or *shrapnel*, are pieces of exploding shells, grenades, or bombs and are the usual causes of penetrating cranial injuries in wartime. The cranial wounds that result from missiles and shrapnel have been classified by Purvis as tangential, with scalp lacerations, depressed skull fractures, and meningeal and cerebral lacerations; penetrating, with in-driven metal particles, hair, skin, and bone fragments; and through-and-through wounds. In most penetrating injuries from high-velocity missiles, the object (such as a bullet) causes a high-temperature coagulative lesion that is sterile and fortunately does not require surgery. In these instances, the main considerations are the development of infection or CSF leaks or, in the long term, epilepsy or aneurysms in distal blood vessels. The latter are considered to be the result of disruption of the vessel wall by the high-energy shock wave.

If the brain is penetrated at the lower levels of the brainstem, death is instantaneous because of respiratory and cardiac arrest. Even through-and-through wounds at higher levels, as a result of energy dissipated in the brain tissue, may damage vital centers sufficiently to cause death immediately or within a few minutes in 80 percent of cases. If vital centers are untouched, the immediate problem is intracranial bleeding and rising intracranial pressure from swelling of the traumatized brain tissue.

Once the initial complications are dealt with, the surgical problems, as outlined by Meirowsky, are reduced to three: prevention of infection by rapid and radical (definitive) debridement, accompanied by the administration of broad-spectrum antibiotics; control of increased intracranial pressure and shift of midline structures by removal of clots of blood and the vigorous administration of mannitol or other dehydrating agents as well as dexamethasone; and the prevention of life-threatening systemic complications.

When first seen, the majority of patients with penetrating cerebral lesions are comatose. A small metal fragment may have penetrated the skull without causing concussion, but this is not true of high-velocity missiles. In a series of 132 patients of the latter type analyzed by Frazier and Ingham, consciousness was lost in 120. The depth and duration of coma seemed to depend on the degree of cerebral necrosis, edema, and hemorrhage. In the series of the

Traumatic Coma Data Bank, the mortality rate in 163 patients who were initially comatose from a cranial gunshot wound was 88 percent—more than twice the mortality that results from severe blunt head injury. On emerging from coma, the patient passes through states of stupor, confusion, and amnesia, not unlike those following severe closed head injuries. Headache, vomiting, vertigo, pallor, sweating, slowness of pulse, and elevation of blood pressure are other common findings. Focal or focal and generalized seizures occur in the early phase of the injury in some 15 to 20 percent of cases.

Recovery may take many months. Frazier and Ingham comment on the “loss of memory, slow cerebration, indifference, mild depression, inability to concentrate, sense of fatigue, irritability, vasomotor and cardiac instability, frequent seizures, headaches and giddiness, all reminiscent of the residual symptoms from severe closed head injury with contusions.” Every possible combination of focal cerebral symptoms may be caused by such lesions. The classic articles by Feiring and Davidoff and also by Russell and by Teuber, listed at the end of this chapter, are still very useful references on this subject.

Epilepsy is the most troublesome sequela and is described below. Ascrott and also Caveness, in reviewing World War II cases, found that approximately half of all patients with wounds that had penetrated the dura eventually developed epilepsy, most often focal in nature; the figures reported by Caveness for Korean War veterans are about the same.

CSF rhinorrhea, discussed earlier and in Chap. 30, may occur as an acute manifestation of a penetrating injury that produces a fracture through the frontal, ethmoid, or sphenoid bones. Cairns listed these acute cases as a separate group in his classification of CSF rhinorrheas, the others being (1) a delayed form after craniocerebral injury, (2) a form that follows sinus and cranial surgery, and (3) a spontaneous variety. *Pneumoencephalocele (aerocele)*—i.e., air entering the cerebral subarachnoid space or ventricles spontaneously or as a result of sneezing or blowing the nose—is evidence of an opening from the paranasal sinus through the dura, as mentioned earlier in relation to skull fracture (Fig. 35-3).

Crushing Injuries of the Skull Aside from the absence of concussion, these relatively rare cerebral lesions present no special clinical features or neurologic problems not already discussed.

Birth Injuries These involve a unique combination of physical forces and circulatory-oxygenation factors and are discussed separately in Chap. 38.

SEQUELAE OF HEAD INJURY

Posttraumatic Epilepsy Epilepsy is the most common delayed sequela of craniocerebral trauma, with an overall incidence of about 5 percent in patients with closed head injuries and 50 percent in those who had sustained a compound skull fracture and wound of the brain. The basis is nearly always a contusion or laceration of the cortex. As one might expect, the risk of developing posttraumatic epilepsy is also related to the overall severity of the closed head injury. In a civilian cohort of 2747 head-injured patients described by Annegers and colleagues, the risk of seizures after severe head injury (loss of consciousness or amnesia for more than 24 h, including subdural hematoma and brain contusion) was 7 percent within 1 year and 11.5 percent in 5 years. If the injury was only moderate (unconsciousness or amnesia for 30 min to 24 h or caus-

ing only a skull fracture), the risk fell to 0.7 and 1.6 percent, respectively. After mild injury (loss of consciousness or amnesia of less than 30 min), the incidence of seizures was not significantly greater than in the general population. In a subsequent study (1998), Annegers et al expanded the original cohort to include 4541 children and adults with cerebral trauma. The results were much the same as those of the first study except that in patients with mild closed head injuries, there was only a slight excess risk of developing seizures—a risk that remained elevated only until the fifth year after injury. The likelihood of epilepsy is said to be greater in parietal and posterior frontal lesions, but it may arise from lesions in any area of the cerebral cortex. Also, the frequency of seizures is considerably higher after penetrating cranial injury, as cited above.

The interval between the head injury and the first seizure varies greatly. A small number of patients have a generalized seizure within moments of the injury (*immediate epilepsy*). Usually this amounts to a brief tonic extension of the limbs, with slight shaking movements immediately after concussion, followed by awakening in a mild confusional state. Whether this represents a true epileptic phenomenon or, as appears more likely, is the result of arrest of cerebral blood flow or a transient brainstem dysfunction is unclear. Some 4 to 5 percent of hospitalized head-injured individuals are said to have one or more seizures within the first week of their injury (*early epilepsy*). The immediate seizures have a good prognosis and we tend not to treat them as if they represented epilepsy; on the other hand, late seizures are significantly more frequent in patients who had experienced epilepsy in the first week after injury (not including the convulsions of the immediate injury) (Jennett). In medical writings, the term *posttraumatic epilepsy* usually refers to late epilepsy, i.e., to seizures that develop several weeks or months after the head injury (1 to 3 months in most cases). Approximately 6 months after injury, half the patients who will develop epilepsy have had their first episode; by the end of 2 years, the figure rises to 80 percent (Walker). The interval between head injury and development of seizures is said to be longer in children. The longer the interval, the less certain one is of its relation to the traumatic incident. Data derived from a 15-year study of military personnel with severe (penetrating) brain wounds indicate that patients who escape seizures for 1 year after injury can be 75 percent certain of remaining seizure-free; patients without seizures for 2 years can be 90 percent certain; and for 3 years, 95 percent certain. For the less severely injured (mainly closed head injuries), the corresponding times are 2 to 6 months, 12 to 17 months, and 21 to 25 months (Weiss et al). Despite this, there is no doubt that seizures in adulthood occur for which there is no other explanation than a scarred cortical contusion that had been acquired decades before.

Posttraumatic seizures (both focal and generalized) tend to decrease in frequency as the years pass, and a significant number of patients (10 to 30 percent, according to Caveness) eventually stop having them. Status epilepticus is uncommon. Individuals who have early attacks (within a week of injury) are more likely to have a complete remission of their seizures than those whose attacks begin a year or so after injury. A low frequency of attacks is another favorable prognostic sign. Alcoholism has an adverse effect on this seizure state. Our colleagues have observed some 25 patients with posttraumatic epilepsy in whom seizures had ceased altogether for several years, only to recur in relation to drinking. In these patients the seizures were precipitated by a weekend or even one evening of heavy drinking and occurred, as a rule, not when the patient was intoxicated but in the “sobering-up,” or withdrawal, period.

The nature of the epileptogenic lesion has been elusive aside from the presence of a cortical scar. From the examination of old cortical contusions (*plaques jaunes*), one cannot, on morphologic grounds, determine whether a lesion had or had not been epileptogenic. Electrocorticograms of the brain in regions adjacent to old traumatic foci reveal a number of spontaneously electrically active zones adjacent to the scars. Microscopically, these foci show neuronal loss and an increase of astrocytes. It is postulated that abnormalities of dendritic branching provide the groundwork for the excitatory focus. Other investigators favor deafferentation of adjacent cortical neurons as the basis of their increased irritability.

Treatment and Prophylaxis Usually the seizures can be controlled by a single anticonvulsant medication, and relatively few are recalcitrant to the point of requiring excision of the epileptic focus. In this small group, the surgical results vary according to the methods of patient selection and techniques of operation. Under the best of neurosurgical conditions three decades ago, with careful selection of cases, Rasmussen (also Penfield and Jasper) was able to eradicate seizures in 50 to 75 percent of cases by excision of the focus; the results currently are somewhat better.

The use of anticonvulsant drugs to prevent the first seizure and subsequent epilepsy has its proponents and opponents. In one study, patients receiving phenytoin developed fewer seizures at the end of the first year than a placebo group, but a year after medication was discontinued, the incidence was the same (and quite low) in the two groups. In another prospective double-blind study, one group of patients was given 60 mg phenobarbital and 200 mg phenytoin daily for 18 months and another group was untreated; at the end of 3- and 6-year periods, there was no significant difference in the occurrence of seizures between treated and untreated groups (Penry et al). Also, in a study of a large number of patients with penetrating head injuries, the prophylactic use of anticonvulsants was ineffective in preventing early seizures (Rish and Caveness), and this guides our own approach.

Autonomic Dysfunction Syndrome in Traumatic Coma A troublesome consequence of severe head injury, observed most often in comatose patients and those in the persistent vegetative state, is the occurrence of episodic seizures combined with violent extensor posturing, profuse diaphoresis, hypertension, and tachycardia lasting minutes to an hour. A slight fever may accompany the spells. Families and staff are greatly disturbed by the display, particularly when accompanying grimacing suggests suffering. These spells of excessive sympathetic activity and posturing may be precipitated by painful stimuli or by distention of a viscus, but often they arise spontaneously. The syndrome is often mistakenly identified as a seizure and in many texts is still incorrectly referred to as "diencephalic epilepsy," but it is more likely the result of the removal of suppressive cortical influences, allowing the hypothalamus to function independently of normal inhibitory mechanisms. A survey of 35 such patients by Baugley and colleagues identified diffuse axonal injury and a period of hypoxia as being the main associated injuries, and this has been our experience as well. Narcotics and diazepines have a slightly beneficial effect, but bromocriptine, which may be used in combination with sedatives or with small doses of morphine, has been most effective according to Rositch and Bullard.

Extrapyramidal and Cerebellar Disorders Following Trauma The question of a causative relationship between cerebral trauma and the development of Parkinson disease has been a controversial

issue for many years—usually with the conclusion that the condition does not exist and that any apparent relationship is superficial and coincidental. Most such patients probably had early symptoms of Parkinson disease, brought to light by the head injury. There are, however, rare cases, such as the one reported by Doder and colleagues, in which traumatic necrosis of the lenticular and caudate nuclei was followed, after a period of 6 weeks, by the onset of predominantly contralateral parkinsonian signs, including tremor, which progressed slowly and were unresponsive to L-dopa, and there are undoubtedly instances of parkinsonism following severe closed head injury and the vegetative state (Matsuda et al). An exception to these statements may be a parkinsonian syndrome in ex-boxers, as a manifestation of the "punch-drunk" syndrome (see below). Cerebellar ataxia is a rare consequence of cranial trauma unless the latter was complicated by cerebral anoxia (causing ataxia with myoclonus) or a hemorrhage strategically placed in the deep midbrain or cerebellum. When cerebellar ataxia is due to the trauma itself, it is frequently unilateral and the result of injury to the superior cerebellar peduncle. An ataxia or "apraxia" of gait may also reflect the presence of a communicating hydrocephalus (see below and Chap. 30).

"Punch-Drunk" Encephalopathy (Dementia Pugilistica) The cumulative effects of repeated cerebral injuries, observed in boxers who had engaged in many bouts over a long period of time, constitute a type of head injury that is difficult to classify. What is referred to is the development, after many years in the ring (sometimes toward the end of the boxer's career, more often within a few years of retirement), of dysarthric speech and a state of forgetfulness, slowness in thinking, and other signs of dementia. Movements are slow, stiff, and uncertain, especially those involving the legs, and there is a shuffling, wide-based gait. In other words, a parkinsonian and dementing syndrome emerges and sometimes a moderately disabling ataxia, but there is no mistaking these for idiopathic Parkinson disease. The plantar reflexes may be extensor on one or both sides. The EEG contains slow waves of theta and sometimes delta frequency. The clinical syndrome was reanalyzed by Roberts and colleagues, who found it present to some degree in 37 of the 224 professional boxers they examined. More recent studies have shown that in about one-half of all professional boxers, both active and retired, the CT scan discloses ventricular dilatation and/or sulcal widening and a cavum septi pellucidi (why the latter, which is a developmental anomaly, would be overrepresented in boxers is unclear). These abnormalities had been demonstrated many years before, by pneumoencephalography, and were found to be related to the number of bouts (Ross et al; Casson et al).

A thorough pathologic study of this disorder has been made by Corsellis and associates. They examined the brains of 15 retired boxers who had shown the punch-drunk syndrome and identified a group of cerebral changes that appear to explain the clinical findings. Mild to moderate enlargement of the lateral ventricles and thinning of the corpus callosum were present in all cases. Also, practically all of them showed a greatly widened cavum septi pellucidi and fenestration of the septal leaves. Readily identified areas of glial scarring were situated on the inferior surface of the cerebellar cortex. In these areas and well beyond them, Purkinje cells were lost and the granule cell layer was somewhat thinned. Surprisingly, cerebral cortical contusions were found in only a few cases. Notably absent also was evidence of previous hemorrhage. Of the 15 cases, 11 showed varying degrees of loss of pigmented cells of the substantia nigra and locus ceruleus, and many of the

remaining cells showed the Alzheimer neurofibrillary change; Lewy bodies were not observed, however. The neurofibrillary changes were scattered diffusely through the cerebral cortex and brainstem but were most prominent in the mediotemporal gray matter. Noteworthy was the absence of discrete senile plaques in this material; however, all cases showed extensive immunoreactive deposits of β -amyloid ("diffuse plaques"). In three boxers who developed a parkinsonian syndrome, Davie and colleagues found a reduction of *N*-acetylaspartate in the putamen and pallidum by protein magnetic resonance spectroscopy. This probably reflected a loss of neurons in these regions and was said by these authors to differentiate it from idiopathic Parkinson disease. The pathogenesis of the punch-drunk state remains unclear.

Posttraumatic Hydrocephalus This is an uncommon complication of severe head injury. Intermittent headaches, vomiting, confusion, and drowsiness are the initial manifestations. Later on, mental dullness, apathy, and psychomotor retardation are seen; by this time the CSF pressure may have fallen to a normal level (normal-pressure hydrocephalus). Postmortem examinations have demonstrated an adhesive basilar arachnoiditis. Since a similar syndrome is observed occasionally after the rupture of a saccular aneurysm with subarachnoid hemorrhage, the same mechanisms, i.e., blocking of the aqueduct and fourth ventricle by blood clot and basilar meningeal fibrosis, may also be operative in traumatic hydrocephalus. Response to ventriculoperitoneal shunt may be dramatic. Zander and Foroglou have had extensive experience with this condition and have written informatively about it.

Posttraumatic Nervous Instability (Postconcussion Syndrome)

This troublesome and frequent sequela of head injury has been mentioned above as well as in the chapter on headache (page 158). When the syndrome is protracted, neurologists are vexed by the condition—a problem intensified by worried patients and family. It has also been called the *posttraumatic* or *postconcussion syndrome*, *posttraumatic headache*, *traumatic neurasthenia* (Symonds), and *traumatic psychasthenia*, among many other names. Headache is the central symptom, either generalized or localized to the part that had been struck. The headache is variously described as aching, throbbing, pounding, stabbing, pressing, or band-like and is remarkable for its variability. The intensification of the headache and other symptoms by mental and physical effort, straining, stooping, and emotional excitement has been mentioned earlier; rest and quiet tend to relieve it. Such headaches may present a major obstacle to convalescence. Dizziness, another prominent symptom, is usually not a true vertigo but a giddiness or light-headedness. The patient may feel unsteady, dazed, weak, or faint. However, a certain number of patients describe symptoms that are consonant with labyrinthine disorder. They report that objects in the environment move momentarily, and that looking upward or to the side may cause a sense of unbalance; labyrinthine tests may show hyporeactivity; far more often they disclose no abnormalities. McHugh found a high incidence of minor abnormalities by electronystagmography both in concussed patients and in those suffering from whiplash injuries of the neck; but we find some of the data difficult to interpret. Exceptionally, vertigo is accompanied by diminished excitability of both the labyrinth and the cochlea (deafness), and one may assume the existence of direct injury to the eighth nerve or end organ.

These symptoms clear up in several weeks in the majority of patients. When the symptoms persist, however, the patient is intolerant of noise, emotional excitement, and crowds. Tension, restlessness, fragmentation of sleep, inability to concentrate, feelings of nervousness, fatigue, worry, apprehension, and an inability to tolerate the usual amount of alcohol complete the clinical picture. The resemblance of these symptoms to those of anxiety and depression and to other forms of "posttraumatic stress disorder" is quite apparent. In contrast to this multiplicity of subjective symptoms, memory and other intellectual functions show little or no impairment, although this has been disputed. Leininger et al, for example, found that most of their 53 patients who suffered minor head injury in traffic accidents performed less well than controls on psychologic tests (category test, auditory verbal learning, copying of complex figures). The fact that those who were merely dazed did as poorly as those who were concussed and that litigation was involved in some cases would lead one to question these results. A further discussion of cognitive sequelae is found below.

The syndrome of posttraumatic nervous instability complicates all types of head injury, mild and severe. Once established, it may persist for months or even years, and it tends to resist all varieties of treatment. Eventually, the symptoms lessen. Strangely, this syndrome is almost unknown in children. Characteristic also is the augmentation of both the duration and intensity of this syndrome by problems with compensation and litigation, suggesting a psychologic factor. In countries where these matters are a less prominent part of the social fabric, the occurrence of posttraumatic syndrome is far less frequent. The constitution of the patient appears to be important. Stable, athletic, tough-fibered individuals take a concussive injury in stride, while the sensitive, nervous, complaining types may be so overwhelmed by such an accident that they are unable to expel it from their minds. Environmental stress assumes importance as well, for if too much is demanded of the patient soon after injury, irritability, insomnia, and anxiety are enhanced. In this connection, an interesting experiment was conducted by Mittenberg and colleagues. A group of subjects with no personal experience or knowledge of head injury were asked to select from a list those symptoms that they would expect after a concussive head injury. They chose a cluster of symptoms virtually identical to that of the postconcussion syndrome.

An approach to treating such patients is given further on, in the section on treatment, under "Patients with Only Transient Unconsciousness."

Other Posttraumatic Cognitive and Psychiatric Disorders In all patients with cerebral concussive injury, there remains a gap in memory (traumatic amnesia) spanning a variable period from before the accident to some point following it. This gap is permanent and is filled in only by what the patient is told. In addition, as stated in the introduction to this section, some degree of impairment of higher cortical function may persist for weeks (or be permanent) after moderate to severe head injuries, even after the patient has reached the stage of forming continuous memories. During the period of deranged mentation, the memory disorder is the most prominent feature; in that respect the state resembles the alcoholic form of the Korsakoff amnesic state and has some resemblance to the state of transient global amnesia (page 379). It has been repeatedly asserted that this amnesic state is a constant feature of every prolonged traumatic mental disorder, but to the authors it reflects in part the ease with which memory can be tested. With more careful testing, other cognitive disorders are evident. Concussed pa-

tients, during the period of posttraumatic amnesia, rarely confabulate and usually have an impaired ability to register events and information, an abnormality not ordinarily observed in patients entering the chronic phases of Korsakoff psychosis. Apart from disorientation in place and time, the head-injured patient also shows defects in attention as well as distractibility, perseveration, and an inability to synthesize perceptual data. Judgment may be mildly impaired, rarely severely, during the amnestic epoch. A perseverative tendency interferes with both action and thought.

As a general rule, the lower the score on the Glasgow Coma Scale immediately after injury (Table 35-1) and the longer the posttraumatic gap in the formation of memories (anterograde amnesia), the more likely the patient is to suffer permanent cognitive and personality changes. Abnormalities in these spheres were found in only 12 percent of head-injured patients who had been in coma for longer than 24 h (Sazbon et al). If respiration and motor function were normal (except for early decorticate posturing) and there was no extraneural trauma, 94 percent of the patients recovered. According to Jennett and Bond, patients with good recovery achieved their maximum degree of improvement within 6 months. Others have found that detailed and repeated psychologic testing over a prolonged period, even in patients with relatively minor cerebral injuries, discloses measurable improvement for as long as 12 to 18 months.

There are other mental and behavioral abnormalities of a more subtle type that remain as sequelae to cerebral injury. As the stage of posttraumatic dementia recedes, the patient may find it impossible to work or to adjust to his family situation. Such patients continue to be abnormally abrupt, argumentative, stubborn, opinionated, and suspicious. Unlike the traumatic mental disorder described above, in which there is a certain uniformity, these traits vary with the patient's age, constitution, past experience, and the environmental stresses to which he is subjected. Extremes of age are important. The most prominent behavioral abnormality in children, described by Bowman et al, is a change in character. They become impulsive, heedless of the consequences of their actions, and lacking in moral sense—much like those who had recovered from encephalitis lethargica. Some adolescents or young adults show the general lack of inhibition and impulsivity that one associates with frontal lobe disease. In the older person it is the impairment of intellectual functions that assumes prominence. In most instances these more serious behavioral changes can be traced to contusions in the frontal and temporal lobes.

The tendency is for all such symptoms to subside slowly though not always completely, even in those in whom an accident has provoked a frank outburst of psychosis (as may happen to a manic-depressive, paranoid schizophrenic, or neurotic patient). These forms of "traumatic insanity" were carefully analyzed for the first time by Adolf Meyer.

Hysterical symptoms that develop after head injury, both cognitive and somatic, appear to be more common than those following injury to other parts of the body. These symptoms are discussed in Chap. 56.

TREATMENT

Patients with Only Transient Unconsciousness

Patients with an uncomplicated concussive injury who have already regained consciousness by the time they are seen in a hospital and

have a normal neurological examination pose few difficulties in management. They should not be discharged until the appropriate examinations (CT scans, skull films, if necessary) have been made and the results prove to be negative. Also, the patient should not be released until the capacity for consecutive memories has been regained and arrangements have been made for observation by the family of signs of possible though unlikely delayed complications (subdural and epidural hemorrhage, intracerebral bleeding, and edema). Most such patients become mentally clear, have mild or no headache, and are found to have a normal neurologic examination. They do not require hospitalization or special testing, but in the current litigious climate of the United States, some form of brain imaging is nonetheless often performed. Acetaminophen may be prescribed for headache. Any increase in headache, vomiting, or difficulty arousing the patient should prompt a return to the emergency department.

The patients with persistent complaints of headache, dizziness, and nervousness, the syndrome that we have designated as *posttraumatic nervous instability*, are the most difficult to manage, as discussed above. A treatment program must be planned in accordance with the basic problem. If there is mainly an anxious depression, antidepressant medications—such as fluoxetine, paroxetine, or a tricyclic—are often useful. Simple analgesics, such as acetaminophen or nonsteroidal anti-inflammatory drugs, should be prescribed for the headache. Litigation should be settled as soon as possible. To delay settlement usually works to the disadvantage of the patient. Long periods of observation, repetition of a multitude of tests, and waiting only reinforce the patient's worries and fears and reduce the motivation to return to work. Neuropsychologic tests may be useful in the group with persistent cognitive difficulty, but the results should be interpreted with caution, since depression and poor motivation will degrade performance.

Patients with Severe Head Injury

If the physician arrives at the scene of an accident and finds an unconscious patient, a quick examination should be made before the patient is moved. First it must be determined whether the patient is breathing and has a clear airway and obtainable pulse and blood pressure, and whether there is dangerous hemorrhage from a scalp laceration or injured viscera. Severe head injuries that arrest respiration are soon followed by cessation of cardiac function. Injuries of this magnitude are often fatal; if resuscitative measures do not restore and sustain cardiopulmonary function within 4 to 5 min, the brain is usually irreparably damaged. Oxygen should be administered. Bleeding from the scalp can usually be controlled by a pressure bandage unless an artery is divided; then a suture becomes necessary. Resuscitative measures (artificial respiration and cardiac compression) should be continued until they are taken over by ambulance personnel.

The likelihood of a cervical fracture-dislocation, which may be associated with any severe head injury, is the reason for taking precautions in immobilizing the neck and moving the patient, as outlined on page 1054. In the awake patient, neck pain calls attention to this complication. It should be recalled that even in the absence of a spinal fracture, the spinal cord may be threatened by the instability resulting from ligamentous injuries (posing the risk of subluxation). In the study of 292 patients with cervical injuries by Demetriades and colleagues, 31 (11 percent) showed subluxations without fracture and 11 (4 percent) had cord injuries with neither fracture nor subluxation. The combined use of standard

cervical spine films and cervical CT scanning detected all cervical injuries. After severe head or neck injury, it is therefore advisable also to obtain standard anteroposterior, lateral, and oblique neck films, with additional gentle flexion (20°) and extension (30°) views of the neck and a neck CT scan. If these are normal and there is little or no neck pain, the cervical collar is no longer required. If these studies cannot be obtained or if there is significant persistent pain or other neurologic findings induced by head movement, a cervical MRI is advisable.

In the hospital, the first step is to clear the airway and ensure adequate ventilation by endotracheal intubation if necessary. A careful search for other injuries must be made, particularly of the abdomen, chest, spine, and long bones. Chestnut et al, in analyzing the data from the Traumatic Coma Data Bank, found that sustained early hypotension (systolic blood pressure <90 mmHg) was associated with a doubling of mortality. If shock was present on admission to the emergency ward, the mortality was 65 percent. Although the hypotension that follows some injuries is a vasodepressor response and usually comes under control without pressor drugs, a large, unimpeded intravenous line should be inserted. Persistent hypotension due to head injury alone is an uncommon occurrence and should always raise the suspicion of a ruptured viscus or thoracic or abdominal internal bleeding, extensive fractures, or trauma to the cervical cord. Initially, the infused fluid should be normal saline, avoiding the administration of excessive free water because of its adverse effect on brain edema. Oxygen should continue to be administered until it can be shown that the arterial oxygen saturation is normal without it.

A rapid survey can now be made, with attention to the depth of coma, size of the pupils and their reaction to light, ocular movements, corneal reflexes, facial movements during grimace, swallowing, vocalization, gag reflexes, muscle tone and movements of the limbs, predominant postures, reactions to pinch, and reflexes. Bogginess of the temporal or postauricular area (Battle sign), bleeding from the nose or ear, and extensive conjunctival edema and hemorrhage are useful signs of an underlying basal skull fracture. However, it should be remembered that rupture of an eardrum or a blow to the nose may also cause bleeding from these parts. Fracture of the orbital bones may displace the eye, with resulting strabismus; fracture of the jaw results in malocclusion and discomfort on attempting to open the mouth. If urine is retained and the bladder is distended, a catheter should be inserted and kept there. Temperature, pulse, respiration, blood pressure, arterial oxygen saturation, and state of consciousness should be checked and charted every hour. The *Glasgow Coma Scale*, mentioned above, has provided a practical means by which the state of impaired consciousness can be evaluated at frequent intervals (Table 35-1), but it should not be considered a substitute for a more complete neurologic examination. A deteriorating scale dictates a change in management.

CT scanning is of central importance at this juncture. A sizable epidural, subdural, or intracerebral blood clot is an indication for immediate surgery. The presence of contusions, brain edema, and displacement of central structures calls for measures to monitor progression of these lesions and to control intracranial pressure. These measures are best carried out in a critical care unit.

Management of Raised Intracranial Pressure It is the practice on some services to insert one of several available devices that permits continuous recording of intracranial pressure (ICP) in cases of moderate and severe head injury (Narayan et al). Pressure measurements through a lumbar puncture needle do not accurately re-

flect the ICP and increase the risk of a cerebellar or temporal lobe herniation. Nor do the neurologic signs that constitute the Glasgow Coma Scale reflect the pressure in the cranium. The arguments for and against monitoring the ICP have been addressed earlier (page 532). Our impression is that in comatose patients, monitoring of the ICP, at a minimum, prevents errors in fluid administration and refines all the other details of management, including the appropriate use of osmotic diuretics and the correct level of hyperventilation. In these respects, monitoring can be helpful. However, there are few critical data to support the routine use of ICP monitoring; certainly the patient who is only drowsy or shows only minimal mass effect on CT scanning is not likely to be of benefit. In the absence of data to help in making the decision regarding the insertion of these devices, as a practical guide we favor their use to warn of impending deterioration from brain edema or hemorrhage if the patient shows sustained drowsiness with inability to follow commands, has a Glasgow Coma Scale score of <8 , and has evidence of mass effect on a CT scan. The current generation of ICP monitors employs fiberoptic strain gauges that can be inserted directly into the cerebral cortex without apparent damage. While the risk of infection is low, prolonged use may be complicated by bacterial meningitis. The monitor is left in place for 3 to 5 days or less if the clinical state and ICP are stable for 24 to 48 h.

The first step in lowering high ICP is to control the incidental factors that are known to raise the pressure, such as hypoxia, hypercarbia, hyperthermia, awkward head positions that compress the jugular veins, and high mean airway pressures (see the monograph by Ropper and colleagues). If the intracranial pressure exceeds 15 to 20 mmHg, several measures can be instituted, such as inducing hypocarbia by controlled ventilation (maintaining PCO_2 at 28 to 33 mmHg) and hyperosmolar dehydration (0.25 to 1.0 g of 20% mannitol every 3 to 6 h or 0.75 to 1 mg/kg of furosemide, see below) to maintain serum sodium above 138 meq/L and an osmolality of 290 to 300 mosmol/L. Even if ICP monitoring is not utilized, an attempt should be made to maintain this level of osmolality for the first days if contusion and brain swelling are detected on the CT scan. Elevations in osmolality due to excessive concentrations of diffusible solutes such as glucose are not useful in reducing intracranial volume because they do not provide a water gradient across the cerebral vasculature. For this reason, the measurement of serum sodium is in some ways a more accurate reflection of free water depletion. An initial sodium level of 136 to 141 meq/L is adequate. Intravenous fluids with free water should be avoided so as not to intensify cerebral edema. This poses a particular danger in children who, because of inappropriate secretion of antidiuretic hormone, easily develop water intoxication. With this exception, however, restriction of the overall volume of fluid is less of a concern than effecting a reduction in free water. Fluids such as 5% dextrose in water, 0.5% saline, and 5% dextrose in 0.5% saline are therefore avoided; lactated Ringer's solution is permissible; normal saline, with or without added dextrose, is ideal.

The effects of mannitol have been of great interest to neurosurgeons who treat head trauma, but the best plan for its use has never been established. Among the randomized studies that provide clinical data, only the one by Cruz and colleagues has demonstrated a clear benefit and particularly in relation to acute subdural hematoma. These authors administered mannitol in a bolus, 0.6 g/kg, to all patients immediately, and then, once a subdural hematoma was identified by CT scan, gave an additional similar second dose to those with reactive pupils and twice the original dose to those with unreactive pupils or anisocoria. Benefits were obtained

in these patients and another study of patients with temporal lobe contusion by the same investigators. In the end, it must be concluded that large boluses of mannitol are beneficial in closed head injury, especially if there is an acute subdural hematoma or contusions, and this may extend to patients who have pupillary abnormalities. Hypertonic saline (3 percent) probably has a comparable effect to mannitol in the treatment of acutely raised ICP.

Hypocarbia, induced by hyperventilation, is effective in reducing ICP for only a limited period of time, since the pH of the spinal fluid equilibrates over hours and allows cerebral blood volume to return to its previous level. A single-step reduction in PCO₂ typically lowers ICP for approximately 20 to 40 min. Attempts to prolong the effect of hypocarbia and the alkalosis by the intravenous administration of ammonium buffers have met with mixed success. It has even been suggested that hyperventilation may be harmful to some head-injured patients because of a reduction in cerebral blood flow, but the risk, if any, appears to be minimal. For these reasons, hypocarbia is not often used in cases of head trauma. The method of deep cooling has had its proponents over the years, but most attempts to demonstrate improved outcome have been unsuccessful (see Clifton et al). Lowering of the body temperature will, however, transiently reduce ICP.

If the ICP continues to rise and brain swelling progresses despite these measures, the outlook for survival is bleak. Hypothermia and barbiturate anesthesia to reduce ICP have been used, but relatively few patients respond to such measures for long. A randomized controlled trial of cooling patients with severe closed head injury (Glasgow Coma Scale scores of 3 to 7) to 33°C for 24 h appeared to hasten neurologic recovery and may have modestly improved outcome (Marion et al). Since on rewarming, however, there may be a rapid increase in ICP, the body temperature must be raised very gradually over a day or more. It has been suggested by Shann, who has summarized the many trials of hypothermic treatment, that most were unlikely to show benefit because the degree and duration of cooling were inadequate. Barbiturates, while they lower ICP, may lower the blood pressure as well; hence they may diminish cerebral perfusion. However, Marshall and coworkers claimed a high rate of improvement and survival by using barbiturates even in cases where the ICP exceeded 40 mmHg. The more definitive randomized study by Eisenberg and associates showed no benefit from barbiturate-induced anesthesia in head-injured patients. Several large controlled studies have established that the administration of high-dose steroids does not significantly affect the clinical outcome of severe head injuries. Consequently, their use has been abandoned except for cases of marked edema surrounding a contusion or hematoma; even then, the benefit is uncertain (Gudeman et al; Dearden et al; Braakman et al; Saul et al). The use of wide decompression craniectomy in cases of intractable brain swelling is commented on below.

The management of posttraumatic systemic hypertension can be a difficult problem. Immediately after head injury, the sympathoadrenal response and elevation of blood pressure will recede spontaneously in a matter of a few hours or days. Unless the blood pressure elevation is extreme (greater than 180/95 mmHg), it can be disregarded in the early stages. In animal experiments, it has been found that severe hypertension leads to increased perfusion of the brain and an augmentation of the edema surrounding contusions and hemorrhages. As mentioned earlier, edema is the main element in the genesis of brain swelling and of raised ICP in most head-injured patients (Marmarou et al). This reflects a failure of autoregulatory vascular mechanisms, with resulting transudative

edema in damaged areas of the brain. The control of high blood pressure must be balanced against the risk of reducing cerebral perfusion pressure and the observation that even a brief period of mild hypotension may provoke a cycle of cerebral vasodilation, increased cerebral blood volume, and elevated ICP in the form of plateau waves (Rosner and Becker). Observations such as these emphasize the need for immediate and vigorous management of hypotension in severely head-injured patients.

Since most therapies for elevated ICP dehydrate the patient or reduce cardiac filling pressures, thereby leading to hypotension, a middle course, of avoiding both severe hypertension and any degree of hypotension, seems the best compromise. In lowering high levels of blood pressure, diuretics, beta-adrenergic blocking agents, or angiotensin converting enzyme inhibitors should be used, rather than agents that may dilate the cerebral vasculature (nitroglycerin and nitroprusside, hydralazine, and some of the calcium channel blockers). Hypotension should be corrected by vasoconstrictor agents such as neosynephrine. The precise level of blood pressure that requires treatment must be judged in the context of the ICP and the presence of plateau waves (the goal being to maintain normal cerebral perfusion) as well as the patient's previous blood pressure level; evidence of organ failure, such as cardiac or renal ischemia, must also be taken into account.

General Medical Measures If coma persists for more than 48 h, a nasogastric tube should be passed and fluids and nutrition given by this route. Agents that reduce gastric acid production—or the equivalent, antacids by stomach tube to keep gastric acidity at a pH above 3.5—are of value in preventing gastric hemorrhage. The prophylactic use of anticonvulsant drugs, as discussed earlier, under "Posttraumatic Epilepsy," has recently been favored, but there is no evidence that delayed epileptic seizures are reduced (see Chand and Lowenstein). Only if there has been a seizure are anticonvulsants given.

Restlessness is controlled by diazepam or a similar sedative, but only if careful nursing fails to quiet the patient and provide sleep for a few hours at a time. Haloperidol is usually avoided in the acute stage. Fever is counteracted by antipyretics such as acetaminophen, and, if necessary, by a cooling blanket. The use of morphine or bromocriptine to quiet episodes of vigorous extensor posturing and accompanying adrenergic activity has already been mentioned.

Surgical Measures The need for surgical intervention during the acute posttraumatic period is decided by two factors: the clinical status of the patient and CT scanning. The presence of a subdural or epidural clot that is causing a shift of central brain structures calls for its immediate evacuation. The approach to subdural hematomas has been discussed earlier in this chapter. Should the elevated ICP not respond to this procedure or to the standard osmotic agents and other medical measures outlined above, or should the condition of the patient and vital signs then begin to deteriorate (pulse rising, temperature rising or falling below normal, state of consciousness worsening, hemiplegia more obvious, plantar reflexes more clearly extensor), a renewed search must be undertaken for a late-occurring cerebral mass. Usually in these clinical circumstances, CT scanning will disclose a new or enlarged epidural, subdural, or intracerebral hematoma, marked cerebral edema, and a lateral shift of central cerebral structures. *If death or severe disability is to be avoided, operation in these cases must be undertaken before the advanced signs of brainstem compression—de-*

cerebrate or decorticate posturing, hypertension, bradycardia—have appeared.

The use of *decompressive craniectomy* in patients with progressive and intractable traumatic brain swelling has been a subject of renewed interest in recent years, after having been practically abandoned several decades ago. Guerra and colleagues have reported on 57 such patients, mostly young adults, who underwent wide frontotemporal craniectomy, unilateral in 31 and bilateral in 26. Of these, 11 patients died, 5 remained in a persistent vegetative state, and 6 survived in a severely damaged condition; however, 33 patients (58 percent) attained surprisingly good states of rehabilitation. These authors were of the opinion that these results represented a significant improvement over the expected outcome in this particular group of patients. Similar results in children have been reported by Polin et al. The few cases with which we have been involved, mostly children operated late, have not been as encouraging, but the procedure deserves further evaluation, especially in younger patients.

The treatment of other problems attendant on protracted coma has been outlined in Chap. 17. Each patient presents unique problems that must be dealt with individually.

PROGNOSIS

In respect to severe head injury, as has been intimated, the outcome is particularly discouraging. Some aspects of prognosis have been mentioned earlier but the following general comments serve to frame the problem. In the survey of the large European Brain Injury Consortium, comprising 10,005 adult patients, the injury proved fatal in 31 percent; 3 percent were left in a persistent vegetative state, and 16 percent remained severely disabled neurologically (Murray et al). Data from the extensively analyzed Traumatic Coma Data Bank are comparable (Marshall et al). The signs of focal brain disease, whether due to closed head injuries or to open and penetrating ones, tend always to ameliorate as the months pass. A hemiplegia is often reduced to a minimal hemiparesis or to an ineptitude of voluntary motor function with exaggerated reflexes

and an equivocal Babinski sign on that side, and an aphasia is gradually transformed into a stuttering or hesitant paraphasia or dysnomia that is not disabling except to a professional person, speaker, or writer. Many of the signs of brainstem disease (cranial nerve dysfunction and ataxia) improve also, usually within the first 6 months after injury (Jennett and Bond) and often to a surprising extent. Most patients who had been in coma for many hours or days—i.e., those with severe brain injuries—are left with memory impairment and other cognitive defects and with personality changes. These may be the only lasting sequelae. According to Jennett and Bond, these mental and personality changes are a greater handicap than focal neurologic ones as far as social adjustment is concerned. In open head wounds and penetrating brain injuries, Grafman and coworkers found that the magnitude of tissue loss and location of the lesion were the main factors affecting the outcome.

The prognosis of head injury is influenced by several other factors. The *age of the patient* is the most important of these (Vollmer et al). Increasing age reduces the chances of survival and of good recovery. Older patients often remain disabled, especially when compensation is involved. Young and middle-aged ones do better, particularly if they are not entitled to compensation. Russell has pointed out that the severity of the injury as measured by the duration of *traumatic amnesia* is a useful prognostic index. Of patients with a period of amnesia lasting less than 1 h, 95 percent were back at work within 2 months; if the amnesia lasted longer than 24 h, only 80 percent had returned to work within 6 months. However, about 60 percent of the patients in his large series still had symptoms at the end of 2 months, and 40 percent at the end of 18 months. Of the most severely injured (those comatose for several days), many remained permanently disabled. However, the degree of recovery was often better than one had expected; the motor impairment, aphasia, and dementia tended to lessen and sometimes cleared. Improvement could continue over a period of 3 or more years. Children seemed to recover more completely than adults.

CHAPTER 36

MULTIPLE SCLEROSIS AND ALLIED DEMYELINATIVE DISEASES

It has long been the practice to set apart a group of diseases of the brain and spinal cord in which destruction of myelin (demyelination) is a prominent feature. To define these diseases precisely is difficult, for the simple reason that there is probably no disease in which myelin destruction is the exclusive pathologic change. The idea of a demyelinative disease is, more or less, an abstraction that serves primarily to focus attention on one of the more striking and distinctive features of one group of pathologic processes.

The commonly accepted pathologic criteria of a demyelinative disease are (1) destruction of the myelin sheaths of nerve fibers with *relative sparing* of the other elements of nervous tissue, i.e., of axons, nerve cells, and supporting structures, as reflected by a relative lack of wallerian or secondary degeneration of fiber tracts; (2) infiltration of inflammatory cells in a perivascular and particularly paravenous distribution; (3) a distribution of lesions that is primarily in white matter, either in multiple small disseminated foci or in larger foci spreading from one or more centers.

A classification of the demyelinative diseases is presented in Table 36-1. The diseases included in this classification conform approximately to the criteria enumerated above. Like all classifications that are not based on etiology, this one has its shortcomings in that it is somewhat arbitrary. In some of the diseases here classified as demyelinative, notably Schilder disease and necrotizing hemorrhagic leukoencephalitis and even multiple sclerosis, there can be a severe degree of damage to axis cylinders and vascular structures as well as to myelin. Contrariwise, a number of diseases in which demyelination is a prominent feature are not included. In some cases of anoxic encephalopathy, for example, the myelin sheaths of the radiating nerve fibers in the deep layers of the cerebral cortex or in ill-defined patches in the convolutional and cen-

tral white matter are destroyed, while most of the axis cylinders are spared. A relatively selective degeneration of myelin may also occur in some small ischemic foci due to vascular occlusion or in larger confluent areas, as is the case in Binswanger disease (see Chap. 34). In subacute combined degeneration (SCD) of the spinal cord associated with pernicious anemia and in tropical spastic paraparesis (TSP), a demyelinating spinal cord disease, myelin may be affected earlier and to a greater extent than axis cylinder. The same is true of progressive multifocal leukoencephalopathy (PML), central pontine myelinolysis, and Marchiafava-Bignami disease. Some of these disorders and several others are no longer classified as demyelinative because their etiology has been established. Also, for reasons that will become clear in subsequent discussion, the chronic progressive leukodystrophies of childhood and adolescence (e.g., globoid body, metachromatic, and adrenal leukodystrophies), while clearly diseases of myelin, are set apart and called *dysmyelinative* because of their unique genetic and morphologic features and are discussed in Chap. 37. Occupying an uncertain place in this nosology are demyelinative lesions associated with connective tissue diseases or merely with autoantibodies directed against DNA or phospholipids. Again, the central nervous system (CNS) lesions may be multiple and cannot easily be distinguished radiologically from multiple sclerosis (MS). But, as noted further on, their nature is uncertain, and some are clearly due to a vasculopathy. Excluded from discussion in this chapter are demyelinative diseases of the peripheral nerves. Although they share a number of pathologic features with demyelinating diseases of the CNS, they are described with diseases of the peripheral nervous system in Chap. 46.

In the language of neurology, therefore, the term *demyelination* has acquired a special meaning; if it is to retain its value, it should be used in the restricted sense indicated above and not as a synonym for any destructive process of nerve fibers or cerebral white matter or for inherent and inherited defects in myelin, even though the lesions may look alike in a section stained for myelin.

Table 36-1
Classification of the demyelinative diseases

- I. Multiple sclerosis (disseminated sclerosis)
 - A. Chronic relapsing encephalomyopathic form
 - B. Acute multiple sclerosis
 - C. Diffuse cerebral sclerosis (Schilder disease and concentric sclerosis of Balo)
- II. Neuromyelitis optica (Devic disease)
- III. Acute disseminated encephalomyelitis
 - A. Postinfectious: following measles, chickenpox, smallpox, mumps, rubella, influenza, and other viral and some bacterial infections (*Mycoplasma*, *Rickettsia*)
 - B. Following rabies or smallpox and rarely other types of vaccination (postvaccinal)
- IV. Acute and subacute necrotizing hemorrhagic encephalitis
 - A. Acute encephalopathic form (Hurst hemorrhagic leukoencephalitis)
 - B. Subacute necrotic myelopathy

MULTIPLE SCLEROSIS

Multiple sclerosis, called "MS" by most physicians, is referred to by the British as *disseminated sclerosis* and by the French as *sclérose en plaques*. It is among the most venerable of neurologic diseases and one of the most important by virtue of its frequency, chronicity, and tendency to attack young adults. It is a chronic condition characterized clinically by episodes of focal disorders of the optic nerves, spinal cord, and brain, which remit to a varying extent and recur over a period of many years. The neurologic manifestations are protean, being determined by the varied location and extent of the demyelinative foci; nevertheless, the lesions have a predilection for certain parts of the CNS, resulting in complexes of symptoms and signs and radiologic appearances that can often be recognized as characteristic of MS.

Classic features include motor weakness, paraparesis, paresthesias, loss of sight, diplopia, nystagmus, dysarthria, intention tremor, ataxia, impairment of deep sensation, and bladder dysfunction. The diagnosis may be uncertain at the onset and in the early years of the disease, when symptoms and signs point to a lesion in only one locus of the nervous system. Later, as the disease recurs and disseminates throughout the cerebrospinal axis, diagnostic accuracy approaches 100 percent. A long period of latency (1 to 10 years or longer) between a minor initial symptom, which may not even come to medical attention, and the subsequent development of more characteristic symptoms and signs may delay the diagnosis. In most cases there is a relapsing-remitting pattern, i.e., the initial manifestations improve partially or completely, to be followed after a variable interval by the recurrence of the same abnormalities or the appearance of new ones in other parts of the nervous system. However, in fewer than half of patients, the disease takes the form of an intermittently progressive illness (*relapsing-remitting*, the typical type of MS), and sometimes of a steadily progressive one, especially in patients more than 40 years of age at the time of onset (*primary progressive MS*). Or, as happens more often, an initially relapsing profile later becomes steadily progressive (*secondary progressive MS*). Some data are accumulating to suggest that the pathogenesis of the chronic progressive, nonremitting clinical types may be different from that of the relapsing-remitting cases, but in the authors' opinion this is still questionable.

A rule that has guided clinicians for many years is that the diagnosis of MS is not secure unless there is a history of remission and relapse and evidence on examination of more than one discrete lesion of the CNS. The advent of certain ancillary procedures—notably magnetic resonance imaging (MRI) and evoked potentials—and their capacity to identify clinically evident lesions—has obviated the exclusive dependence on clinical criteria for the diagnosis.

Pathologic Findings

Before being sectioned, the brain generally shows no evidence of disease, but the surface of the spinal cord may appear and feel uneven. Sectioning of the brain and cord discloses numerous scattered patches where the tissue is slightly depressed below the cut surface and stands out from the surrounding white matter by virtue of its pink-gray color (due to loss of myelin). The lesions may vary in diameter from less than a millimeter to several centimeters; they affect principally the white matter of the brain and spinal cord and do not extend beyond the root entry zones of the cranial and spinal nerves. It is because of their sharp delineation that they were called *plaques* by French pathologists.

The topography of the lesions is noteworthy. A periventricular localization is characteristic, but only where subependymal veins line the ventricles (mainly adjacent to the bodies and atria of the lateral ventricles). Other favored structures are the optic nerves and chiasm (but rarely the optic tracts) and the spinal cord, where pial veins lie next to or within the white matter (Fig. 36-1; see also "MRI in MS," page 783). The lesions are distributed randomly throughout the brainstem, spinal cord, and cerebellar peduncles without reference to particular systems of fibers but always confined predominantly to the white matter. In the cerebral cortex and central nuclear and spinal structures, the acute lesions destroy myelin sheaths but leave the nerve cells essentially intact. Severe and more chronic lesions, however, may destroy axons and neurons in the affected region, but the essential lesion is still demyelinative.

The histologic appearance of the lesion depends on its age. Relatively recent lesions show a partial or complete destruction and loss of myelin throughout a zone formed by the confluence of many small, predominantly perivenous foci; the axons in the same region are relatively spared or less affected. There is a variable but only slight degeneration of oligodendroglia, a variable neuroglial (astrocytic) reaction, and perivascular and para-adventitial infiltration with mononuclear cells and lymphocytes. Later, large numbers of microglial phagocytes (macrophages) infiltrate the lesions, and astrocytes in and around the lesions increase in number and size. Long-standing lesions, on the other hand, are composed of thickly matted, relatively acellular fibrogliatissue, with only occasional perivascular lymphocytes and macrophages; in such lesions, a few intact axis cylinders may still be found. Sparing of axis cylinders (axons) prevents wallerian degeneration. However, in old lesions with interruption of axons, there may be descending and ascending degeneration of long fiber tracts in the spinal cord. Partial remyelination is believed to take place on undamaged axons and to account for partially demyelinated "shadow patches" (Prineas and Connell). A few of the most severe older lesions will have undergone cavitation, indicating that the disease process has affected not only myelin and axons but also supporting tissues and blood vessels as well. All gradations of histopathologic change between these two extremes may be found in lesions of diverse size, shape, and age, consistent with the extended clinical course. This emphasis on the pathologic destruction of myelin obscures the central fact that the immune system effects this change, the myelin itself being normal in the structure and immune composition.

An insight into the complexity of the immunopathologic process can be appreciated in a recent microscopic analysis by Lucchinetti and colleagues (2000) of 83 autopsy and brain biopsy specimens from patients with MS. They categorized several distinct histologic subgroups. In most, the inflammatory response was distinguished by extensive perivenular deposition of immunoglobulin and complement, suggesting a role for a humoral pathogenesis. In others, inflammation was present only at the periphery of plaques and the distinctive feature was a marked apoptosis of oligodendrocytes. In yet another group, perhaps the end stage of the last one described, there was nearly complete loss of oligodendrocytes without apoptosis and an absence of remyelination. Two features are of interest here. First, each case demonstrated only one pattern of pathology, suggesting that perhaps different pathophysiologic processes operated in each patient. Moreover, the last two histopathologic types were considered to represent a primary oligodendroglial degeneration. A possible confirmation of the primary process in oligodendrocytes is the material from newly symptomatic lesions reported by Barnett and Prineas. In 7 of 12 cases there were some lesions with oligodendrocyte apoptosis and microglial activation but without an inflammatory or macrophage response. Aside from this novel idea regarding the oligodendrocytes, the overall implication is that the pathologic characteristics of the chronic progressive type of MS may differ from those of the typical relapsing type (see further on). However, further study will be required to determine whether these perspectives are valid or the differences simply reflect limited sampling, the age of the plaque, or the severity of an immune process. At the moment, the authors regard observations of a primary role for oligodendrocyte destruction to be provisional and continue to conceptualize MS as an inflammatory-immune process that targets central myelin along the lines of the observations of Adams and Kubik in their earlier studies.

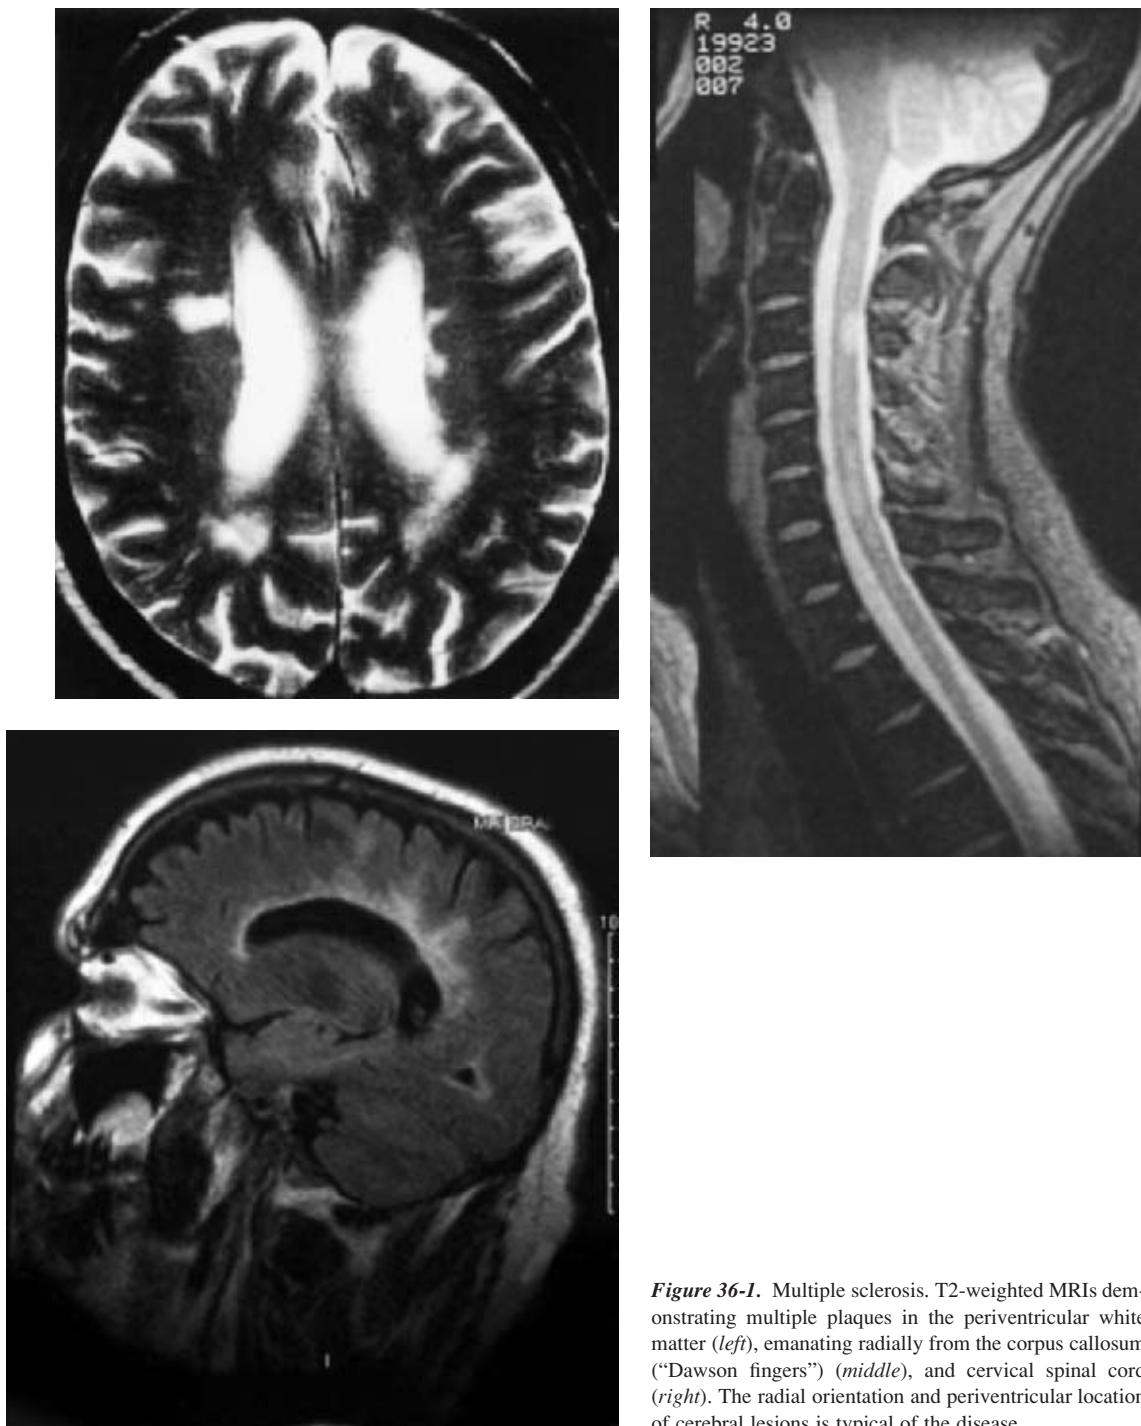

Figure 36-1. Multiple sclerosis. T2-weighted MRIs demonstrating multiple plaques in the periventricular white matter (*left*), emanating radially from the corpus callosum ("Dawson fingers") (*middle*), and cervical spinal cord (*right*). The radial orientation and periventricular location of cerebral lesions is typical of the disease.

Etiology and Epidemiology

Cruveilhier (circa 1835), in his original description of the disease, attributed it to suppression of sweat, and since that time there has been endless speculation about the etiology. Many of the early theories appear ludicrous in the light of present-day concepts, and others are of mainly historical interest. There is little point in enumerating them here; complete accounts are to be found in the reviews of DeJong (1970), Prineas (1970), R. T. Johnson (1978), and McDonald (1986).

Although the precise cause of MS remains undetermined, a number of epidemiologic facts have been clearly established and will eventually have to be incorporated in any etiologic hypothesis. The disease has a prevalence of less than 1 per 100,000 in equatorial areas; 6 to 14 per 100,000 in the southern United States and southern Europe; and 30 to 80 per 100,000 in Canada, northern Europe, and the northern United States. More recently, Mayr and colleagues reported an incidence of 8 and a prevalence of 177 cases per 100,000 in Olmstead County, MN; this prevalence has been stable for approximately 30 years. A less well defined gradient

exists in the Southern Hemisphere. Kurland's studies indicate that there is a threefold increase in prevalence and a fivefold gradient in mortality rate between New Orleans (30 degrees north latitude), on the one hand, and Boston (42 degrees north) and Winnipeg (50 degrees north) on the other. In Japan there is a similar though less distinct geographic gradient (the prevalence of MS there is much lower than in corresponding latitudes of North America and northern Europe).

The increasing risk of developing MS with increasing latitude has been confirmed by J. B. Barlow and Kurtzke and associates. The latter studied a series of unprecedented size (5305 undoubted cases of MS and matched controls). They showed also that in the United States, African Americans are at lower risk than whites at all latitudes, but both races show the same south-to-north gradient in risk, probably indicating the importance of an environmental factor regardless of race. Supporting this view are the descriptions, by Kurtzke and Hyllested, of an "epidemic" of MS in the Faroe Islands of the North Atlantic. They found a much higher than expected incidence of the disease, occurring as three separate outbreaks of decreasing extent between the years 1943 and 1973. (It should be pointed out that the largest outbreak consisted of only 21 cases.) It was their contention, confirmed by Poskanzer, that the disease was due possibly to an unidentified infection introduced by British troops who occupied the islands in large numbers in the years immediately preceding the outbreak. Kurtzke and colleagues have also described a similar postwar epidemic in Iceland.

Several studies indicate that persons who migrate from a high-risk to a low-risk zone carry with them at least part of the risk of their country of origin, even though the disease may not become apparent until 20 years after migration. Such a pattern has been demonstrated in both South Africa and Israel. Dean determined that the prevalence of MS in native-born white South Africans was 3 to 11 per 100,000, whereas the rate in immigrants from northern Europe was about 50 per 100,000, only slightly less than among the nonimmigrating natives of those countries. The data of Dean and Kurtzke indicate further that in persons who had immigrated before the age of 15, the risk was similar to that of native-born South Africans; whereas in persons who had immigrated after that age, the risk was similar to that of their birthplace. Alter and colleagues found that in the descendants of European immigrants born in Israel, the risk of MS was low, similar to that of other native-born Israelis, whereas among recent immigrants the incidence in each national group approached that of the land of birth. Again, the critical age of immigration appeared to be about 15 years. These epidemiologic studies and others have shown that MS is associated with particular localities rather than with a particular ethnic group in those localities and again implicate environmental factors in the genesis of the disease.

Also, a familial aggregation of MS is now well established. About 15 percent of MS patients have an affected relative, with the highest risk of concurrence being observed in the patient's siblings (Ebers, 1983). In a large population-based study carried out in British Columbia by Sadovnick and colleagues, it was found that almost 20 percent of index cases had an affected relative, again with the highest risk in siblings. In a subsequent study, Sadovnick and colleagues sought to determine the degree of heritability of MS by comparing the risk of disease in the half-sibs (one biologic parent in common) of affected individuals with the risk in full sibs; the risk for full sibs was two to three times greater than for half-sibs and they interpreted these results as largely genetic in basis.

The case for heritability is supported by studies of twins in

whom one of each pair is known to have MS. In the most extensive of these studies (Ebers et al), the diagnosis was verified in 12 of 35 pairs of monozygotic twins (34 percent) and in only 2 of 49 pairs of dizygotic twins (4 percent). Furthermore, in two additional sets of monozygotic twins who were clinically normal, lesions were detected by MRI. The concordance rate in dizygotic pairs is similar to that in nontwin siblings. Despite these provocative findings, no consistent pattern of mendelian inheritance has emerged. (Of course, one must not assume that all diseases with an increased familial incidence are hereditary in that instances of the same condition in several members of a family may simply reflect an exposure to a common environmental agent. Paralytic poliomyelitis, for example, was about eight times more common in immediate family members than in the population at large.)

Nonetheless, further evidence of a genetic factor in the causation of MS is the finding that certain histocompatibility locus antigens (HLAs) are more frequent in patients with MS than in control subjects. The strongest association is with the DR locus on the sixth chromosome. Other HLA haplotypes that are overrepresented in MS (HLA-DR2 and, to a lesser extent, -DR3, -B7, and -A3) are thought to be markers for an MS "susceptibility gene"—possibly an immune response gene. The presence of one of these markers increases the risk that an individual will develop MS by a factor of 3 to 5. These antigens may indeed prove to be related to the frequency of the disease, but their presence is not invariable and their exact role is far from clear (see Compston).

The low conjugal incidence of MS, on the other hand, indicates that any common exposure to an inciting infection or environmental agent must occur early in life. In order to test this hypothesis, Schapira and coworkers determined the periods of common exposure (common habitation periods) in members of families with two or more cases. From this they calculated the mean common exposure to have happened before 14 years of age, with a latency of about 21 years—figures that are in general agreement with those derived from the migration studies quoted above.

The incidence of MS is two or three times higher in women than in men, but the significance of this fact is unclear, the best current explanation being that women are generally more susceptible to immune and inflammatory conditions. The incidence in children is very low; only 0.3 to 0.4 percent of all cases appear during the first decade. In an analysis of three childhood-onset cases, Hauser and colleagues found no phenotypic differences between childhood and adult cases. Beyond childhood, the risk of first developing symptoms of the disease rises steeply with age, reaching a peak at about 30 years, remaining high in the fourth decade, then falling off sharply and becoming low in the sixth decade. It has been pointed out that MS has a unimodal age-specific onset curve, similar to the age-specific onset curves of many infectious and connective tissue diseases.

About two-thirds of cases of MS have their onset between 20 and 40 years of age. Of the remainder, most cases begin before the age of 20; in a smaller number, the disease appears to develop in late adult life (late fifties and sixties). In the latter patients, early symptoms may have been forgotten or may never have declared themselves clinically (we have several times found the typical lesions of MS in aged autopsied individuals who had no history of neurologic illness). Gilbert and Sadler report five such cases and from their pathologic findings declare that the true incidence of MS may be three times higher than stated figures.

Several studies from northern Europe and Canada have suggested that the likelihood of developing MS is somewhat greater

among rural than among urban dwellers; studies of American army personnel indicate the opposite (Beebe et al). A number of surveys in Great Britain have intimated that the disease is more frequent in the higher socioeconomic groups than in the lower ones. Yet in the United States, no clear relationship has been established to the poverty or social deprivations that are part of a low socioeconomic status. Numerous other environmental factors [surgical operations, trauma, anesthesia, exposure to household pets (small dogs), mercury in silver amalgam fillings in teeth] have been proposed but are unsupported by firm evidence and probably are mostly spurious associations.

Pathogenesis

These epidemiologic data point to both a genetic susceptibility and some environmental factor that is encountered in childhood and, after years of latency, evokes the disease. In recent years, speculation has grown that this factor is an infection, most often viral. A body of indirect evidence has been marshaled in support of this idea, based largely on alterations in humoral and cell-mediated immunity to viral agents (see reviews of R. T. Johnson, Lampert, K. P. Johnson et al, McFarlin and McFarland). However, to this day no virus (including all known members of the human retrovirus family) has been seen in or isolated from the tissues of patients with MS despite innumerable attempts to do so. Moreover, no satisfactory viral model of MS has been produced experimentally. Recently, the bacterial agents *Chlamydia pneumoniae* and *Borrelia burgdorferi* (the agent of Lyme disease) and herpesvirus type 6 have been similarly implicated by the finding of their genomic material in MS plaques, but the evidence for their direct participation in the disease is, at the moment, not compelling.

If indeed some obscure infection is the initial event in the genesis of MS, then a secondary factor must be operative in later life to reactivate the neurologic disease and cause exacerbations. One popular view is that this secondary mechanism is an autoimmune reaction, attacking some component of myelin and, in its most intense form, destroying all tissue elements, including axons. Several lines of argument have been advanced in support of this view. One is inclined to draw an analogy between the lesions of MS and those of acute disseminated encephalomyelitis, which is almost certainly an autoimmune disease of delayed hypersensitivity type (see further on). In support of this possibility is the finding of antibodies to specific myelin proteins—e.g., myelin basic protein (MBP)—in both the serum and cerebrospinal fluid (CSF) of MS patients, and these antibodies, along with T cells that are reactive to MBP and to other myelin proteolipids, increase with disease activity; moreover, MBP cross-reacts to some extent with measles virus antibodies. The arguments that a chronic viral infection reactivates and perpetuates the disease are, however, less convincing than those proposing a role for viruses in the initiation of the process in susceptible individuals.

A possible way in which viral infections and autoimmune reactions in the nervous system might be linked to the abnormal expression of autoantigens on CNS cells has been suggested by R. T. Johnson. He found that several different viruses (rubeola, rubella, varicella) could cause the sensitization of T lymphocytes against myelin basic protein. This implies that the T lymphocyte recognizes an identical structure in both the virus and the myelin sheath. The hypothesis continues with the notion that once the autoimmune process is initiated by a virus in childhood, it can later be reactivated by any of the common viral infections to which the

individual is exposed, particularly in the far higher northern and southern latitudes. This phenomenon of “molecular mimicry” (a shared antigen between the virus and CNS myelin, the oligodendrocyte, or cerebral vessels) has been invoked as a mechanism in several diseases, notably in rheumatic fever, certain paraneoplastic diseases, and Guillain-Barré syndrome, but remains speculative in MS.

The role of humoral and cellular factors in the production of MS plaques is not fully understood. The deposition of immunoglobulin in the plaques of patients with acute and relapsing-remitting disease, but not those with progressive MS, has been alluded to earlier. That the humoral immune system is involved is evident from the presence in the CSF of most patients of oligoclonal immune protein antibodies, which are produced by B lymphocytes within the CNS. Sera from patients with MS (and some normal controls), when added to cultures of nervous system tissue from newborn mice in the presence of complement, can damage myelin, inhibit remyelination, and block axonal conduction. Antibodies to oligodendrocytes are present in the serum of up to 90 percent of patients in some studies but far less frequently in others. Of note also are the findings of Berger and colleagues that show a relationship between the clinical progression of early and monosymptomatic MS and the presence of serum autoantibodies against oligodendrocyte glycoprotein and myelin basic protein. They have reported that the absence of antibodies, a finding in 38 percent of their patients, identified a group with more benign disease, at least for several years. Whether this further indicates, as they suggest, that humoral immune mechanisms are essential to the production of MS is uncertain.

Autoantibodies have been found that are directed against myelin oligodendrocyte glycoprotein (MOG) and myelin basic protein (MBP). It has also been demonstrated that subsets of T cells (CD41 Th2 cells) are activated by MBP and MOG to activate B cells, the production of oligoclonal bands and membrane attack complexes, and the release of cytokines [tumor necrosis factor alpha (TNF- α), interleukins, interferon gamma (IFN- γ)]. The inflammatory process erodes the blood-brain barrier and ultimately destroys both oligodendroglia and axons. The eventual functional outcome reflects both the activity of this inflammatory cascade and the degree of axonal damage. In other cases, there may be a compromise of oligodendroglial function and axonal degeneration in the absence of prominent inflammation (see reviews by French-Constant and Hemmer).

Nevertheless, most immunologists currently subscribe to the notion that MS is mediated by a T-cell sensitization to myelin. This idea is supported by numerous lines of evidence including the observation that T cells initiate the lesions of experimental allergic encephalomyelitis (EAE), which is assumed to be an animal model of MS, as suggested by Adams. Although the entry of autoreactive T cells into the CNS results in a perivascular inflammatory reaction, its relationship to MS is unclear. Conceivably, intense T-cell stimulation is in itself sufficient to induce demyelination, but it is also possible that the primary target of the immune reaction is the myelin sheath or some component thereof and that the T-cell infiltration is the result of the demyelination. Other investigators believe that an additional insult is required, as illustrated by the EAE animal model, in which myelin alone is not a sufficient factor but always requires an adjuvant immune stimulus. EAE is clearly an imperfect model; it is not a naturally occurring disease but one in which a demyelination of the CNS is induced in susceptible animals in a single episode by autologous myelin antigens. The

inducing antigen in EAE is known, whereas the putative antigen in MS is not.

Also incorporated into most theories of the immune pathogenesis is an alteration of the blood-brain barrier, represented by adhesion of lymphocytes to endothelial cells. Whether this is an active interaction or a passive event triggered by antigenic attraction is not clear; nonetheless, these cell-vascular interactions have been incorporated into pathogenic theories and is the basis of newer treatments for MS.

As matters now stand, the focus of attention is on the pathogenic role of specific subsets of T lymphocytes, which regulate humoral immune responses either as potentiators (T-helper cells) or as inhibitors (T-suppressor cells) of immunoglobulin production by the B lymphocytes. So-called helper (CD41) T cells are found in abundance within MS plaques and surrounding venules (perivascular cuffing). It has been demonstrated that T-cell receptors respond to antigens presented by (major histocompatibility complex, or MHC) class II molecules on macrophages and astrocytes. This interaction is thought to stimulate T-cell proliferation and a cascade of related cellular events, including the activation of B cells and macrophages and the secretion of cytokines (one of which is IFN- β and another IFN- γ ; see further on). These cellular events are accompanied by a breakdown of the blood-brain barrier and, if sufficiently intense, by destruction of myelin (see review by French-Constant). A reduction in T cells, both helper and suppressor subsets, or an increase in the ratio of helper-suppressor cells, may precede an acute attack and appears to be associated with increasing disability in patients with MS. Always in the background is the element of genetic susceptibility, presumably making certain individuals prone to these immunologic events.

The foregoing data notwithstanding, it must be added that the immune mechanisms in MS are not fully specified and the autoimmune hypothesis is not beyond challenge. It is noteworthy that the prevalence of other diseases of presumed autoimmune origin is no higher in MS patients than in the general population (De Keyser). Moreover, the course of MS has been altered only inconsistently by the administration of any of the nonspecific immunosuppressive therapies (Goodkin et al, 1992).

Also worthy of comment is the relatively ineffective remyelination of the MS plaque. When remyelination of denuded axons occurs, thinly myelinated fibers are produced, creating areas of so-called shadow plaques. Histologic evidence suggests that some of the oligodendrocytes are destroyed in areas of active demyelination but also that some of the remaining ones have little ability to proliferate. Instead, there is an influx of oligodendroglial precursor cells, which mature into oligodendrocytes and provide the remaining axons with new myelin. Probably the astrocytic hyperplasia in regions of damage and the persistent inflammatory response account for some of the inadequacy of the reparative process (see Primeas et al).

Physiologic Effects of Demyelination

The main physiologic effect of demyelination is to impede saltatory electrical conduction of nerve impulses from one node of Ranvier, where sodium channels are concentrated, to the next node. The resulting failure of electrical transmission is thought to underlie most of the abnormalities of function resulting from demyelinating diseases of both the central and peripheral nerves. As an example, the delay in electrical conduction in the optic nerve (found by using pattern-shifting visual stimuli in MS patients) raises a number of

points about the pathophysiology of demyelination. When the demyelinative process is acute and reversible within a few days, the block in nerve fiber conduction is obviously physiologic rather than pathologic; in such a brief period, recovery is unlikely to have been due to remyelination. Probably recovery is due to subsidence of the edema and acute inflammatory changes in and around the lesion. Remyelination probably does occur, as described above, but it is a slower process and partial at best, and its functional effects in the CNS are possibly expressed as a slowing of nerve conduction, which, if present in an eye with normal vision, may account for the reduction in flicker fusion and in the perception of multiple visual stimuli (Halliday and McDonald). It also explains one of the classic symptoms of optic neuritis—a reduction in the intensity (desaturation) of the color red. It is clear, however, that many of the plaques visualized on MRI are unaccompanied by corresponding symptoms; in some cases, there is no electrophysiologic abnormality as tested with evoked responses. Either there has been complete remyelination in these plaques, sufficient to support clinical functioning, or, in the acute stage, the plaque may represent edema rather than demyelination.

Another classic feature of MS is the temporary induction, by heat or exercise, of symptoms such as unilateral visual blurring (the Uhthoff phenomenon) or tingling and weakness of a limb (the basis of the hot-tub test used in previous years). This has been shown experimentally to represent an extreme sensitivity of conduction in demyelinated nerve fibers to an elevation in temperature. A rise of only 0.5°C (0.9°F) can block electrical transmission in thinly myelinated or demyelinated fibers. Likewise, hyperventilation slows conduction of the visual evoked response, an effect that is rarely perceived by the patient. The remarkable sensitivity of demyelinated and remyelinated regions to subtle metabolic and environmental changes provides an explanation for the rapid onset of symptoms in some patients and the apparent fluctuations of MS that show no laboratory evidence of active inflammatory changes in the CNS. Smoking, fatigue, hyperventilation, and a rise in environmental temperature are all capable of briefly worsening neurologic functioning and are easily confused with relapses of disease.

Precipitating Factors

A variety of events occurring immediately before the initial symptoms or exacerbations of MS have been invoked as precipitating factors. The most common are infection, trauma, and pregnancy. However, in our view, none of these has been convincingly related to an increased risk of new attacks of MS, and there are no adequately controlled studies that would contradict this view. Nonetheless, we have had experience with several patients who regularly had acute exacerbations of MS following each outbreak of labial genital herpes. The incidence of respiratory or gastrointestinal viral infections that precede the onset or exacerbations of the disease varies greatly in different series, from 5 to 50 percent. The swine influenza vaccine, which was given to 45 million persons in the United States in late 1976, caused a slight increase in the incidence of Guillain-Barré disease but not of MS (Kurland et al), and more recent surveys of immunization programs, such as the one by Confavreux and colleagues (2001), confirm this.

The possible role of trauma in precipitating MS is more difficult to assess. McAlpine and Compston found that the incidence of trauma within a 3-month period preceding the onset of MS was slightly greater than in a random control group of hospital patients.

Furthermore, there appeared to be a relationship between the site of the injury and the site of initial symptoms, particularly in patients who developed symptoms within a week of injury. We do not find this evidence convincing. Other forms of trauma (including lumbar puncture and general surgical procedures) that occur after the onset of the neurologic disorder have not been shown to have an adverse effect on the course of the illness. Matthews, who has extensive personal experience with survivors of penetrating head wounds, did not find a single instance of MS among them. One of the most meaningful prospective studies of the relation of physical injury to MS is that of Sibley and colleagues, who followed 170 MS patients and 134 controls for an average of 5 years, during which they recorded all (1407) instances of trauma and measured their effects on exacerbation rate and progression of the disease. With the possible exception of a case or two of electrical injury, there was no significant correlation between traumatic episodes and exacerbations.

Certain other epidemiologic data have a bearing on this subject. There are, in the United States, 250,000 to 350,000 cases of physician-diagnosed MS (Anderson et al). Also, a study from the National Center for Health Statistics has determined that trauma sufficiently severe to be recalled at a periodic health examination occurs in one-third of the population of the United States (some 83 million persons) each year. Moreover, MS patients suffer physical injuries two or three times more often than normal persons (Sibley et al). In light of these data, it is perhaps not surprising that a traumatic event and an exacerbation should sometimes coincide, quite by chance.

Clinical Manifestations

The conventional view of MS as a disease that strikes young people at a time when they are enjoying perfect health is not always accurate. In some patients, the history discloses that fatigue, lack of energy, weight loss, and vague muscle and joint pains had been present for several weeks or months before the onset of neurologic symptoms. Nor is it generally appreciated that the neurologic disorder may have an acute, almost apoplectic onset. In fact, McAlpine and coworkers (1972), who analyzed the mode of onset in 219 patients, found that in about 20 percent the neurologic symptoms were fully developed in a matter of minutes, and, in a similar number, in a matter of hours. In about 30 percent the symptoms evolved more slowly, over a period of a day or several days, and in another 20 percent more slowly still, over several weeks to months. In the remaining 10 percent the symptoms had an insidious onset and slow, steady, or intermittent progression over months and years. The classic relapsing-remitting pattern of disease is more likely to appear in patients who are less than 40 years of age. The inflammatory process of MS affects no organ system other than the CNS.

Early Symptoms and Signs Weakness or numbness, sometimes both, in one or more limbs is the initial symptom in about half the patients. Symptoms of tingling of the extremities and tight band-like sensations around the trunk or limbs are commonly associated and are probably the result of involvement of the posterior columns of the spinal cord. The symptoms generally appear over a period of hours or days, at times being so trifling that they are ignored, and less often, coming on so acutely and prominently as to bring the patient urgently to the doctor. The resulting clinical syndromes vary from a mere dragging or poor control of one or both legs to

a spastic or ataxic paraparesis. The tendon reflexes are retained and later become hyperactive with extensor plantar reflexes; disappearance of the abdominal reflexes and varying degrees of deep and superficial sensory loss may be associated. It is a useful adage that *the patient with MS presents with symptoms in one leg but with signs in both*; the patient will complain of weakness, incoordination, or numbness and tingling in one lower limb and prove to have bilateral Babinski signs and other evidence of bilateral corticospi-
nal and posterior column disease.

Flexion of the neck may induce a tingling, electric-like feeling down the shoulders and back and, less commonly, down the anterior thighs. This phenomenon is known as a *Lhermitte sign*, although it is more a symptom than a sign and was originally described by Babinski in a case of cervical cord trauma. Lhermitte's contribution was to draw attention to the frequent occurrence of this phenomenon in MS. It is attributable to an increased sensitivity of demyelinated axons to the stretch or pressure on the spinal cord induced by neck flexion.

There are, in addition, several syndromes that are typical of multiple sclerosis and may be the initial manifestations. These common modes of onset are: (1) optic neuritis, (2) transverse myelitis, (3) cerebellar ataxia, and (4) various brainstem syndromes (vertigo, facial pain or numbness, dysarthria, diplopia). These are often features of the established disease as well. When they represent the initial phases of the illness, they may pose diagnostic questions, since they also certainly occur with numerous diseases other than MS.

Optic Neuritis (See also page 213) In about 25 percent of all MS patients (and in a larger proportion of children), the initial manifestation is an episode of *optic neuritis*. It will be recalled that the optic nerve is in fact a tract of the brain, and involvement of the optic nerves is therefore consistent with the rule that lesions of MS are confined to the CNS. Characteristically, over a period of several days, there is partial or total loss of vision in one eye. Many patients, for a day or two before the visual loss, experience pain within the orbit, worsened by eye movement or palpation of the globe. Rarely, the visual loss is steadily progressive for several weeks, mimicking a compressive lesion or intrinsic tumor of the optic nerve (Ormerod and McDonald). Usually a scotoma involving the macular area and blind spot (ceccentral) can be demonstrated, but a wide variety of other field defects may occur, rarely even hemianopic involvement (sometimes homonymous). In some patients, both optic nerves are involved, either simultaneously or, more commonly, within a few days or weeks of one another, and at least 1 in 8 patients will have repeated attacks. Serial examinations may disclose evidence of swelling or edema of the optic nerve head (papillitis) in about half the patients. The occurrence of papillitis depends on the proximity of the demyelinating lesion to the nerve head. As emphasized in Chap. 13, papillitis can be distinguished from the papilledema of increased intracranial pressure by the severe and acute visual loss that accompanies only the former. More often, the optic nerve head appears normal or nearly so; this represents a *retrobulbar neuritis*. Subtle manifestations of optic nerve affection—such as an afferent pupillary defect (page 206), atrophy of retinal nerve fibers or sheathing of retinal veins (page 213) and abnormalities of the visual evoked response (page 30)—should be sought in patients who have no visual complaints but are suspected of having MS. In cases of substantial visual loss there is a diminished pupillary response to light (afferent pupillary paralysis) and instability of the direct pupillary response,

but the pupil is said never to be dilated in ambient light. If the optic neuritis is unilateral, the consensual light reflex from the normal eye is retained. (Demyelination of the third nerve in its brainstem course, however, may be associated with a fixed enlargement of the pupil.)

As noted in Chap. 13, about half of patients with optic neuritis recover completely, and most of the remaining ones improve significantly, even those who present initially with profound visual loss and, later, pallor of the optic disc (Slamovits et al). Any pain in the globe is short-lived and persistent pain should prompt an evaluation for local disease. In a cohort of 397 patients enrolled in the Optic Neuritis Treatment Trial and examined 5 years after the initial attack of optic neuritis, visual acuity had returned to 20/25 or better in 87 percent of patients and to 20/40 or better in 94 percent—even if there had been a recurrence of optic neuritis during the 5-year period. Moreover, the mode of treatment did not appear to influence the outcome. Dyschromatopsia, generally taking the form of a perceived desaturation of colors, frequently persists. When improvement occurs, it usually begins within 2 weeks of onset, as is true of most acute manifestations of MS, perhaps sooner with corticosteroid treatment. Once improvement in neurologic function begins, it may continue for several months.

The main point to be made here is that *one-half or more of adult patients who present with optic neuritis will eventually develop other signs of MS*. The prospective investigation of Rizzo and Lessell showed that MS developed in 74 percent of women and 34 percent of men by the 15th year after onset of visual loss; similar results were reported by the Optic Neuritis Study Group (Beck and associates 2003). The risk is much lower if the initial attack of optic neuritis occurs in childhood [26 percent developed after 40 years of follow-up; Lucchinetti et al (1997)]; this suggests that some instances of the childhood disease may be of a different type, perhaps viral or postinfectious. Of more practical value is the observation, in the later study by Beck and colleagues, that the risk is also considerably lower (22 percent at 10 years) if the cranial MRI fails to reveal demyelinative lesions. The longer the period of observation and the greater the care given to detection of mild cases, the greater the proportion of patients who are found to develop signs of MS; however, most do so within 5 years of the original attack (Ebers, Hely et al). In fact, in many patients with clinically isolated optic neuritis, MRI has disclosed lesions of the cerebral white matter—suggesting that dissemination, albeit asymptomatic, had already occurred and thereby establishing the diagnosis of MS (Jacobs et al, Ormerod et al). The Optic Neuritis Study Group has made the point, well known to neurologists, that the recurrence of optic neuritis greatly increases the chances of developing MS.

It is unclear whether optic neuritis that occurs alone and is not followed by other evidence of demyelinating disease is simply a restricted form of MS or a manifestation of some other disease process, such as postinfectious encephalomyelitis. By far the most common pathologic basis for optic neuritis is demyelinative disease, though it is known that a vascular lesion or compression of an optic nerve by a tumor or mucocoele may cause a central or cecocentral scotoma that is indistinguishable from the defect of optic neuritis. Also, there may exist a special form of chronic relapsing optic neuritis that is due to an undefined granulomatous process such as sarcoid and not to MS, as suggested by Kidd and colleagues. Spinal cord lesions have developed months or years later in almost all such cases under our care.

Uveitis and sheathing of the retinal veins are other ophthalmic

disorders that occur with higher than expected incidence in patients with MS. The retinal vascular sheathing is due to T-cell infiltration, identical to that in typical plaques, but this is an anomalous finding, since the retina usually contains no myelinated fibers (Lightman et al).

The treatment of optic neuritis is discussed further on.

Acute Myelitis (Transverse Myelitis) This is the common designation for an acutely evolving inflammatory-demyelinative lesion of the spinal cord, which proves in many but not all instances to be an expression of MS. In this sense the myelitic lesion is analogous to that of optic neuritis. The term *transverse* in relation to the myelitis is somewhat imprecise, implying that all of the elements in the cord are involved in the transverse plane, usually over a short vertical extent. Instead, in MS, the spinal cord signs are asymmetrical and incomplete and involve only a part of the long ascending and descending tracts, i.e., paraparesis and complete sensory loss are unusual.

Clinically, the illness is characterized by a rapidly evolving (several hours or days) symmetrical or asymmetrical paraparesis or paraplegia, ascending paresthesias, loss of deep sensibility in the feet, a sensory level on the trunk, sphincteric dysfunction, and bilateral Babinski signs. The CSF shows a modest number of lymphocytes and increase in total protein but both may be normal early in the illness. As many as one-third of patients report an infectious illness in the weeks preceding the onset of neurologic symptoms, in which case a monophasic postinfectious demyelinating disease rather than MS is the likely cause of the myelitis. The MRI usually shows indications of focal demyelination in the spinal cord at the appropriate level and there may be enhancement with gadolinium infusion, but neither of these findings is invariable. The lesions, as shown in Fig. 36-1 (right panel), are almost indistinguishable from those of postinfectious myelitis. In those instances associated with existing MS, even if not previously symptomatic, MRI of the cerebral hemispheres will show lesions consistent with demyelination; the absence of such lesions, however, does not assure that the illness is monophasic and will not later turn out to be MS.

We have found that fewer than half the patients have evidence of an asymptomatic demyelinative lesion elsewhere in the nervous system or develop clinical evidence of dissemination within 5 years of the initial attack of acute myelitis (Ropper and Poskanzer). Not entirely in accord with our experience is the analysis of subgroups in a trial of interferon therapy conducted by Beck and colleagues (2002), in which the cumulative probability of developing MS after 2 years was similar after either optic neuritis or transverse myelitis. Our sense has been that acute transverse myelitis is somewhat less often an initial expression of MS than is optic neuritis.

A special problem is presented by patients with *recurrent myelitis* at one level of the spinal cord but in whom no other signs of demyelinative disease can be found by careful clinical examination or MRI. Some of them may even have oligoclonal bands in the CSF, which are commonly associated with MS (see further on). Enough cases of this limited nature have come to our attention to permit the conclusion that there is a recurrent form of spinal cord MS in which cerebral dissemination is infrequent (Tippet et al). It should be mentioned that isolated recurrent myelitis or myelopathy occurs also with lupus erythematosus, sarcoid, Sjögren syndrome, mixed connective tissue disease, and the antiphospholipid antibody syndrome or in the presence of other autoantibodies, as well as with dural and cord vascular fistulas and arteriovenous malformations. An analogous situation pertains in respect to some instances

of optic neuritis—repeated attacks that remain confined to the optic nerve.

Other aspects of transverse myelitis are discussed in Chap. 44, "Diseases of the Spinal Cord," and under "Acute Disseminated Encephalomyelitis" later in this chapter.

Other Patterns of Multiple Sclerosis (See also "Variants of MS," page 780) Like the modes of onset cited above, other early manifestations of MS, in descending order of frequency, are unsteadiness in walking, brainstem symptoms (diplopia, vertigo, vomiting, etc.), paresthesias or numbness of an entire arm or leg, facial pain often simulating tic doloreux, and disorders of micturition. Vertigo of central type is also a frequent initial sign of MS, but it more often appears in established cases. Discrete manifestations—such as hemiplegia, trigeminal neuralgia or other pain syndromes, facial paralysis, deafness, or seizures—occur in a small proportion of cases. Most often the disease presents with more than one of the aforementioned symptoms almost simultaneously or in rapid succession. Another relatively isolated syndrome of note, occurring mainly in older women, is a slowly progressive cervical myelopathy with weakness and ataxia. This is particularly difficult to differentiate from cervical spondylosis.

Not infrequently a prominent feature of the disease is *nystagmus and ataxia*, with or without weakness and spasticity of the limbs—a syndrome that reflects involvement of the cerebellar and corticospinal tracts. Ataxia of cerebellar type can be recognized by scanning speech, rhythmic instability of the head and trunk, intention tremor of the arms and legs, and incoordination of voluntary movements and gait, as described in Chap. 5. The combination of nystagmus, scanning speech, and intention tremor is known as the *Charcot's triad*. But while this group of symptoms is often seen in the advanced stages of the disease, most neurologists would agree that it is not a common mode of presentation. The most severe forms of cerebellar ataxia, in which the slightest attempt to move the trunk or limbs precipitates a violent and uncontrollable ataxic tremor, are observed among patients with long-standing MS. The responsible lesion probably lies in the tegmentum of the midbrain and involves the dentatorubrothalamic tracts and adjacent structures. Cerebellar ataxia may be combined with sensory ataxia, owing to involvement of the posterior columns of the spinal cord or medial lemnisci of the brainstem. In most cases of this type the signs of spinal cord involvement ultimately predominate; in others, the cerebellar signs are more prominent.

Diplopia is another common presenting complaint. It is due most often to involvement of the medial longitudinal fasciculi, producing an internuclear *ophthalmoplegia* (see page 236). The signs are characterized by paresis of the medial rectus on attempted lateral gaze, with a coarse nystagmus in the abducting eye; in MS, this abnormality is usually bilateral (unlike small pontine infarcts, which cause a unilateral internuclear ophthalmoplegia). As a corollary, *the presence of bilateral internuclear ophthalmoplegia in a young adult is virtually diagnostic of MS*. Occasionally, internuclear ophthalmoplegia in one direction is combined with a horizontal gaze paresis in the other, although this "one-and-a-half syndrome" is more typical of brainstem stroke (see also page 236). Other palsies of gaze (due to interruption of supranuclear connections) or palsies of individual ocular muscles (due to involvement of the ocular motor nerves in their intramedullary course) also occur, but less frequently. Additional manifestations of brainstem involvement include myokymia or paralysis of facial muscles, deafness, tinnitus, unformed auditory hallucinations (because of

involvement of cochlear connections), vertigo—as noted above, vomiting (vestibular connections), and rarely stupor and coma. The occurrence of *transient facial hypesthesia or anesthesia or of trigeminal neuralgia* in a young adult should always suggest the diagnosis of MS implicating the intramedullary fibers of the fifth cranial nerve.

Dull, aching, but otherwise nondescript *pain* in the low back is a common complaint, but its relation to the lesions of MS is uncertain. Infrequently, there is sharp, burning, poorly localized, or lancinating-radicular pain, localized to a limb or discrete part of the trunk. Nevertheless, these types of pains, presumably caused by demyelinative foci involving the dorsal root entry zones, have a few times been the presenting feature of the disease or have appeared at a later time in established cases (see Ramirez-Lassepas et al for a discussion of pain in MS).

Symptoms and Signs in the Established Stage of the Disease

When the diagnosis of MS has become virtually certain, a number of clinical syndromes are observed to occur with regularity. Approximately one-half of the patients will manifest a clinical picture of *mixed or generalized type* with signs pointing to involvement of the optic nerves, brainstem, cerebellum, and spinal cord—specifically signs relating to the posterior columns and corticospinal tracts. Another 30 to 40 percent will exhibit only varying degrees of spastic ataxia and deep sensory changes in the extremities, i.e., essentially a *spinal form of the disease*. In either case, an asymmetrical spastic paraparesis with some degree of impaired joint position and vibration sense in the legs is probably the most common manifestation of progressive MS. A predominantly *cerebellar* or *pontobulbarcerebellar form* will be noted in only about 5 percent of cases. Thus the mixed and spinal forms together have made up at least 80 percent of our clinical material.

It has become evident from some studies that some degree of cognitive decline is present in perhaps one-half of patients with long-standing MS. The process is characterized by reduced attention, diminished processing speed and executive skills, and memory decline, while language skills and other intellectual functions are preserved—features that have been subsumed under "subcortical dementia," as discussed in Chap. 21. Other mental disturbances—such as a loss of retentive memory, a global dementia, or a confusional-psychotic state—are also said to occur with some regularity in the advanced stages of the disease, but we have found this degree of deterioration to be exceptional. The decline in cognitive functions correlates with quantifiable MRI measurements, particularly loss of white matter volume, thinning of the corpus callosum, and brain atrophy (reviewed by Bobholz and Rao).

Traditional teaching has probably overemphasized the frequency of *euphoria*, a pathologic cheerfulness or elation that seems inappropriate in the face of the obvious neurologic deficit. (Charcot spoke of this phenomenon as "stupid indifference" and Vulpian as "morbid optimism.") Some patients do show this mental abnormality, always in association with other signs of cerebral impairment. In some instances it is manifestly a part of the syndrome of pseudobulbar palsy. A much larger number of patients, however, are *depressed*, irritable, and short-tempered as a reaction to the disabling features of the disease; the incidence of depression is estimated to be as high as 25 to 40 percent in some series. Dalos and coworkers, in comparing MS patients with a group of traumatic paraplegics, found a significantly higher incidence of emotional disturbance in the former group, especially during periods of relapse. Other mental disturbances—such as a loss of retentive mem-

ory, a global *dementia* with deteriorated executive function, or a confusional-psychotic state—also occur in the advanced stages of the disease. The cognitive impairment is more in keeping with what has been ascribed to “*subcortical dementia*” (page 372).

Symptoms of *bladder dysfunction*—including hesitancy, urgency, frequency, and incontinence—occur commonly with spinal cord involvement. Urinary retention, due to affection of sacral segments, is less frequent (Fig. 26-5). In males, these symptoms are often associated with impotence, a symptom that the patient may not report unless specifically questioned in this regard.

Abrupt attacks of neurologic deficit, lasting a few seconds or minutes and sometimes recurring many times daily, are a relatively infrequent but well-recognized feature of MS (see Osterman and Westerbeek). Usually the attacks occur during the relapsing and remitting phase of the illness, rarely as an initial manifestation. These clinical phenomena are referable to any part of the CNS but tend to be stereotyped in an individual patient. The most common phenomena are dysarthria and ataxia, paroxysmal pain and dysesthesia in a limb, flashing lights, paroxysmal itching, or tonic seizures, taking the form of flexion (dystonic) spasm of the hand, wrist, and elbow with extension of the lower limb. The paroxysmal symptoms, particularly the tonic spasms, may be triggered by sensory stimuli or can be elicited by hyperventilation. On a few occasions we have seen dystonic hand and arm spasms as the first symptoms; an acute plaque was detected in the opposite internal capsule. In advanced cases, the spasms may involve all four limbs and even a degree of opisthotonus. The cause of paroxysmal phenomena is uncertain. They have been attributed by Halliday and McDonald to ephaptic transmission (“cross-talk”) between adjacent demyelinated axons within a lesion. Carbamazepine is usually effective in controlling such attacks.

These transitory symptoms appear suddenly, may recur frequently for several days or weeks, sometimes longer, and then remit completely, i.e., they exhibit the temporal profile of a relapse or an exacerbation. It is sometimes difficult to determine whether they represent an exacerbation or a new lesion. Years ago, Thygesen pointed out, in an analysis of 105 exacerbations in 60 patients, that there were new symptoms in only 19 percent; in the remainder there was only a recurrence of old symptoms. Another problem is that the original lesion may have been asymptomatic. This is most obviously reflected in the many patients who are found to have impaired visual evoked responses but have never had symptomatic visual changes. Thus, new symptoms and signs may be manifestations of previously formed but asymptomatic plaques. However, the observations of Prineas and Connell indicate that symptoms and signs may progress without the appearance of new plaques. These and other factors need to be taken into consideration in evaluating the clinical course of the illness and the effects of a therapeutic program (see Poser).

Unusually severe *fatigue* is another peculiar symptom of MS; it is often transient and more likely to occur when there is fever or other evidence of disease activity, but it can be a persistent complaint and a source of considerable distress. Depression may play a role in these recalcitrant cases, although the response to pharmacologic agents suggests that these two aspects of the disease are dissociable. Thus, antidepressants often do not improve fatigue, while drugs that alleviate fatigue, such as modafinil and amantadine, do not function as antidepressants.

A number of other interesting manifestations of MS have come to our attention over the years and have given rise to difficulties in diagnosis. The occurrence of typical tic douloureux in

young patients has already been mentioned; only their young age and the bilaterality of the pain in some of them raised the suspicion of MS, confirmed later by sensory loss in the face and other neurologic signs. It is notable, however, that facial palsy along the lines of Bell’s palsy is almost never a sign of MS. Brachial, thoracic, or lumbosacral pain consisting mainly of thermal and algesic dysesthesias, was a source of puzzlement in several other patients until additional lesions developed. Other types of pain in MS have been addressed earlier. In two of our cases, the relatively acute occurrence of a right hemiplegia and aphasia first raised the probability of a cerebrovascular lesion; in still others, a more slowly evolving hemiplegia had led to an initial diagnosis of a cerebral glioma. The dystonic and paroxysmal symptoms are mentioned above; they do not typically bring the diagnosis of MS to mind.

Approximately 3 percent of patients reportedly have focal seizures, but it should be emphasized that this is usually in relation to an obvious cerebral lesion and advanced disease of many years duration. Seizures at an early stage of illness are almost always attributable to previous head injury, idiopathic epilepsy, or as in a recent case, withdrawal of sleep medication. Several times we have seen coma during relapse of MS, and in each instance it continued to death. In one case it occurred in a 64-year-old woman who had had two previous episodes of nondisabling spinal MS at 30 and 44 years of age. A confusional psychosis with drowsiness was the initial syndrome in another patient whom we saw later with a relapse involving the cerebellum and spinal cord. Another unusual syndrome is one of slow intellectual decline with slight cerebellar ataxia. A 10-year, slowly progressive cerebellar ataxia in an adolescent girl was perplexing until she later developed internuclear ophthalmoplegia. A rapid onset of ascending paralysis of legs, bladder and bowel, and trunk with severe pain in sacral parts, areflexia, and a mononuclear pleocytosis of 1600 cells per cubic millimeter occurred in another of our patients and lasted 2 years before she began to walk again; earlier she had had diplopia and retrobulbar neuritis. Cases similar to these develop a necrotic myelopathy that is similar to Devic disease and there is little recovery.

As mentioned in the chapter on spinal cord disease, some instances of MS in late adult life take the form of a slowly progressive cervical myelopathy. There is also certainly a form of spinal MS without cerebral involvement, as noted further on.

Seemingly more frequently in recent years, we have observed patients whose illness satisfied all the clinical criteria for the diagnosis of MS except for the onset of symptoms in the sixth or seventh decade. Presumably we were witnessing the late deteriorative phase of the illness, earlier symptoms having been forgotten or having never been recognized. Contrariwise, in our pathologic material (and increasingly with the ubiquitous use of MRI scans), we have several times found a few typical lesions of MS to which the clinical records make no reference.

Variants of Multiple Sclerosis

Several variants of MS merit more extended discussion. They are acute MS, neuromyelitis optica, acquired Schilder disease, and the conjunction of MS and polyneuropathy. The chronic progressive variety of MS presents special problems that are addressed in a later section on “Clinical Course and Prognosis.”

Acute Multiple Sclerosis Rarely, MS takes a rapidly progressive and highly malignant form; Marburg’s name has been attached to this variant. A combination of cerebral, brainstem, and spinal man-

ifestations evolves over a few weeks, rendering the patient stuporous, comatose, or decerebrate, with prominent cranial nerve and corticospinal abnormalities. Death may end the illness within a few weeks to months without any remission having occurred, or there may be partial recovery, as noted below. At autopsy the lesions are of macroscopic dimensions, in essence very large acute plaques of MS. The only difference from the usual form of MS is that many plaques are of the same age and the confluence of many perivenous zones of demyelination is more obvious. Large acute plaques may have associated mass effect and enhancement that simulates a tumor in radiographic appearance, but they tend to evolve at a more rapid pace clinically. Two of our most striking examples of this rapidly fatal form were in a 6-year-old girl and a 16-year-old boy, both of whom died within 5 weeks of the onset of symptoms. Another was a 30-year-old man who lived 2 months. In none of them had there been a preceding exanthem or inoculation or any symptoms suggestive of demyelinative disease. Mendez and Pogacar present such a case and point out the extensive contrast enhancement of the brain lesions on a CT scan. Usually the CSF shows a cellular response but no oligoclonal bands.

Nonfatal clinical cases of similar type in children, adolescents, and young adults are admitted to our hospitals once or twice a year. Some have responded to high doses of intravenous corticosteroids; others worsened while receiving this medication. We have also had experience with two patients who improved rapidly after the institution of plasma exchange treatments, similar to the report by Rodriguez and coworkers. However, it is clear that most patients with acute MS, especially those with myelitis, do not respond to this treatment. Some have made an astonishing recovery after several months, and a few have then remained well for 25 to 30 years. Others have relapsed, and the subsequent clinical course was typical of MS.

Most neurologists are familiar with similar episodes of acute deterioration that punctuate otherwise typical cases of MS. These aggressive relapses occur most often in the first year of illness and in middle-aged patients and take the form of an exacerbation of a pre-existing myelopathy in combination with a new brainstem syndrome. After a severe episode of this sort or multiple ones, a few of the lesions are found to be cavitating on imaging studies rather than demyelinative.

It seems to the authors that more than one disease is being included in the clinical category of acute MS. One type conforms in its temporal profile to a rather protracted form of acute disseminated encephalomyelitis—an acute monophasic illness extending over 4 to 8 weeks. Others subsequently prove to be typical polyphasic MS. The main considerations in differential diagnosis are a CNS vasculitis and intravascular lymphoma.

In all the variants of MS, diagnosis becomes secure only when there is evidence of multiple cerebral and spinal lesions, usually verified by MRIs taken over an interval of time. A word of caution in using MRI for this purpose: small lesions may be overlooked and, as noted earlier, lesions similar to those of MS are caused by a large number of other processes.

Neuromyelitis Optica (Devic Disease, Necrotic Myelopathy; See also Chap. 46) Here, there is a simultaneous or successive and usually severe involvement of optic nerves and spinal cord. The combination was remarked upon by Clifford Albutt in 1870, and Gault (1894), stimulated by his teacher Devic, devoted his thesis to the subject. Devic subsequently endeavored to crystallize medical thought about a condition that has come to be known as neu-

romyelitis optica. Its principal features are the acute to subacute onset of blindness in one or both eyes, preceded or followed within days or weeks by a severe transverse or ascending myelitis (Mandler et al). The spinal cord lesions in cases of neuromyelitis optica are often necrotizing rather than purely demyelinative in type, leading eventually to cavitation; as would be expected, the clinical effects are more likely to be permanent than those of demyelination. A few of the patients have been children; in a number of instances, they suffered only a single episode of neurologic illness.

Although it is true that cases corresponding to this prototype are seen on occasion in every large medical center and at all age periods, the isolation of such an entity on clinical grounds alone has been unsatisfactory. At least half of our patients have proved by subsequent clinical developments, and in a few instances by autopsy, to have chronic relapsing MS. In one notable example, where hemiplegia and aphasia were followed within 2 weeks by a necrotizing myelitis from which there was no recovery, the patient later developed typical attacks of MS, including retrobulbar neuritis. At autopsy, more than 15 cm of the spinal cord had been destroyed, reducing it to a collapsed membranous tube. Elsewhere in the brain and cord the lesions were typically demyelinative.

One might conclude from cases such as these that neuromyelitis optica is but a variant form of MS (or some other type of demyelinative disease). Many cases of neuromyelitis optica, however, stand apart from MS by virtue of a number of distinctive clinical and pathologic features—namely, a failure to develop brainstem, cerebellar, or cerebral demyelinative lesions and normality of the cerebral white matter on MRI, even after several years of illness; almost uniform absence of oligoclonal bands and other abnormalities of IgG in the spinal fluid; and finally, the necrotizing and cavitary nature of the spinal cord lesion, affecting white and gray matter alike with prominent thickening of vessels but without inflammatory infiltrates. On the basis of these differences, Mandler and O'Riordan and their colleagues and others have favored the separation of Devic disease from MS. For reasons mentioned above, we are uncertain that the distinction is quite so clear or perhaps there are two types of disease, only one of which is allied with MS. Recently, evidence of antibody binding, complement activation, and eosinophilic infiltration has led to the conclusion that the Devic process is a humoral disease, in contrast to the cellular mechanism that has been proposed for MS (see Lucchinetti et al, 2002). In support of this notion is the finding of a serum IgG antibody directed against capillaries in the brainstem and cerebellum. Lennon and colleagues have reported that this is a marker for neuromyelitis optica in half of the cases and is absent in MS. Insofar as the cause of neither MS nor Devic disease is known, uncertainties about the relationship of these diseases cannot be resolved with finality. It should also be noted that acute disseminated encephalomyelitis may occasionally present as a neuromyelitis optica syndrome.

There is in addition a progressive and saltatory *subacute necrotic myelopathy* without optic neuritis that shares all the myelopathic features of Devic disease but not the optic neuropathy and, in our view, probably represents the same entity (Katz and Ropper). In our clinics, such purely myelopathic cases outnumber those of Devic disease. The differential diagnosis here is broader and includes specifically arteriovenous malformation of the cord or dura and, of lesser resemblance, infarction or neoplasm of the cord. Also, a rare isolated vasculitis of the cord may cause a necrotic myelopathy; it is associated with an active CSF pleocytosis (Ropper et al). The cord in the cases we have studied was swollen on

MRI in the early stages, often with edema extending many segments above and below the area of primary disease, and later became atrophic. Up to 50 cells are typical in the CSF and the protein is elevated, but the spinal fluid may be normal during periods of clinical stability. Several of these cases have had positive IgG antibodies as tested in Weinshaker's laboratory (see above), further supporting the notion that these cases are allied with Devic disease but leaving ambiguous the relationship of both entities to MS.

Treatment The treatment of neuromyelitis optica and of subacute necrotic myelopathy has been largely unsuccessful, most cases progressing despite aggressive therapy, including high-dose corticosteroids, plasma exchange, intravenous immunoglobulin, azathioprine, and cyclophosphamide. A study of several patients by Mandler and colleagues (1998) suggested that perhaps a combination of high-dose methylprednisolone and azathioprine led to clinical improvement; we cannot affirm this approach, but most other treatments have given poor results in our experience. Because some individuals respond (albeit infrequently) to them, it is appropriate to try one or more of these therapies in these cases.

Diffuse Cerebral Sclerosis of Schilder (Schilder Disease, Encephalitis Periaxialis Diffusa) Exceptionally the cerebrum is the site of massive demyelination, occurring in multiple foci or as a single large focus. Such cases are more frequent in childhood and adolescence than in adult life. Despite the undoubted occurrence of such cases, to call them "Schilder disease" is to refer to a clinical entity of ambiguous standing.

The term *diffuse sclerosis* was probably first used by Strümpell (1879) to describe the hard texture of the freshly removed brain of an alcoholic; later the term was applied to widespread cerebral gliosis of whatever cause. In 1912, Schilder described an instance of what he considered to be "diffuse sclerosis." The case was that of a 14-year-old girl with progressive mental deterioration and signs of increased intracranial pressure, terminating fatally after 19 weeks. Postmortem examination disclosed large, well-demarcated areas of demyelination in the white matter of both cerebral hemispheres as well as a number of smaller demyelinative foci, resembling the common lesions of MS. Because of the similarities of the pathologic changes to those of MS (prominence of the inflammatory reaction and relative sparing of axons), Schilder called this disease *encephalitis periaxialis diffusa*, bringing it in line with *encephalitis periaxialis scleroticans*, a term that Marburg had used to describe a case of acute MS. Unfortunately, in subsequent publications, Schilder applied the same term to two other conditions of different type. One appears to have been a familial leukodystrophy (probably adrenoleukodystrophy) in a boy, and the other, quite unlike either of the first two cases, was suggestive of an infiltrative lymphoma. The last two reports seriously confused the subject, and for many years the terms *Schilder disease* and *diffuse sclerosis* were therefore indiscriminately attached to quite different conditions.

One group of diseases of the cerebral white matter, which can be readily culled from the overall category of diffuse sclerosis, is the leukodystrophies, including adrenoleukodystrophy of boys and young men, globoid-cell leukodystrophy of Krabbe, sudanophilic leukodystrophy, and metachromatic leukodystrophy—all of which may involve peripheral nerves as well as the CNS tissue. The leukodystrophies (discussed in detail in Chap. 37) are characterized clinically by progressive visual failure, mental deterioration, and spastic paralysis and pathologically by massive and more or less symmetrical destruction of the white matter of the cerebral hemi-

spheres. In each of them there is a specific inherited biochemical defect in the metabolism of myelin proteolipids.

If one sets aside the hereditary metabolic leukodystrophies and other childhood disorders of cerebral white matter that were incorrectly included under the rubric of "Schilder disease" or "diffuse sclerosis," there remains a characteristic group of cases that does indeed correspond to Schilder's original case description. They are nonfamilial and are most frequently encountered in children or young adults. As with the case reported by Ellison and Barron, the disease may follow the course of MS, either steady and unrelenting or punctuated by a series of episodes of rapid worsening. In rare instances the disease may become arrested for many years, or the patient may even improve for a time. Dementia, homonymous hemianopia, cerebral blindness and deafness, varying degrees of hemiplegia and quadriplegia, and pseudobulbar palsy are the usual clinical findings. Optic neuritis may occur before or after the cerebral symptoms. The CSF may show changes similar to those in chronic relapsing MS, but often there are no oligoclonal bands; instead, myelin basic protein is found in large quantity in the CSF. Death occurs in most patients within a few months or years, but some survive for a decade or longer. In the differential diagnosis, a diffuse cerebral neoplasm (gliomatosis or lymphoma), adrenoleukodystrophy, and progressive multifocal leukoencephalopathy (Chap. 33) are the main considerations.

The characteristic lesion in these cases is a large, sharply outlined, asymmetrical focus of myelin destruction often involving an entire lobe or cerebral hemisphere, typically with extension across the corpus callosum and involvement of the opposite hemisphere (Fig. 36-2). In some cases both hemispheres may be symmetrically involved. A careful examination of the optic nerves, brainstem, and spinal cord often discloses the typical discrete lesions of MS. Histologically, the large single focus as well as the smaller disseminated ones show the characteristic features of MS.

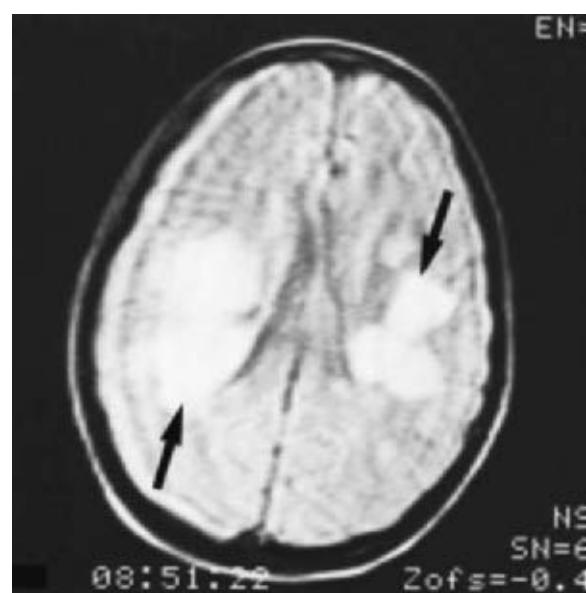

Figure 36-2. Diffuse cerebral sclerosis (Schilder disease). MRI showing large asymmetric foci of involvement of white matter in a 12-year-old boy 2 1/2 months after onset of symptoms. The clinical picture was one of rapidly worsening episodes of bilateral hemiplegia and hemianopia. (Reproduced by permission from Bisceglie JH, *Cranial MRI*, New York, McGraw-Hill, 1991.)

Poser's review of the literature in 1957 uncovered 105 cases that could be designated as the Schilder type of diffuse sclerosis in the original sense of the term. In 33 of these, the only lesions were the extensive areas of demyelination involving the centrum ovale; most of the patients in this group were children, and the disease had a tendency to take a subacute progressive course. In 72 patients, in addition to the large foci in the cerebral white matter, isolated demyelinative plaques were found in other parts of the central nervous system; the age of onset in this latter group was similar to that of chronic, relapsing MS. Frequently, the illness ran a protracted and remitting course. These findings were elaborated by Poser and colleagues in a subsequent (1986) review of this subject. It is apparent that diffuse cerebral sclerosis of this type must be closely related to MS and may indeed be a variant of it, as Schilder originally proposed.

The *concentric sclerosis of Balo* is probably a variety of Schilder disease, which it resembles in its clinical aspects and in the overall distribution of its lesions. The distinguishing feature is the occurrence of alternating bands of destruction and preservation of myelin in a series of concentric rings. The occurrence of lesions in this pattern suggests the centrifugal diffusion of some factor that is damaging to myelin. A similar pattern of lesions, although far less extensive, is seen in occasional cases of chronic relapsing MS.

Multiple Sclerosis in Conjunction with Peripheral Neuropathy
From time to time there have been patients with MS who also have a polyneuropathy or mononeuropathy multiplex. This relationship always invites speculation and controversy. The rarity of the combination suggests a purely coincidental occurrence, perhaps with another underlying disease as an explanation (e.g., Lyme disease, AIDS). Another view, expressed by Thomas and colleagues and by Mendell et al, is that an autoimmune demyelination has been incited in both spinal cord and peripheral nerve, the latter taking the form of a chronic inflammatory polyradiculoneuropathy. Of course, radicular and neuropathic symptoms, motor and/or sensory, can result from the involvement of myelinated fibers in the root entry zone of the cord or fibers of exit in the ventral white matter. And in the late stages of MS there is always the possibility of vitamin deficiency polyneuropathy or multiple pressure palsies. At the moment, we consider the two components to be different in origin.

Laboratory Findings

Cerebrospinal Fluid In about one-third of all MS patients, particularly those with an acute onset or an exacerbation, there may be a slight to moderate mononuclear pleocytosis (usually in the range of 6 to 20 and in any case, less than 50 cells per cubic millimeter). In rapidly progressive cases of neuromyelitis optica (see above) and in certain instances of severe demyelinative disease of the brainstem, the total cell count may reach or exceed 100 and rarely 1000 cells per cubic millimeter; in the hyperacute cases, the greater proportion of these may be polymorphonuclear leukocytes. This pleocytosis may in fact be the only measure of activity of the disease.

It has been shown that the gamma globulin proteins in the CSF of patients with MS are synthesized in the CNS (Tourtellotte and Booé) and that they migrate in agarose electrophoresis as abnormal discrete populations, so-called *oligoclonal bands*. This is currently the most widely used CSF test for the confirmation of the diagnosis. Determination of the IgG index and testing for oligoclonal IgG bands is done in most commercial and hospital labor-

ratories and will show several bands in the CSF in more than 90 percent of cases of MS. Such bands also appear in the CSF of patients with syphilis, Lyme, and subacute sclerosing panencephalitis—disorders, with perhaps the exception of the second one, that should not be difficult to distinguish from MS on clinical grounds. The demonstration of oligoclonal bands in the CSF and not in the blood is particularly helpful in confirming the diagnosis of MS, but they are not always found with the first attack or even in the later stages of the disease. The presence of such bands in a first attack of MS is predictive of chronic relapsing MS, according to Moulin and coworkers and others. Oligoclonal bands are usually reported as being present if there is more than one band; the meaning of a single band is not clear, and we have treated this result as a negative test. As already pointed out, some of the dramatic variants of MS such as necrotic myopathy and Devic disease generally lack oligoclonal bands.

Also, in about 40 percent of patients, the total protein content of the CSF is increased. The increase is slight, however, and a concentration of more than 100 mg/dL is so unusual that the possibility of another diagnosis should be entertained. More importantly, the proportion of gamma globulin (essentially IgG) is increased (greater than 12 percent of the total protein) in about two-thirds of patients. Another less frequently used diagnostic measure is the IgG index, which is obtained by measuring albumin and gamma globulin in both the serum and CSF and using the following formula:

$$\frac{\text{CSF IgG/serum IgG}}{\text{CSF alb/serum alb}}$$

A ratio of more than 1.7 indicates the probability of MS.

It has also been shown, by the use of a sensitive radioimmunoassay, that the CSF of many patients contains high concentrations of myelin basic protein (MBP) during acute exacerbations of MS and that these levels are lower or normal in slowly progressive MS and normal during remissions of the disease (Cohen et al). Other lesions that destroy myelin (e.g., infarction) can also increase the level of MBP in the spinal fluid. Thus the assay is not particularly useful as a diagnostic test and probably simply reflects the destruction of central myelin. The method is not simple but is available commercially.

When cells, total protein, gamma globulin, and oligoclonal bands are all taken into account, some abnormality of the spinal fluid will be found in the great majority of patients with MS. At present the measurement of gamma globulins as a fraction of total protein and oligoclonal bands in the CSF are the most reliable of the chemical tests for MS, particularly when the test is taken some interval after an acute exacerbation or during the chronic progressive phase of disease. We are not convinced that other, more complicated laboratory procedures, such as CSF measurements of globulin production or MBP, provide additional diagnostic sensitivity.

The results of Berger and colleagues, mentioned earlier in the discussion of pathogenesis, may in the future introduce into practice the measurement of serum antibodies against myelin basic protein and oligodendrocyte glycoprotein, as noted further on.

Magnetic Resonance Imaging in Multiple Sclerosis It is now widely appreciated that MRI is the most helpful ancillary examination in the diagnosis of MS, by virtue of its ability to reveal asymptomatic plaques in the cerebrum, brainstem, optic nerves, and spinal cord (see Fig. 36-1). Most experience accords with that

of Stewart and coworkers, who found multifocal lesions in the cerebrum in 80 percent of their established cases. In a series of 114 patients with clinically definite MS, Ormerod and colleagues detected T2-intense periventricular MRI abnormalities in all but 2 patients and discrete cerebral white matter lesions in all but 12. With newer imaging sequences, the proportion with lesions is even higher, greater than 90 percent in some series. It is remarkable that even when there are a multitude of cerebral lesions, they tend to be asymptomatic; by contrast, spinal cord lesions are almost always symptomatic. Also, attention has been drawn by Bot and colleagues to lesions in the spinal cord that allow for diagnosis based on the identification of a second involved site in the nervous system. However, even in their series of 104 patients, only 3 had an abnormality in the cord and none in the cerebrum.

Several MRI features are characteristic of the chronic MS lesion; some of these are dependent on the field strength of the magnet and the ratio of T1 and T2 weighting. In general, chronic MS plaques are hyperintense (white) on T2-weighted images and even more strikingly obvious on FLAIR images (although we have seen the opposite pattern in some posterior fossa lesions). Lesions that have undergone some degree of cavitation, as happens only occasionally, are hypointense on T1-weighted images. Longitudinal analyses reveal a slow increase over time in the total burden of hypointense T1 images; in one study, these increased with the numbers of enhancing lesions in untreated patients (Simon).

The discrete cerebral lesions of MS do not always impart a specific MRI appearance; but the finding on T2-weighted images of several asymmetrical, well-demarcated lesions immediately adjacent to the ventricular surface usually denotes MS. *Especially diagnostic are oval or linear regions of demyelination, oriented perpendicularly to the ventricular surface;* they correspond to the radially oriented fiber bundles of the white matter and periventricular veins. When viewed in sagittal images, they extend outward from the corpus callosum in a fimbriated pattern and have been termed "Dawson fingers." These areas may extend into the centrum semiovale and may reach the convolutional white matter (Fig. 36-1). Even one highly characteristic lesion is sometimes enough to confirm the diagnosis in the proper clinical circumstances; multiple lesions are more convincing. The presence of such lesions in the corpus callosum is diagnostically useful, as this structure is spared in many other disorders.

Early in the evolution of an MS lesion there is disruption of the blood-brain barrier, presumably as a consequence of inflammation. The MRI correlate is enhancement following the administration of gadolinium. Although usually readily apparent, this aspect may be exposed only by administration of double or triple the usual dose of gadolinium. Gadolinium enhancement may last for 3 to 4 months following the development of the acute lesion. Otherwise, the signal characteristics of MS lesions are not obviously dependent on the age of the lesions.

In advanced cases of MS, the lesions become confluent, usually at the poles of the ventricles. The spectrum of these changes has been commented on by Berry and colleagues. Infrequently, a large acute lesion may have a mass effect and a ring-like contrast-enhancing border, resembling a glioblastoma or an infarct; the correct diagnosis may then be made only by biopsy. A series of focal tumor-like lesions of the brain, the demyelinative nature of which became evident only after biopsy, has been reported by Kepes. Serially performed MRIs can demonstrate the progress of the disease by the accumulation of increasing numbers of cerebral lesions; but even then they usually remain asymptomatic. As mentioned,

lesions in the spinal cord that are detected by MRI are more likely to be symptomatic, but there are striking exceptions. As with other laboratory procedures, MRI changes assume maximal diagnostic significance when they are consistent with the clinical findings.

Increasingly, other aspects of the pathology of MS lesions have been delineated using MRI studies, such as the processes of plaque remyelination, axonal degeneration and brain atrophy. As assessed histologically in 36 brains with both autopsies and MRI studies, remyelinated foci were quite common and correlated well with persistent T2 hyperintensity; on the other hand, T1 hypointensity was inversely proportional to the degree of remyelination (Barkhof). Several studies have documented that slowly progressive brain atrophy, as gauged by volumetric MRI measurements, is a feature of long-standing MS. This is demonstrable both early and late in the disease and correlates loosely with disability. The basis for the atrophy is not fully defined. It probably reflects both the loss of glial cells and, importantly, wallerian degeneration and loss of axons triggered acutely by inflammation and more chronically by other neurodegenerative stimuli (Miller). In the investigation of brain atrophy in MS, volumetric studies have been supplemented by spectroscopic biochemical analyses; some studies have demonstrated a correlation between various measures of atrophy, levels of N-acetyl-aspartate (NAA, a marker of axons), and disability.

It should be stressed that foci of periventricular hyperintensity are observed with a variety of pathologic processes and even in normal persons, particularly older ones; in the older individuals, the periventricular changes are usually milder in degree, less dense, and smoother in outline than the lesions of MS.

Evoked Potentials and Other Confirmatory Tests When the clinical data point to only one lesion in the CNS, as often happens in the early stages of the disease or in the spinal form, a number of other sensitive physiologic and radiologic tests may establish the existence of additional asymptomatic lesions. These include visual, auditory, and somatosensory evoked responses and the less standardized and infrequently tested perceptual delay on visual stimulation; electro-oculography; altered blink reflexes; and a change in flicker fusion of visual images. At our hospitals, abnormal visual evoked responses have been found in 70 percent of patients with the clinical features of definite MS and 60 percent of patients with probable or possible MS. The corresponding figures for somatosensory evoked responses have been 69 percent and 51 percent, and for brainstem auditory evoked responses (usually prolonged interwave latency or decreased amplitude of wave 5), 47 percent and 20 percent, respectively according to our colleague K. Chiappa (see Chap. 2).

CT scanning may also demonstrate cerebral lesions, often unexpectedly. Doubling the dose of contrast material and delaying the scan for an hour postinfusion increases the yield of lesions during exacerbations of MS. Two points worth noting about the CT scan are that acute plaques can appear as contrast-enhanced ring lesions, simulating abscess or tumor, and that some contrast-enhanced periventricular lesions become radiologically inevident after steroid treatment, as occurs also with CNS lymphoma.

As mentioned earlier, the ancillary examinations in common use—MRI, evoked potentials, and oligoclonal bands in the CSF—have broadened the criteria for the diagnosis of MS. Often these procedures disclose the presence of multiple plaques when clinical examination has failed to do so. Stated differently, the time-honored rule that the diagnosis of MS requires evidence of "lesions

scattered in time and space" is still valid, but the evidence now includes certain laboratory findings as well as purely clinical ones. Finally, it should be noted that no single laboratory procedure—including MRI, altered blood-brain barrier, immunoglobulin synthesis, and MBP in CSF—when viewed alone or at a single time is a totally reliable marker for MS.

Clinical Course and Prognosis

The intermittency of the clinical manifestations—the disease advancing in a series of attacks, each permitting less and less remission—is perhaps the most important clinical attribute of MS. Some patients will have a complete clinical remission after the initial attack, or, there may be a series of exacerbations, each with complete remission; such exacerbations may rarely be severe enough to have caused quadriplegia and pseudobulbar palsy. The average relapse rate is 0.3 to 0.4 attacks per year according to the calculations of McAlpine and Compston, but the interval between the opening symptom and the first relapse is highly variable. It occurred within 1 year in 30 percent of McAlpine's cases and within 2 years in another 20 percent. A further 20 percent relapsed in 5 to 9 years, and another 10 percent in 10 to 30 years. Not only the length of this latent interval is remarkable but also the fact that the basic pathologic process can remain potentially active for such a long time.

Weinshenker and colleagues, on the basis of observations in 1099 MS patients over a 12-year period, have identified a number of features of the early clinical course that are predictive, in a general way, of the outcome of the illness. Perhaps not surprisingly, they found that a high degree of disability, as measured by the Kurtzke Disability Status Scale, was reached earlier in patients with a higher number of attacks, a shorter first interattack interval, and a shorter time to reach a state of moderate disability. Kurtzke had earlier reported that the feature most predictive of long-term disability was the degree of disability at 5 years from the first symptom.

Whether the aforementioned tests for serum antibodies against oligodendrocytes and myelin have the predictive value indicted by Berger and colleagues remains to be seen, but their results are provocative. Only 23 percent of patients who lacked these antibodies had further attacks after their first one, despite the presence of oligoclonal bands, whereas 95 percent of those who had both antibodies suffered a relapse at an average time of 7 months.

After a number of years there is an increasing tendency for the patient to enter a phase of slow, steady, or fluctuating deterioration of neurologic function, attributable to the cumulative effect of increasing numbers of lesions. However, in about 10 percent of cases the clinical course is almost evenly progressive from the beginning (*primary progressive MS*; see Thompson et al). In these latter cases the disease usually takes the form of a chronic asymmetrical spastic paraparesis and probably represents the most frequent type of obscure myelopathy observed by the authors. In Thompson's review of primary progressive MS, there was little change over time in the MRI findings, a negligible response to therapy, and a poor outcome. However, the validity of a fundamental distinction between relapsing and progressive MS is inevitably called into question since some lesions are silent and their accretion over time could be gradual. The frequency with which acute MS blends into the progressive variety has already been emphasized. (See earlier comments on page 772 regarding the pathologic distinctions between types of MS.)

Contrary to commonly held opinion, pregnancy does not have an adverse effect on MS. In fact, pregnancy is typically associated with clinical stability or even with improvement (as it is in a number of autoimmune diseases). The average relapse rate in established cases declines in each trimester, reaching a level less than one-third of the expected rate by the third trimester. However, there appears to be an increased risk of exacerbations, up to twofold, in the first few months postpartum (see Birk and Rudick). An extensive study of 269 pregnancies by Confavreux and colleagues established a rate of relapse of 0.7 per woman per year before pregnancy and rates of 0.5 in the first, 0.6 in the second, and 0.2 in the third trimester, the rate then increasing substantially to 1.2 in the first 3 months postpartum.

The duration of the disease is exceedingly variable. A small number of patients die within several months or years of the onset, but the average duration is in excess of 30 years. A 60-year appraisal of the resident population of Rochester, Minnesota, disclosed that 74 percent of patients with MS survived 25 years, as compared with 86 percent of the general population. At the end of 25 years, one-third of the surviving patients were still working and two-thirds were still ambulatory (Percy et al). Other statistical analyses have given a less optimistic prognosis; these have been reviewed by Matthews. Patients with mild and quiescent forms of the disease are, of course, less likely to be included in such surveys. Although exceptional, one of our patients relapsed and developed massive brainstem demyelination and coma after 30 years (confirmed by postmortem examination), and cases of an aggressive myelopathy that appears after years quiescence are well known.

No environmental, dietary, or activity-related changes are known to alter the course of the illness.

Differential Diagnosis

In the usual forms of MS—that is, in those with a relapsing and remitting course and evidence of disseminated lesions in the CNS—the diagnosis is rarely in doubt. Meningovascular syphilis, certain rare forms of cerebral arteritis, vascular malformations such as cavernous angiomas of the brainstem or spinal cord with multiple episodes of bleeding, brain lymphoma, lupus erythematosus, the antiphospholipid antibody syndrome, and Behcet disease simulate relapsing MS, and each of these has its own characteristic and diagnostic features. The list can be expanded by the inclusion of corticosteroid-responsive cerebral lymphoma, intravascular lymphoma, and the numerous causes of multiple, well-demarcated white matter abnormalities on MRI, such as embolic infarcts, progressive multifocal leukoencephalopathy, Lyme disease, sarcoid, tumors, etc. Difficulties are most likely to arise when the standard clinical criteria for the diagnosis of MS are lacking, as occurs in the acute initial attack of the disease and in cases with an insidious onset and slow, steady progression. *Other features that call for caution in diagnosis of MS are an absence of symptoms and signs of optic neuritis, the presence of widespread amyotrophy, entirely normal eye movements, a hemianopic field defect, pain as the predominant symptom, and a progressive nonremitting illness that begins in youth.* Other points against MS are fever and nonneurologic features such as joint inflammation, skin rash, Sicca syndrome, or evidence of peripheral neuropathy.

As has been stated, the initial attack of MS may mimic acute labyrinthine vertigo or tic douloureux (trigeminal neuralgia). Careful neurologic examination of such patients usually discloses other signs of a brainstem lesion; the CSF examination may be particu-

larly helpful in these circumstances. Extensive brainstem demyelination of subacute evolution, involving tracts and cranial nerves sequentially, may be mistaken for a pontine glioma. With brainstem symptoms of acute onset, there may be difficulty in distinguishing an MS plaque from a small infarction due to a basilar branch occlusion. In several patients that we have observed, recurrent bleeding from cavernous vascular malformations and small brainstem arteriovenous malformations simulated MS. Only with MRI, visualization of blood products surrounding the small vascular lesions may the diagnosis be clarified (see Fig. 34-26). Sequential MRIs and the course of the illness settle the matter; symptoms of brainstem MS remit as a rule, and to a surprisingly complete degree in many cases.

Disseminated encephalomyelitis (see further on) is an acute illness with widely scattered small demyelinative lesions, but it is self-limited and monophasic; furthermore, fever, stupor, and coma, which are characteristic of severe cases, rarely occur in MS. The encephalomyelitis may, however, progress for several weeks, making the distinction from MS difficult.

In systemic lupus erythematosus and rarely in other autoimmune diseases (mixed connective tissue disease, Sjögren syndrome, scleroderma, primary biliary cirrhosis), there may be multiple lesions of the CNS white matter. These may parallel the activity of the underlying immune disease or the level of autoantibodies, particularly those against native DNA or phospholipids, but myelitis or lesions in the cerebral hemispheres are known to occur before other organ systems are affected. Conversely, between 5 and 10 percent of MS patients have antinuclear or anti-double stranded DNA antibodies without signs of lupus, but the significance of this finding is not at all clear. In addition, it has been pointed out that the relatives of patients with MS have a higher than expected incidence of autoantibodies of various types, suggesting an as yet unproved connection between autoimmune disease and MS. On MRI, the lesions of lupus and of antiphospholipid antibody syndrome appear similar to plaques, and both the optic nerve (rarely) and the spinal cord may be involved, even repeatedly, in a succession of attacks resembling MS. Nevertheless, in our pathologic material, the lesions represent small zones of infarct necrosis rather than demyelination and are traceable to small-vessel occlusion or cardiogenic embolism. In a few instances, inflammatory demyelination without vascular changes may be seen. It is best for the moment to consider these as special vascular manifestations of lupus or related diseases that mimic MS.

Periarteritis nodosa or vasculitis confined to the nervous system may produce multifocal lesions simulating MS. The distinction may be particularly difficult in rare instances of the vasculitic process in which the neurologic manifestations take the form of a relapsing or steroid-responsive myelitis. In these cases, the CSF may contain 100 or more white blood cells per cubic millimeter and there may be no evidence of disease elsewhere in the nervous system. Occasionally, a young individual with Lyme disease may have complaints of inordinate fatigue and vague neurologic symptoms coupled with bright lesions on the T2-weighted cranial MRI. Close attention to the characteristic history (rash, arthritis, etc.) and serologic findings should permit the distinction of the two diseases.

The distinguishing features of Behcet disease are recurrent iridocyclitis and meningitis, mucous membrane ulcers of mouth and genitalia, and symptoms of articular, renal, lung, and multifocal cerebral disease. The chronic forms of brucellosis in the Mediterranean regions and Lyme borreliosis throughout North America and Europe may cause myelopathy or encephalopathy with multi-

ple white matter lesions on imaging studies, but in each case the history and other features of the disease help to identify the infectious illness (see Chap. 32).

The *purely spinal form of MS*, presenting as a progressive spastic paraparesis, hemiparesis, or—in several of our cases—spastic monoparesis of a leg with varying degrees of posterior column involvement, is a special source of diagnostic difficulty. A tendency to affect older women has already been mentioned. Such patients require careful evaluation for the presence of spinal cord compression due to neoplasm or cervical spondylosis. Dural arteriovenous fistula is also a consideration. Radicular pain at some point in the illness is a frequent manifestation of these disorders and is much less frequent in MS. Pain in the neck, restricted mobility of the cervical spine, and severe muscle wasting due to spinal root involvement, as is sometimes seen in spondylosis, are almost unknown in MS. Moderate atrophy of the first dorsal interosseous muscles has, however, been commented on as a common finding in MS. As a general rule, loss of abdominal reflexes, impotence in males, and disturbances of bladder function occur early in the course of demyelinative myelopathy but late or not at all in cervical spondylosis. The CSF protein in the latter condition is apt to be significantly elevated, but the other typical protein abnormalities of MS are absent. The definitive tests are MRI and CT myelography and perhaps electromyography (EMG), which is sensitive to the radicular features of spondylosis. Every patient with progressive spastic paraparesis in whom the neurologic signs are limited to the spinal cord should be investigated by these methods. In a patient with subacute, saltatory, and painful myelopathy restricted to one level (usually thoracic), a search for an arteriovenous malformation or fistula may be required. A special problem arises when imaging procedures reveal a regional swelling of the spinal cord suggestive of a tumor, which happens occasionally with an episode of myelitis. In several of our patients, this finding has led to fruitless laminectomy. Sarcoidosis affecting the cord presents similar problems; steroid-responsive granulomatous lesions of sarcoid that follow a venous pattern in the cerebrum may cause confusion with MS when viewed by MRI. The subpial pattern of enhancement with gadolinium is helpful in identifying sarcoid.

The problem of differentiating chronic spinal MS from tropical spastic paraparesis (human lymphotropic virus, myelitis of the HTLV-1 type) and progressive familial spastic paraparesia may also arise occasionally. Amyotrophic lateral sclerosis (ALS) and subacute combined degeneration (SCD) of the cord should not be confused with MS. ALS can be identified by the presence of muscle wasting, fasciculations, and the absence of sensory involvement, while SCD is characterized by symmetrical involvement of the posterior and then lateral columns of the spinal cord, low serum levels of vitamin B₁₂, gastric achlorhydria, the presence of multilobed polymorphonuclear cells, megaloblastic marrow and macrocytic anemia in many cases, high serum concentrations of methylmalonic acid and homocystine, and defective absorption of vitamin B₁₂ as determined by the Schilling test (page 995). Reports that vitamin B₁₂ levels are marginally low in a proportion of MS patients have been suggested as reflecting an underlying disturbance of homocysteine metabolism, but this has not been confirmed (Vrethem).

Platybasia and basilar impression of the skull should also be considered in the differential diagnosis, but patients with these conditions have a characteristic shortening of the neck; careful radiographs of the base of the skull will be diagnostic. Neurologic syndromes resulting from the Chiari malformation, syringomyelia, and tumors of the foramen magnum, cerebellopontine angle, clivus, and

other parts of the posterior fossa have been misdiagnosed as MS. In each of these instances, a solitary, strategically placed lesion may give rise to a variety of neurologic symptoms and signs referable to the lower brainstem and cranial nerves, cerebellum, and upper cervical cord, giving the impression of dissemination of lesions. It is an excellent clinical rule that a diagnosis of MS should be made with caution when all the patient's symptoms and signs can be explained by a single lesion in one region of the neuraxis.

Occasionally MS may be confused with the hereditary ataxias, particularly the spinocerebellar types. The latter are generally distinguished by their familial incidence and other associated genetic traits; by their insidious onset and slow, steady progression; and by their relative symmetry and stereotyped clinical pattern. Intactness of abdominal reflexes and sphincteric function and the presence of pes cavus, kyphoscoliosis, and cardiac disease are other features that favor the diagnosis of a heredodegenerative disorder (see Chap. 39). Finally, as mentioned above, the periventricular lesions of cerebral lymphoma—an increasingly common tumor—and intravascular lymphoma (page 565) may closely resemble MS plaques on MRI and may also produce a multifocal, relapsing, steroid-responsive illness of the CNS. This last disease has been associated at times with oligoclonal bands in the spinal fluid.

With routine use of MRI and its central use for the diagnosis of MS, the issue of interpreting multiple white matter lesions arises frequently. As already discussed, numerous small, radically oriented and periventricular lesions are most suggestive of MS. Multifocal subcortical lesions, however, also arise in diverse processes, such as granulomatous angiitis of the nervous system, lymphoma, sarcoid, Lyme, antiphospholipid antibody syndrome, lupus, polycythemia vera, thrombocytosis, and others. Notably, most of these processes cause small infarctions; others fluctuate in appearance with the use of steroids. The periventricular changes of chronic hypertension in the elderly are more confluent and diffuse than MS plaques, as discussed earlier, but when problems arise in differentiating the two, the patient's age and the sparing of the corpus callosum and immediately adjacent white matter are hints to the vascular-gliotic process. The difficulty of misinterpreting as a tumor a nodular enhancing mass of the acute MS lesion in the cerebrum has already been mentioned.

Careful clinical appraisal will usually lead to accurate diagnosis, but the label of MS should not be attached to a patient until the evidence is unequivocal. Once such a label is applied, it is difficult to discard, and since the diagnosis of MS will explain almost any subsequent neurologic event, attention may be directed away from consideration of another, perhaps more treatable disease.

Treatment

As one might expect, numerous forms of treatment have been proposed over the years, and many were thought to be successful, no doubt because of the remitting nature of the disease. To enumerate them all here would serve no useful purpose. The many therapeutic trials of recent years, utilizing mainly anti-inflammatory and immunosuppressive drugs, have been critically reviewed by Matthews and by Ebers and more recently by Rudick and colleagues. On the basis of controlled clinical trials, only adrenocorticotropic hormone (ACTH), methylprednisolone, prednisone, cyclophosphamide, copolymer, IFN- β , mitoxantrone and now, natalizumab have proved to have a beneficial effect on the disease and on MRI lesions each in specific circumstances.

Some current notions suggest that the definition of distinct clinical subsets of MS may be important in selecting therapy. Typical MS that is associated with episodic inflammation (relapsing-remitting) will probably be most responsive to immunomodulatory therapy. On the other hand, these measures may be less effective for chronic progressive subtypes. Indeed, while immunomodulatory therapies have shown at least short-term benefit in relapsing-remitting disease, none—with limited exceptions—has been clearly beneficial in chronic progressive MS. Therefore, as discussed earlier, therapy may be guided by the nature of the disease in each individual.

Corticosteroids Under the influence of corticosteroids, recovery from an acute attack, including an attack of optic neuritis, appears to be hastened. However, a substantial group of patients with acute exacerbations fail to respond; in others, benefit is not apparent for a month or longer after the course of treatment has been completed. There is limited evidence that steroids have a significant effect on the ultimate course of this disease or that they prevent recurrences. Accordingly, there is limited justification for steroid treatment over a period of many months or years except in those infrequent cases where withdrawal of the medication consistently leads to relapse (alternative diagnoses should be considered in this event). It should be noted, however, that in a study of intravenous methylprednisolone administered at 1 g/day for 5 days per month over 5 years, there was a reduction in disability as well as in the degree of brain atrophy and total volume of hypodense lesions on T1-weighted MRI (Zivadinov).

As to the dosage of corticosteroids for an acute attack, it has seemed to us that initially a high dose is more effective, but this has been disputed by others, as noted below. The intravenous administration of massive doses of methylprednisolone (a bolus of 500 to 1000 mg daily for 3 to 5 days), followed by high oral doses of prednisone (beginning with 60 to 80 mg daily and tapering to a lower dosage over a 12- to 20-day period) is generally effective in aborting or shortening an acute or subacute exacerbation of MS or of optic neuritis. This plan is probably as effective as, and far less cumbersome than, the administration of ACTH, which was popular during the 1970s. When it is impractical to administer parenteral methylprednisolone, one may substitute oral methylprednisolone—48 mg in a single daily dose for 1 week, followed by 24 mg daily for 1 week, and finally 12 mg daily for 1 week—or the equivalent amount of prednisone (Barnes et al). This has the added advantage of avoiding hospitalization; however, we have the impression that severe attacks, especially of myelitis, respond more quickly to high-dose intravenous medication. It can be stated that a randomized trial comparing oral and intravenous methylprednisolone in acute relapses of MS has demonstrated no clear advantage of the intravenous regimen (Barnes et al).

We attempt to limit the period of corticosteroid administration to 2 to 3 weeks or less but prolong the period of tapering the drug if neurologic signs return. This brief period of corticosteroid administration generally produces few adverse effects, but some patients complain of insomnia and a few will develop depressive or manic symptoms. Patients who, because of clinical relapse on withdrawal of the medication, require treatment for more than several weeks are subject to the effects of hypercortisolism, including the facial and truncal cosmetic changes of Cushing syndrome, hypertension, hyperglycemia and erratic diabetic control, osteoporosis, aseptic necrosis of the acetabulum, and cataracts; less often, there may be gastrointestinal hemorrhage and activation of tuberculosis. Modest potassium replacement is advisable. Alternate-day steroid

treatment offers little benefit in our experience. However, pulses of high-dose intravenous steroids, as described above, administered once each month, seem to keep some patients from having relapses and are better tolerated than the continuous administration of oral medication. It must be acknowledged that the corticosteroid regimens and dosages in common use are derived from anecdotal experience (the Optic Neuritis Treatment Trial being an exception) and that certain patients appear, at least for a period of time, to respond better to one or another method of treatment.

Treatment of Optic Neuritis The Optic Neuritis Treatment Trial, reported by Beck and colleagues, cautioned against the use of oral prednisone in the treatment of acute optic neuritis (see also Lessell). In this study it was found that the use of intravenous methylprednisolone followed by oral prednisone did indeed speed the recovery from visual loss, although at 6 months there was little difference between patients treated in this way and those treated with placebo. They reported that treatment with oral prednisone alone slightly increased the risk of new episodes of optic neuritis. In a subsequent randomized trial conducted by Sellebjerg and colleagues, it was found that methylprednisolone 500 mg orally for 5 days had a beneficial effect on visual function at 1 and 3 weeks. However, at 8 weeks, no effect could be shown (compared with the placebo-treated group), nor was there an effect on the subsequent relapse rate.

Interferon Beta and Copolymer I These forms of treatment for patients with relapsing-remitting MS modestly alter the natural history of the disease. IFN- β -1b (Betaseron), a nonglycosylated bacterial cell product with an amino acid sequence identical to that of natural IFN- β , was the first of these agents to be tested (see Arnsdorf). Several trials have now shown that the subcutaneous injection of this agent every second day for up to 5 years decreases the frequency and severity of relapses by almost one-third and also the number of new or enlarging lesions ("lesion burden") in serial MRIs. A large-scale trial (European Study Group) has extended the observations with IFN- β -1b to patients with the secondarily progressive type of MS; progression of the disease was delayed for 9 to 12 months in a study period of 2 to 3 years.

The treatment of relapsing-remitting MS with IFN- β -1a (a glycosylated mammalian-cell product, Avonex) is equally effective and has the advantage that it may be taken once weekly as an intramuscular injection (PRISMS Study Group). The dose currently used is 30 mg, or 6.6 million units. Copolymer I (glatiramer acetate; Copaxone), which was synthesized to mimic the actions of myelin basic protein, a putative autoantigen in MS, is given daily in subcutaneous doses of 20 mg. Glatiramer acetate may be particularly useful in patients who become resistant, i.e., develop serum antibodies to IFN- β (Rudick et al). The rate of such antibody emergence varies directly with the frequency of use of interferon: after a period of years, 30 percent of patients demonstrate antibodies with daily administration, 18 percent with alternate-day use, and less than 5 percent with weekly use. More recent changes in the preparation of interferon have led to reported rates of only 2 percent with antibodies after 1 year of use. There is some evidence that the presence of these antidrug antibodies diminishes the effectiveness of interferon. Antibodies do not develop to glatiramer acetate, and this has been emphasized as a relative advantage of the latter drug.

Overall, the side effects of these interferon agents are modest, consisting mainly of flu-like symptoms, sweating, and malaise beginning several hours after the injection and persisting for up to 14 h; they are reduced by nonsteroidal anti-inflammatory drugs and tend to abate with continued use of the agents. Nevertheless, some

patients cannot tolerate them. A few migraineurs complain of exacerbation of their headaches. There may also be a tendency to depression in susceptible patients treated with interferon, and in our experience, this information, when openly discussed with the patient, has sometimes influenced the decision regarding choice of treatment. A rare but notable problem is the induction of a "systemic capillary leak syndrome" in patients with a monoclonal gammopathy who receive interferon. With more than weekly use, there may be an increase in liver function enzymes. Patients receiving glatiramer acetate should be warned of an infrequent complication consisting of flushing, chest tightness, dyspnea, palpitations, and severe anxiety. Injection site reactions occur with both classes of drugs but are rarely troublesome if the sites are rotated.

The salutary effects of treatment are definite though not overly impressive. These issues have been summarized by Hughes and Sharrack. Treatment is somewhat disruptive and quite expensive. Although most writers on the subject indicate that virtually all patients with proven MS should be treated soon after the diagnosis is established, the long-term effects on the illness still remain to be clarified. Nonetheless, the consistency with which various studies have demonstrated a reduction in relapses and in the accumulation of MRI lesions is notable. From these studies, the concept has emerged that subclinical lesions are of importance and that, over time, cognitive decline and neurologic deficits are more likely to occur if the rate of progression is not reduced by treatment. There are few circumstances where such treatment is mandated immediately and we allow enough time for the patient to consider the alternatives. The endless discussions about the superiority of weekly, every-other-day, or daily medications cannot be resolved except to say that more frequent administration is probably marginally better. In the case of interferon, however, it leads to a higher rate of antibody production over years. With all of these treatments it should be acknowledged that there is no certain correlation between the number of relapses and the ultimate disability despite authoritative statements to the contrary (see Confavreux et al, 2000).

The need to treat patients with optic neuritis alone with interferon has not been satisfactorily resolved. We have generally avoided this approach except in a few patients with repeated episodes involving both eyes at various times. Some guidance is given by the CHAMPS trial, which examined the effect of interferon (weekly) in patients with a first episode of optic neuritis and at least two lesions on MRI that were compatible with MS. Over 3 years, there was a modest reduction in clinical progression or relapse from 37 percent to 28 percent; if further MRI lesions were included, the difference from placebo treatment was even greater. If nothing else, this points to the value of a cerebral MRI in patients who have their first optic attack.

Immunosuppressive Drugs A number of agents that modify immune reactivity have been tried, with limited success. Drugs such as azathioprine and cyclophosphamide, as well as total lymphoid irradiation, have been given to small groups of patients and seem to have improved the clinical course of some (Aimard et al, Hauser et al, Cook et al). However, the risks of prolonged use of immunosuppressive drugs, including a chance of neoplastic change, will probably preclude their widespread use. The careful study by the British and Dutch Multiple Sclerosis Azathioprine Trial Group attributed no significant advantage to treatment with this drug. For the chronic, progressive phase of the disease, an MS study group has reported a modest delay in the advance of the disease after a 2-year trial of prednisolone and cyclophosphamide. They caution,

however, that the “burdensome and potentially serious toxicity must temper consideration of its use in this disease.” At least one subsequent blinded, placebo-controlled study with cyclophosphamide has failed to show any benefit. In one trial involving patients with chronic progressive MS, weekly low-dose oral methotrexate has made a slight clinical difference and produced some reduction in the volume of cerebral lesions on the MRI compared with control cases (Goodkin et al). Because this regimen is well tolerated, it may still have some use in otherwise untreatable progressive cases.

Several new drugs have been introduced for the treatment of MS, but they have not been widely adopted and their role, while provocative, has not been clarified. Among these, mitoxantrone, a drug with broad immunosuppressant and cytotoxic activity used for various cancers, has attracted interest, because one study has shown a slight beneficial effect on the progressive form of the disease (Hartung et al). Some have disputed the interpretation of these results; additionally, there is little effect on the number of MRI lesions. Mitoxantrone is well tolerated and has the advantage of requiring administration one dose every 3 months (12 mg/m^2 intravenously); but it is known from experience with cancer treatment that the total dose is limited by several cardiotoxic effects, including congestive heart failure and arrhythmias. It is therefore given for only 2 years.

Natalizumab A novel approach to treatment is the use of natalizumab, an integrin antagonist used in rheumatoid arthritis, which blocks lymphocyte and monocyte adhesion to endothelial cells and their migration through the vessel wall. In a study that ran for 6 months, Miller and colleagues (2003) were able to demonstrate a slight reduction in the number of relapses and a marked effect on MRI lesions.

A recent double-blind, placebo-controlled study of 942 patients with relapsing-remitting MS (the AFFIRM study) showed a 68 percent reduction in relapses, an 80 percent reduction in new or enlarging T2 cerebral lesions and a 96 percent reduction in gadolinium-enhancing lesions on MRI after a year. Although this data is preliminary, it represents a twofold improvement in efficacy compared to what has been reported with interferon and glatiramer acetate. There was a 2 percent rate of anaphylactic reactions. Moreover, another preliminary study suggests that the use of interferon and natalizumab may give even better results (the SENTINEL study).

The advantages are once monthly intravenous treatments and a virtual lack of side effects (undoubtedly some will emerge as more experience is gained). We do not anticipate encouraging patients who are doing well on interferon or glatiramer to switch to natalizumab, but it seems reasonable to use the drug for newly diagnosed cases of relapsing-remitting disease. At this time, although this drug is overtaking other treatments, indications for its use are still being evaluated because of rare cases of PML in patients taking interferon and natalizumab for long periods.

Other Therapies There are no valid studies to substantiate claims that have been made for the value of synthetic polypeptides other than copolymer, for hyperbaric oxygen, low-fat and gluten-free diets, or linoleate supplementation of the diet. As mentioned under “Acute Multiple Sclerosis,” there may be a role for plasma exchange (Rodriquez et al) and perhaps immunoglobulin in fulminant cases, but these have not been tested rigorously. One limited trial has shown some benefit, in patients with relapsing-remitting disease, of monthly infusions of intravenous immunoglobulin (0.2 g/kg) for 2 years (Fazekas et al).

General Measures These include the provision of an adequate period of bed rest and convalescence to ensure maximum recovery from the initial attack or exacerbation, prevention of excessive fatigue and infection, the use of all possible rehabilitative measures to postpone the bedridden stage of the disease (braces, chairs, ramps, lifts, cars with manual controls, etc.), and meticulous attention to the prevention of bedsores in the bedridden patient by the use of alternating-pressure mattresses, silicone gel pads, and other special devices.

Fatigue, a common complaint of MS patients, particularly in relation to acute attacks, responds to some extent to amantadine (100 mg morning and noon), modafinil (200 to 400 mg/day), or pemoline (20 to 75 mg each morning). Fatigue and weakness are both reportedly ameliorated with potassium channel blockers (3, 4-diaminopyridine), although access to these non-FDA-approved compounds is difficult and they are epileptogenic at high doses. Confirmation of their benefit will be required before they come into general use.

Disorders of bladder function may raise serious problems in management. Where the major disorder is one of urinary retention, bethanechol chloride is helpful. In this situation, monitoring and reducing the residual urinary volume is an important means of preventing infection; volumes up to 100 mL are generally well tolerated. Some patients with severe bladder dysfunction, particularly those with urinary retention, benefit from intermittent catheterization, which they can learn to do themselves and which lessens the constant risk of infection from an indwelling catheter. More often the problem is one of urinary urgency and frequency (spastic bladder), in which case the use of propantheline (Pro-Banthine) or oxybutynin (Ditropan) may serve to relax the detrusor muscle (Chap. 26). These drugs are best used intermittently. Severe constipation is best managed with properly spaced enemas. Often a program of bowel training can be successfully undertaken. Sexual dysfunction, a very common problem in men with MS, has been successfully treated with sildenafil and similar drugs. When pain is a prominent symptom, its management follows the general principles of pain management outlined in Chap. 8. Carbamazepine or gabapentin are often helpful and these agents also reduce paroxysmal symptoms in MS.

In patients with severe spastic paralysis and painful flexor spasms of the legs, oral and then intrathecal infusion of baclofen through an indwelling catheter and implanted pump, as in other spastic states, is sometimes of value. The selective injection of botulinum toxin into the most hypertonic muscles may help some patients. Patients with lesser degrees of spasticity have benefited from the oral administration of baclofen. Failing this measure, one of several surgical procedures—dorsal rhizotomy, myelotomy, crushing of the obturator nerves, and, most useful of all in severe cases, intrathecal baclofen infusion by pump—may give relief for a prolonged period.

The severe and disabling tremor that is brought out by the slightest movement of the limbs, if unilateral, can be managed surgically by ventrolateral thalamotomy or implanted stimulator of the type used for the treatment of Parkinson disease. Most surgical series report that about two-thirds of patients achieve a satisfactory reduction in their intention tremor (Critchley and Richardson; Geny et al). In the experience of others, the results have not been quite this reliable. In the series of Hooper and Whittle, only 3 of 10 MS patients who underwent thalamotomy for a severe tremor had sustained improvement. Hallett and colleagues have reported that severe postural tremor of this type can be improved by the ad-

ministration of isoniazid (300 mg daily, increased by weekly increments of 300 mg to a dose of 1200 mg daily) in combination with 100 mg of pyridoxine daily. How isoniazid produces its beneficial effects is not known, and careful monitoring of liver tests is required. Variable success may also be achieved with carbamazepine or clonazepam. Necessary vaccinations are not interdicted in patients with MS.

The importance of an understanding and sympathetic physician in the care of patients with a chronic incapacitating neurologic disease of this kind cannot be overemphasized. Enlisting the support of physical and occupational therapists, visiting nurses, and social workers can be equally important. From the beginning, when patients first inquire about the nature of their illness, they require advice about their daily routine, marriage, pregnancy, the use of drugs, inoculations, and so on. As indicated earlier, the term *MS* should not be introduced until the diagnosis is certain, and then it should be qualified by a balanced explanation of the symptoms, stressing always the optimistic aspects of the disease. Most patients desire an honest appraisal of their condition and prognosis; some consider the uncertainty of their prognosis worse than their actual disability.

ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM)

Postinfectious, Postexanthem, Postvaccinal Encephalomyelitis

Some of these terms, used originally to refer to the neurologic sequelae of infectious fevers, were introduced into medicine in the late nineteenth century, but it was not until the late 1920s that Perdrau, Pette, Greenfield, and others identified a type of pathologic reaction common to a number of exanthems and vaccines. The current view of this entity is that it represents an acute inflammatory and demyelinative disease, distinguished pathologically by numerous foci of demyelination scattered throughout the brain and spinal cord and some restricted to the cerebellum or spinal cord. These lesions vary from 0.1 to several millimeters (when confluent) in diameter and invariably surround small and medium-sized veins. The axons and nerve cells are more or less intact. Equally distinctive is the perivenular inflammatory reaction of lymphocytes and mononuclear cells. The adjacent regions of white matter are invaded by monocytes and microglia corresponding to the zones of demyelination. Multifocal meningeal infiltration is another invariable feature but is rarely severe in degree. With the exception of this last feature, ADEM is indistinguishable on histopathologic grounds from acute MS. It is the setting, further course, and certain special features of each that set them apart. Indeed, even the monophasic nature of ADEM and its clear separation from MS on clinical grounds has been questioned by Schwarz and colleagues, who found that 14 of 40 adults later developed clear signs of MS, usually within a year.

An acute encephalitic, myelitic, or encephalomyelitic process of this type is observed in a number of clinical settings and is more common in children. In our own experience we have found that most often in children the disease follows a febrile illness by days or weeks; this is less often the case in adults. In the originally described form, it occurred within a few days of onset of the exanthem of measles, rubella, smallpox, or chickenpox. Prior to widespread immunization against measles, an epidemic in a large city might have resulted in 100,000 cases of measles and clinically evident neurologic complications in 1 in 800 to 1 in 2000 cases. The

mortality among patients with such complications ranged from 10 to 20 percent; about an equal number were left with persistent neurologic damage. The neurologic complications of measles alone provide sufficient justification for immunization against the disease. The incidence of encephalomyelitis was less following chickenpox and rubella and much less following mumps (the latter never seen in our pathologic material). In the past, a similar illness was observed to follow vaccination against rabies and smallpox and, reportedly, after administration of tetanus antitoxin (rare), as discussed further on. Now, however, most cases, clinically and pathologically indistinguishable from these two categories of ADEM, appear to develop after seemingly banal respiratory infections and after documented infections with Epstein-Barr, cytomegalovirus, and *Mycoplasma pneumoniae* and even HIV (Narisco et al); occasionally there is no clearly defined preceding illness or inoculation. Many if not most instances of acute transverse myelitis may represent the same postinfectious process. The neurologic illness may coincide with the later stages of the manifestations of the infection, in which case the term *parainfectious* may be appropriate.

Irrespective of the clinical setting in which it occurs, disseminated encephalomyelitis in its severe form is of grave import because of the significant rate of neurologic defects in patients who survive. In children, recovery from the acute stage is sometimes followed by a permanent disorder of behavior, mental retardation, or epilepsy; paradoxically, most adults make good recoveries. The *cerebellitis* and acute ataxia that follow chickenpox and other infections are more benign, normally clearing over several months, and may represent a different process, as discussed further on.

Pathogenesis The pathogenesis of disseminated encephalomyelitis is still unclear despite its obvious association with viral infections. In the exanthem cases, a definite interval usually separates the onset of disseminated encephalomyelitis from the onset of the rash; also, the pathologic changes are quite different from those of viral infections and virus is rarely if ever recovered from the CSF or brains of patients with disseminated encephalomyelitis. For these reasons it is believed that the disorder represents an immune-mediated complication of infection rather than a direct infection of the CNS, a process comparable to the Guillain-Barré syndrome. However, as discussed in Chap. 33, new molecular techniques have been able to detect fragments of DNA from varicella zoster virus, *Mycoplasma*, and other organisms, so that the question of pathogenesis cannot be answered with finality. Nevertheless, Waksman and Adams found the pathologic changes in these two circumstances—postinfectious demyelination and direct viral infection of the CNS—to be quite different.

A laboratory model of the disease, experimental allergic encephalomyelitis (EAE), has been produced by inoculating animals with a combination of sterile brain tissue and adjuvants. The experimental disease appears most commonly between the eighth and fifteenth days after sensitization (see below) and is characterized by the same perivenular demyelinative and inflammatory lesions that one observes in the human disease. Presumably the lesions are the result of a T-cell-mediated immune reaction to components of myelin or oligodendrocytes. Recently, evidence of antibody binding, complement activation, and eosinophilic infiltration has led to the notion that ADEM is a humoral disease, in contrast to the cellular mechanism that has been proposed for MS but further confirmation of this notion is required (see Lucchinetti et al).

The notion that EAE and disseminated encephalomyelitis have a similar pathogenesis has received support from the observations of R. T. Johnson and colleagues. They studied 19 patients

with postinfectious encephalomyelitis complicating natural measles virus infections. Early myelin destruction was demonstrated by the presence of MBP in the CSF, and lymphocyte proliferative responses to MBP were found in 8 of 17 patients tested. Similar responses were observed in patients with encephalomyelitis after rabies vaccine and after varicella and rubella virus infections, suggesting a common immune-mediated pathogenesis. Moreover, the patients with postmeasles encephalomyelitis showed a lack of intrathecal synthesis of antibody against measles virus, indicating that the neurologic disease was not dependent on viral replication within the CNS.

Clinical Features The encephalitic form is expressed more fully in children than in adults. As an acute infectious illness is resolving or after a latency of several days or longer, there is the abrupt onset, over hours or a day or two, of confusion, somnolence, and sometimes convulsions with headache, fever, and varying degrees of neck stiffness. Ataxia is common but myoclonic movements and choreoathetosis are observed less frequently. In more severe cases, stupor, coma, and at times decerebrate rigidity may occur in rapid succession. In many cases the disease is less severe and the patient suffers a transient encephalitic illness with headaches, confusion, and slight signs of meningeal irritation.

The latency between infection and the first neurologic symptoms that it is acceptable to impute to this diagnosis is a matter of debate, but there are convincing cases (postexanthematous) in which the two phases of illness are separated by 3 or 4 weeks; several days is more typical, as noted below. Curiously, in the encephalitic form, new signs may continue to appear for up to 2 or 3 weeks from the onset. This is emphasized in the series of affected children collected by Hynson and colleagues. The imaging changes may also display delayed or continued evolution, as noted below. These authors note that ataxia was the most common initial feature in their cases, which is not entirely in accordance with our experience (see below).

In the myelitic form (*postinfectious myelitis, acute transverse myelitis*), there is partial or complete paraparesis or quadriplegia,

diminution or loss of tendon reflexes, sensory impairment, and varying degrees of paralysis of bladder and bowel. A syndrome that simulates anterior spinal artery occlusion (spastic paraparesis and loss of pain sensation below a level on the trunk but tending to spare large-fiber sensibility) is not uncommon in our experience. Also, we have cared for a few patients with a limited sacral form of postinfectious myelitis. Midline back pain may be a prominent symptom at the onset.

In both the encephalitic and myelitic types, there may be slight fever, particularly in the more aggressive cases and in younger individuals, where we have seen temperatures reaching 39.4°C (103°F), but the peripheral white blood cell count is normal if the initiating infection has resolved. A few of our cases have had elevated sedimentation rates, but it is not possible to know whether this reflects the precipitating infection. Separating these two entities may nonetheless be difficult, especially in children who have more of a tendency to develop fever and convulsions with ADEM. Either process may be associated with an aseptic meningitis.

The CSF shows a slight increase in lymphocytes and protein content, but these are highly variable, with a few of our cases having only an increase in protein and no cells and others having up to several hundred cells. The MRI shows several bilateral confluent white matter lesions in both cerebral hemispheres early in the course of ADEM (Fig. 36-3); when these are large and numerous, the diagnosis is more certain. The lesions all appear to be of similar age, but we cannot account for several cases we have seen in which serial MRIs show new lesions accumulating over 2 or 3 weeks, as already noted. Moreover, as pointed out by Honkanen and colleagues, there may be a delay of several days between the clinical manifestations and the first appearance of changes in the MRI, a situation to which we can attest. Whether a single lesion on MRI can be considered compatible with ADEM is unclear.

In the case of postexanthem encephalomyelitis, the syndrome generally begins 2 to 4 days after the appearance of the rash. Usually the rash is fading and other symptoms are improving when the patient, usually a child, suddenly develops a recrudescence of fever, convulsions, stupor, and sometimes coma. Less commonly, the pa-

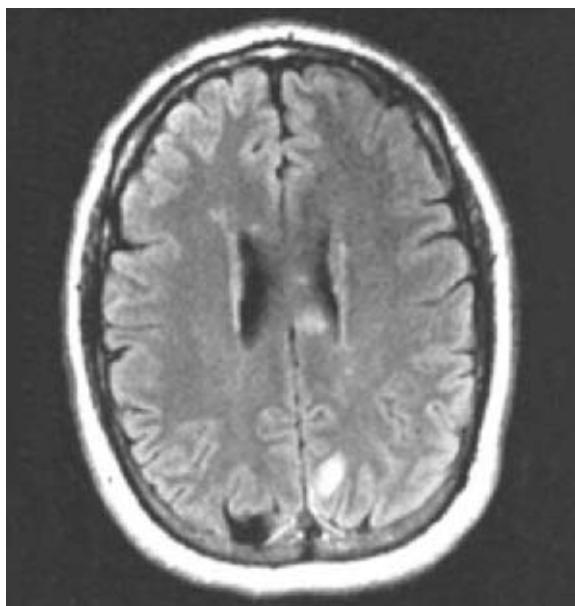

Figure 36-3. Acute (postinfectious) disseminated encephalomyelitis. Cranial FLAIR MRI (left) and spine MRI (right) showing numerous lesions of varying size throughout the white matter of both hemispheres and in the spinal cord.

tient may develop hemiplegia or a virtually pure cerebellar syndrome, as noted below (particularly after chickenpox), and occasionally a transverse myelitis, sphincteric disturbance, or other signs of spinal cord involvement. Choreoathetotic movements are seen infrequently. Likewise, optic neuritis is uncommon, but it does occur.

A variant of postinfectious encephalomyelitis that involves solely or predominantly the cerebellum deserves special comment. Typically, a mild ataxia with variable corticospinal or other signs appears within days of one of the childhood exanthems as well as after Epstein-Barr virus, *Mycoplasma*, *Legionella*, and cytomegalovirus infections and after a number of vaccinations and nondescript respiratory infections. It is described in detail on page 641 because it has a close relationship to certain viruses, particularly varicella, suggesting that some if not most cases are due to an infectious meningoencephalitis. Others—for example, following mycoplasmal infection—occur after a long latency and show pathologic changes that are consistent with a postinfectious demyelination. Thus it is possible that there may be two types of acute cerebellitis, one para- or postinfectious and the other due to a direct infection of the brain and meninges. The benign nature of the illness has precluded adequate pathologic examination, hence some of these statements are speculative.

Differential Diagnosis It must be re-emphasized that not all the neurologic complications of measles and other exanthems and acute viral infections are examples of postinfectious encephalomyelitis. As already noted, the illness is at times difficult to distinguish from viral meningoencephalitis. Infectious mononucleosis, herpes simplex, mycoplasmal infection, and other forms of encephalitis may all mimic the postinfectious variety. In some cases cerebrovascular disease (particularly cortical vein or dural sinus thrombosis), hypoxic encephalopathy, or acute toxic hepatoencephalopathy (Reye syndrome) is responsible for these complications. The Reye syndrome is usually not difficult to separate from postinfectious encephalomyelitis, even when it follows chickenpox or viral influenza, because of the normal CSF and high serum concentrations of liver enzymes and ammonia (see page 969). In a child, the first attack of febrile seizures in the course of an exanthematous illness may raise the suspicion of encephalitis or postinfectious encephalomyelitis.

Postvaccinal Encephalomyelitis Since late in the nineteenth century, it has been known that a severe form of encephalomyelitis may complicate the injection of rabies vaccine ("neuroparalytic accident"). Until quite recently, the vaccine in common use consisted of killed virus that had been grown in rabbit brain tissue. Encephalomyelitis occurred in about 1 in 750 patients inoculated with this vaccine, and about 25 percent of cases with this complication proved fatal. Alternative vaccines, made from embryonated duck eggs (and later from human diploid cells) infected with fixed viruses, contain very little or no nerve tissue and are almost free of neurologic complications. In developing countries, where less expensive brain-based vaccines are still in use, neuroparalytic accidents continue to occur. The observations of Hemachudha and colleagues indicate that the altered immune mechanism that is operative in the neuroparalytic accident is the same as that in post-measles encephalomyelitis and experimental allergic encephalomyelitis.

There are numerous recorded instances in which the old rabies vaccine (with neural tissue) induced an attack of what subsequently appeared to be MS. Shiraki and Otani reported such examples from Japan. The evolution of symptoms was subacute, over a period of 2 to 4 weeks, and the demyelinative lesions were macroscopic—

up to 1 to 2.0 cm in diameter—but composed of confluent perivenous lesions. The disease could be reproduced in dogs—persuasive evidence that one form of acute MS is a variant of ADEM.

Encephalomyelitis following vaccination against smallpox has been known since 1860, having occurred about once in 4000 vaccinations. This disease is now of historical interest only, insofar as smallpox has disappeared as a human illness worldwide. In the United States, there have been no new cases for years, and smallpox vaccination is no longer included as part of immunization schedules. Recent political events, which have resurrected a national program of vaccination, perhaps may cause the problem to recur if widespread immunizations are undertaken.

The association of the neurologic disorder with vaccination usually leaves the diagnosis in little doubt, and the characteristic combination of encephalitic and myelitic features will help to distinguish the condition from meningitis, viral encephalitis, and poliomyelitis. Rarely, an atypical case may mimic any one of these disorders. On occasion, the disease may suggest involvement of nerve roots and peripheral nerves and resemble acute inflammatory polyneuritis (Guillain-Barré syndrome). In fact, the rabies vaccine produced in South America from suckling mouse brain causes this type of peripheral nerve disease more often than encephalomyelitis.

Mundane inoculations such as those for influenza or hepatitis must have a very small rate of ADEM, judging from surveillance studies; Ascherio and colleagues were unable to find any increase in cases among two large studies of nurses who received hepatitis B vaccine. The absence of a clear connection of MS to vaccination has already been mentioned.

The mortality rate of postvaccinal encephalomyelitis is high, between 30 and 50 percent. If recovery occurs, it may be surprisingly complete. However, a significant proportion of patients show residual neurologic signs, mainly in the form of seizures, intellectual impairment, or behavioral abnormalities.

Treatment With regard to treatment of ADEM, the use of high-potency steroids appears to be the best choice, although controlled trials of this have not been carried out. Steroids, given before or immediately upon the appearance of neurologic signs, may modify the severity of experimental allergic encephalomyelitis; this provides the logic for their use in the human counterpart of this disease. However, the pathologic process cannot be altered once the first signs appear. Plasma exchange and intravenous immune globulin have also been successful in some fulminant cases (Kanter et al; Stricker et al) but only in a few we have observed.

Acute Necrotizing Hemorrhagic Encephalomyelitis (Acute Hemorrhagic Leukoencephalitis of Weston Hurst)

This, the most fulminant form of demyelinative disease, affects mainly young adults but also children. It is almost invariably preceded by a respiratory infection of variable duration (1 to 14 days), sometimes due to *M. pneumoniae* but more often following a mundane infection or of indeterminate cause. The neurologic symptoms appear abruptly, beginning with headache, fever, stiff neck, and confusion. These are followed in short order by signs of disease of one or both cerebral hemispheres and brainstem—focal seizures, hemiplegia or quadriplegia, pseudobulbar paralysis, and progressively deepening coma. Leukocytosis is usually present, sometimes reaching 30,000 cells per cubic millimeter, and the sedimentation rate is elevated. The CSF is often under increased pressure; cells vary in number from a few lymphocytes to a polymorphonuclear

pleocytosis of up to 3000 cells per cubic millimeter; red cells may be present in variable numbers; protein content is increased, but glucose values are normal. Diagnosis is greatly facilitated by CT scanning and MRI, which reveal bilateral but asymmetrical large, confluent, edematous lesions in the cerebral white matter with a myriad of punctate hemorrhages in gray and white matter (Fig. 36-4). The size of the lesions, their hemorrhagic character, and the extent of the surrounding edema distinguish them from the typical postinfectious ADEM. In many other ways they are similar except for their severity. Many cases terminate fatally in 2 to 4 days, but in others survival is longer. Patients with a similar clinical picture who are thought to have the same disease on the basis of brain biopsy examinations have recovered with almost no residual symptoms. In one of the fatal cases reported by Adams et al, the illness evolved more slowly—over a period of 2 to 3 weeks—while another patient died with temporal lobe herniation within 12 h. A single recurrence of the disease after an interval of 2 years was observed in one of our cases.

Brain abscess, subdural empyema, focal embolic encephalomalacia, and acute encephalitis due especially to type 1 herpes simplex virus are the important considerations in the differential diagnosis.

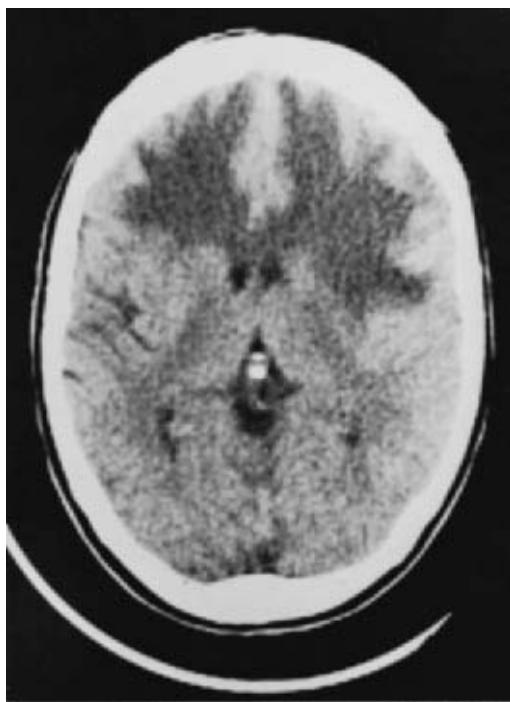

Figure 36-4. Acute necrotizing hemorrhagic leukoencephalitis, mainly bi-frontal showing the large confluent hemorrhagic areas.

The *pathologic findings* are distinctive. On sectioning of the brain, the white matter of one or both hemispheres is seen to be destroyed almost to the point of liquefaction. The involved tissue is pink or yellow-gray and flecked with multiple petechial hemorrhages. Similar changes are often found in the brainstem and cerebellar peduncles and probably in the spinal cord (one form of acute necrotizing myelitis and Devic disease). On histologic examination, one finds widespread necrosis of small blood vessels and brain tissue around the vessels, with intense cellular infiltration, multiple small hemorrhages, and an inflammatory reaction in the meninges of variable intensity. The pathologic picture resembles that of disseminated encephalomyelitis in its perivascular distribution, with the added features of a more widespread necrosis and a tendency of lesions to form large foci in the cerebral hemispheres. The vascular lesions result in a characteristic exudation of fibrin into the vessel wall and surrounding tissue. It is possible that certain patients showing an explosive myelitic illness are suffering from a necrotizing lesion of similar type, but pathologic evidence in support of this view has been difficult to obtain. Fibrin exudation in an acute fatal hemorrhagic myelitis was present in a case examined by Adams and colleagues. We also have experience with a case of this nature that evolved in steps over several months, resulting in death, with a cellular reaction in the spinal fluid on each of several lumbar punctures. There was partial steroid responsiveness.

The etiology of this condition remains obscure, but its resemblance to other demyelinating diseases should be emphasized. The similarities of the histologic changes to those of disseminated encephalomyelitis, noted above, suggest that the two diseases are related forms of the same fundamental process. In fact, cases combining both types of pathologic change have been described (Fisher et al). The observations of Behan and colleagues—that the lymphocytes of a patient with postinfectious encephalomyelitis and of another patient with acute necrotizing hemorrhagic encephalitis underwent transformation to lymphoblasts in response to a pure encephalitogenic MBP—support the view that delayed hypersensitivity mechanisms are operative in both diseases. Earlier, Waksman and Adams had demonstrated that the vascular lesions of experimental allergic encephalomyelitis could be converted to those of necrotizing encephalomyelitis by inducing a Schwartzman reaction (by intravenous injection of meningococcal toxin). It is also noteworthy that, among the small number of patients who have recovered from what appeared to be a typical necrotizing hemorrhagic encephalitis, a few have gone on to develop typical MS.

Treatment These points of similarity are sufficient to suggest that corticosteroids should be used in the treatment of acute necrotizing hemorrhagic encephalopathy; in several personally observed patients, we had the impression that they produced a favorable result. The use of plasma exchange and intravenous immunoglobulin, as for acute disseminated encephalomyelitis, is being explored and has had success in single reported cases when instituted early.

CHAPTER 37

THE INHERITED METABOLIC DISEASES OF THE NERVOUS SYSTEM

Advances in biochemistry and molecular genetics have led to the discovery of such a large number of metabolic diseases of the nervous system that it taxes the mind just to remember their names. Since the causes and mechanisms of the diseases included in this chapter (and in several that follow) are increasingly being expressed in terms of molecular genetics, it seems appropriate, by way of introduction, to consider briefly some basic facts pertaining to the genetics of neurologic disease. A complete account of this subject may be found in the four-volume text edited by Scriver and colleagues.

One must be reminded that the biochemistry of every human organism is unique (i.e., never duplicated) and that every person, in some particular way, has an inborn tendency to develop certain diseases. This constitutional predisposition, or diathesis, lies in the variations of DNA of the chromosomes of each cell. Knowledge of the molecular basis of this constitutional predisposition may ultimately provide the means of diagnosis, prevention, and perhaps treatment of many human diseases.

The diseases grouped in this chapter and the next represent four particular categories of genetic abnormality: (1) monogenic disorders determined by a single mutant gene that follow a mendelian pattern of inheritance; (2) multifactorial disorders, again following a mendelian pattern of inheritance but in which intrinsic (i.e., genetic) factors interact with exogenous environmental ones; (3) nonmendelian chromosomal aberrations, characterized by an excess, a lack, or a structural alteration of one or more of the 23 pairs of chromosomes (these are considered in the next chapter, with the developmental disorders); and (4) mitochondrial transmission of disease in a nonmendelian, mainly maternal pattern.

As stated in the monograph of Scriver et al, 6 to 8 percent of diseases in hospitalized children are attributable to single gene defects and 0.4 to 2.5 percent to a chromosomal abnormality. Another 22 to 31 percent have a disease thought to be gene-influenced. In the general population, when multifactorial inheritance of late-onset diseases is included, the latter figure rises to about 60 percent. Mitochondrial inheritance of mutations is much less frequent and has unusual patterns of transmission, mostly through maternal lines.

The nervous system is more frequently affected by a genetic abnormality than any other organ system, probably because of the large number of genes implicated in its development (an estimated one-third of all the genes in the human genome). Approximately one-third of all inherited diseases are neurologic to some extent; if one adds the inherited diseases affecting the musculature, skeleton, eye, and ear, the number rises to 80 to 90 percent.

Of the almost 6000 entities itemized in the 1998 edition of McKusick's catalogue of inherited diseases, about 500 are identified as enzymopathies—i.e., mendelian disorders with a demonstrated primary enzyme defect. The latter constitute only one-third of the known recessive (autosomal and X-linked) disorders. Most of the enzymopathies become manifest in infancy and childhood;

only a few appear as late as adolescence or adult life. Many damage the nervous system so severely that survival to adult years and reproduction are impossible, and some cause death in utero. As a group, these diseases—along with congenital anomalies (Chap. 38), birth injuries, epilepsy, disharmonies of development, and learning disabilities (Chap. 28)—make up the bulk of the clinical problems with which the pediatric neurologist must contend.

Autosomal and Sex-Linked Patterns of Inheritance

Traditionally, the recognition of these broad categories of genetically determined diseases has rested on their pattern of occurrence in families, segregated according to mendelian inheritance into autosomal dominant, autosomal recessive, and sex-linked types. Mutations of nuclear DNA account for the majority of heritable autosomal and sex-linked diseases described in this chapter, and they are remarkably diverse in nature. Some are lethal and, as mentioned, are therefore not transmitted to successive generations; others are less harmful and may conform to one of the classic mendelian patterns. The mutation may be large and result in duplication (or deletion) of a major part of a chromosome or even of the entire genome (diploidy), or it may create a third copy of the entire complement of genes (triploidy). Other mutations are very small, involving only a single base pair ("point mutation"). Between these two extremes are deletions or duplications that include a portion of a gene, an entire gene, or contiguous genes.

The factors conducive to mutations are poorly understood. An increasing age of the parent is important in relation to some mutations; the size, structure, and placement of the gene on the chromosome are important in others. A mutation of the DNA of a germ cell leaves unchanged the somatic phenotype of the individual in whom it occurs, but it may have a devastating effect on the descendants. Conversely, a DNA mutation of a somatic cell affecting only part of the cell population may change the individual harboring it but is not passed on to the descendants. Such an individual, with both normal cells and cells containing the mutant gene, is referred to as a *mosaic*. Mutations of somatic cells appear to be most pertinent to cancer and aging.

In the monogenic inheritance of all three mendelian patterns, the mutation usually causes an abnormality of a single protein. It may involve an enzyme, peptide hormone, immunoglobulin, collagen, or coagulation factor. Such abnormalities of single genes have been isolated in several hundred diseases, but little is known of their protein products. About one-quarter of these diseases are apparent soon after birth and more than 90 percent by puberty. More than half of them affect more than one organ. Of the 10 in every 1000 live births with genetic diseases, 7 are dominant, 2.5 are recessive, and the remainder are sex-linked.

Autosomal dominant mutations usually cause manifest disease in heterozygotes, but variations in the size of the gene abnor-

mality can produce any one of several phenotypes. This poses a challenge to the current clinical and pathologic classifications of disease. Moreover, an identical clinical syndrome may be traced to a gene on two different chromosomes. Even more surprising, an estimated 28 percent of all gene loci have polymorphic rather than monomorphic effects—that is, the same mutation has several different phenotypic expressions. Another problem is that of differentiating dominant from recessive inheritance. In small families, in which only one descendant is afflicted and the parent is seemingly normal, one may mistakenly conclude that the inheritance is recessive. Variable degrees of penetrance and expressivity are characteristic features of dominant patterns of inheritance but not of recessive ones. There is also a general tendency for dominantly inherited disease to first appear long after birth.

Autosomal recessive forms of inherited metabolic diseases, in contrast to dominant ones, occur only in the homozygous state (both alleles abnormal). They are usually characterized by an onset soon after birth. The basic abnormality in the recessively inherited diseases discussed in this chapter is more often an enzyme deficiency than an abnormality of some other protein.

In disorders of X-linked genes, in which the mutant gene affects mainly one sex, the female will suffer the same fate as the male if one X chromosome has been inactivated, as happens in most cells during embryonic development (the Lyon phenomenon). However, even if the abnormal X chromosome is not widely expressed, the female carrier may still exhibit minor abnormalities. In the latter case, sex-linked inheritance becomes difficult to distinguish from dominant inheritance. Also, sex linkage is deceptive when a disease is lethal to one sex. In contrast to autosomal recessive mutations, the biochemical abnormality has more often been one of a basic protein than an enzyme deficiency.

Multifactorial genetic diseases are also by nature familial. They may present as constitutional disorders with gene abnormalities located on several chromosomes (polygenic, or “complex genetics”). The precise number of such genes required to produce a given abnormality is not known, making the risk of inheritance difficult to calculate. Here also the relative contributions of genetic and environmental influences are highly variable. The methodology for identifying this category of genetic disease has usually required the comparison of large numbers of affected patients and controls or of progeny living with their biologic parents and those adopted by normal families at an early age. Monozygotic and dizygotic twin comparisons provide essential information about “risk genes.” The occurrence of many disorders that display high degrees of familial incidence, such as schizophrenia and Tourette syndrome, but do not strictly conform to classic genetic principles has been attributed to this type of complex genetics.

The Genetics of Mitochondrial Disease

In the past few decades, an entirely new type of genetic transmission relating to the DNA that lies in the mitochondria has been elucidated. Mitochondria contain their own extrachromosomal DNA, distinct from nuclear DNA. Mitochondrial DNA (“the other human genome”) is a double-stranded, circular molecule that encodes the protein subunits required mainly for translation of the proteins located on the mitochondrial inner membrane. Of the 37 mitochondrial genes, small in number by comparison with nuclear DNA, 13 partake in the cellular processes of oxidative phosphorylation and the production of adenosine triphosphate (ATP). A small number of genes in the cell’s nucleus also code for a consid-

erable number of oxidative enzymes of the mitochondria, but their inheritance follows a mendelian pattern.

Each mitochondrion contains up to 10 ringed DNA molecules, and each cell, of course, contains numerous mitochondria. In the cell, mitochondria with mutant genes may exist next to normal mitochondria (*heteroplasmy*), a state that permits an otherwise lethal mutation to persist (Johns). The presence of either completely normal or completely mutant mitochondrial DNA is termed *homoplasm*. The essential feature of mitochondrial genes and the mutations to which they are subject is that they are inherited almost exclusively through *maternal* lineage. This is explained by the transmission of virtually all mitochondria from the ovum at the time of conception. Moreover, mitochondrial DNA does not recombine, thus permitting the accumulation of mutations through maternal lines. Also, the replication and distribution of mitochondrial DNA during cell division does not follow the nuclear mitotic cycle. Instead, there are contributions during cell division from the genes of various mitochondria to the progeny of dividing cells. The combination of a heteroplasmic state and the capricious dispersion of mitochondria to daughter cells (replicative segregation) explain the variable expression of mitochondrial mutations in different tissues and in different regions of the nervous system as well as variations in the age of onset of the mitochondrial diseases.

The genetic error in each of the mitochondrial diseases is most often a single point mutation that leads to the alteration of a single amino acid, but there are also single or multiple deletions or duplications of mitochondrial genes that do not conform to maternal inheritance because they are caused by nuclear DNA defects. It is important to note that about 85 percent of the protein components of the respiratory chain are coded in nuclear DNA and are then imported into the mitochondrion; as mentioned above, this allows for a mitochondrial disease with a mendelian pattern of inheritance rather than a maternal one. Another of the general rules of mitochondrial inheritance is exemplified by an infantile myopathy (cytochrome oxidase deficiency) that is usually fatal but may also occur in a less severe form and have a later onset. In cases of earlier onset, there is less of the normal mitochondrial DNA than in the cases of later onset.

Since the unique function of mitochondria is the production of ATP by oxidative phosphorylation, it is not surprising that many of the genes contained in mitochondria code for proteins in the respiratory chain. However, there is not always concordance between the error in the mitochondrial genome and the enzymatic defect that leads to disease. Of the five complexes that make up the respiratory chain, cytochrome-c oxidase (complex IV) is the one most often disordered, and its deficient function gives rise to lactic acidosis, a feature common to many of the mitochondrial disorders (see further on). In keeping with the mutable nature of this class of disorders, it is thought that some cases of complex IV defect are autosomally transmitted. Complex I defects, which originate in mitochondrial mutations, are seen, for example, in Leber optic atrophy (page 949). A more complete account of the disorders of the mitochondrial respiratory chain can be found in the review by Leonard and Schapira.

As one would expect, aberrant function of the ubiquitous energy-producing mitochondria results in disease of many organs besides skeletal muscle (e.g., diabetes and other endocrinopathies and minor dysmorphic features are seen in several mitochondrial disorders). Nevertheless, most of the mitochondrial disorders affect the nervous system prominently and at times exclusively. Two characteristics traceable to mitochondrial abnormalities are particularly common; one is a special change in muscle fibers termed

ragged red fibers, actually a clumping of mitochondria in muscle fibers, and the other is a systemic lactic acidosis. Other than these, each of the mitochondrial diseases has distinctive features and in their central elements they do not resemble each other. The main syndromes are so-called MELAS and MERRF (acronyms defined further on), Leber hereditary optic atrophy, progressive external ophthalmoplegia, and the Leigh syndrome. These diseases are described in detail in the last part of this chapter.

Diagnostic Features of Hereditary Metabolic Diseases

In clinical practice, one should consider the possibility of a hereditary metabolic disease when presented with the following lines of evidence:

1. A neurologic disorder of similar type in a sibling or close relative
2. Recurrent nonconvulsive episodes of impaired consciousness
3. Some combination of unexplained symmetrical or generalized spastic weakness, cerebellar ataxia, extrapyramidal disorder, deafness, or blindness
4. Progression of a neurologic disease measured in weeks, months, or a few years
5. Mental retardation in a sibling or close relative
6. Mental retardation in an individual, particularly if there are no congenital somatic abnormalities
7. Intractable seizures in infants or young children
8. Infantile spasms and progressive myoclonic seizures with microcephaly in the absence of neonatal hypoxia-ischemia

In the face of such clinical information, one should obtain appropriate biochemical analyses of blood, urine, and cerebrospinal fluid (CSF); magnetic resonance imaging (MRI) of the brain; and, in certain instances, chromosome-genetic studies.

In addition to the investigation of symptomatic individuals, the array of available genetic and biochemical tests has made practical the mass screening of newborns for inborn metabolic defects. Innovative tests have also led to the discovery of a number of previously unknown diseases and have clarified the basic biochemistry of old ones. As a consequence, the neurologist's role is changing. No longer must he wait until a disease of the nervous system has declared itself by conventional symptoms and signs, by which time the underlying lesion may have become irreversible. Now it is possible to find patients who, though asymptomatic, are at risk and to introduce dietary and other measures that may prevent injury to the nervous system. This is especially important to families who have already had an affected infant. To assume this new responsibility intelligently requires some knowledge of genetics, biochemical screening methods, and public health measures.

The many clinical syndromes by which these inborn errors of metabolism declare themselves vary in accordance with the nature of the biochemical defect and the stage of maturation of the nervous system at which these metabolic alterations become apparent. In phenylketonuria, for example, there is a specific effect on the cerebral white matter, mainly during the period of active myelination; once the stages of myelinogenesis are complete, the biochemical abnormality becomes relatively harmless. Even more important from the neurologist's point of view is the level of function that has been achieved by the developing nervous system when the disease strikes. A derangement of function in a neonate or infant,

in whom much of the cerebrum is not fully developed, is much less obvious than one in an older child. Moreover, as the disease evolves, the clinical manifestations are always influenced by the ongoing maturation of the untouched elements in the nervous system. These interactions may give the impression of regression of attained neurologic function, lack of progress of development (developmental delay), or even improvement in function that is attributable to continuing maturation of the normal parts of the nervous system. The separation of metabolic-genetic from degenerative diseases (accorded a separate chapter) may disquiet the reader, for there are many overlaps between the two groups. The current division is tenable only until such time as all the degenerative diseases will have been shown to have a comprehensible pathogenesis.

Because of the overriding importance of the age factor and the tendency of certain pathologic processes to appear in particular epochs of life, it has seemed to the authors logical to group the inherited metabolic diseases not according to their major syndromes of expression, as we have done in other parts of the book, but in relation to the periods of life at which they are most likely to be encountered: the neonatal period, infancy (1 to 12 months), early childhood (1 to 4 years), late childhood, adolescence, and adult life. Only in the last two age periods do we return to the more clinically useful syndromic ordering of diseases.

In adopting this chronological subdivision, we realize that *certain hereditary metabolic defects that most typically manifest themselves at a particular period in life are not necessarily confined to that epoch and may appear, sometimes in variant form, at a later stage*. Such variations are noted at appropriate points in the discussion.

THE METABOLIC DISEASES OF THE NEONATAL PERIOD

A small number of progressive metabolic diseases become evident in the first few days of life. The importance of these diseases relates not to their frequency (they constitute only a small fraction of diseases that compromise nervous system function in the neonate) but to the fact that they must be recognized promptly if the infant is to be prevented from dying or from suffering a lifelong severe mental deficiency. This inherent threat introduces an element of urgency into neonatal neurology. Recognition of these diseases is also important for purposes of family and prenatal testing.

Two approaches to the neonatal metabolic disorders are possible—one, to screen every newborn, using a battery of biochemical tests of blood and urine, and the other, to undertake in the days following birth a detailed neurologic assessment that will detect the earliest signs of these diseases. Unfortunately, not all the biochemical tests have been simplified to the point where they can be adapted to a mass screening program, and many of the commonly used clinical tests at this age have yet to be validated as markers of disease. Moreover, many of the biochemical tests are costly, and practical issues such as cost-effectiveness insinuate themselves, to the distress of the pediatrician. The recent introduction of tandem mass spectrometry for the evaluation of blood and urine has allayed some of the latter concerns.

The Neurologic Assessment of Neonates with Metabolic Disease

As pointed out in Chap. 28, the neonate's nervous system functions essentially at a brainstem-spinal level. The pallidum and visuo-

motor cortices are only beginning to be myelinated and their contribution to the totality of neonatal behavior cannot be very great. Neurologic examination, to be informative, must therefore be directed to evaluating diencephalic-midbrain, cerebellar-lower brainstem, and spinal functions. The integrity of these functions in the neonate is most reliably assessed by noting the following, again as described in Chap. 28:

1. Control of respiration and body temperature; regulation of thirst, fluid balance, and appetite-hypothalamus-brainstem mechanisms
2. Certain elemental automatisms, such as sucking, rooting, swallowing, grasping—brainstem-cerebellar mechanisms
3. Movements and postures of the neck, trunk, and limbs, such as reactions of support, extension of the neck and trunk, flexion movements and steppage—lower brainstem (reticulospinal), cerebellar, and spinal mechanisms
4. Muscle tone of limbs and trunk—spinal neuronal and neuromuscular function
5. Reflex eye movements—tegmental midbrain and pontine mechanisms (a modified optokinetic nystagmus can be recognized by the third day of life)
6. The state of alertness and attention (stimulus responsiveness and capacity of the examiner to make contact) as well as sleep-waking and electroencephalographic patterns—mesencephalic-diencephalic mechanisms
7. Certain reflexive reactions such as the startle (Moro) response and placing reactions of the foot and hand—upper brainstem-spinal mechanisms with possible cortical facilitation

Derangements of these functions are manifest as impairments of alertness and arousal, hypotonia, disturbances of ocular movement (oscillations of the eyes, nystagmus, loss of tonic conjugate deviation of the eyes in response to vestibular stimulation, i.e., to rotation of the upright infant), failure to feed, tremors, clonic jerkings, tonic spasms, opisthotonus, diminution or absence of limb movements, irregular or chaotic breathing, hypothermia or poikilothermia, bradycardia, circulatory difficulties, poor color, and seizures.

In most instances of neonatal metabolic disease, the pregnancy and delivery proceed without mishap. Birth at full term is usual. The infant is of a size and weight expected for the duration of pregnancy, and there are no signs of a developmental abnormality (in a few instances the infant is somewhat small, and in GM₁ gangliosidosis there may be a pseudo-Hurler appearance; see further on). Furthermore, function continues to be normal in the first few days of life. The first hint of trouble may be the occurrence of feeding difficulties: food intolerance, diarrhea, and vomiting. The infant becomes fretful and fails to gain weight and thrive—all of which should suggest a disorder of amino acid, ammonia, or organic acid metabolism.

The first definite indication of disordered nervous system function is likely to be the occurrence of seizures. These usually take the form of unpatterned clonic or tonic contractions of one side of the body or independent bilateral contractions, sudden arrest of respiration, turning of the head and eyes to one side, or twitching of the hands and face. Some of the ill-formed seizures may become generalized. They occur singly or in clusters, and in the latter instance are associated with unresponsiveness, immobility, and arrest of respiration.

The other clinical abnormalities in the motor realm, according to authorities such as Precht and Beintema, can be subdivided roughly into three groups, each of which constitutes a kind of syndrome: (1) hyperkinetic-hypertonic, (2) apathetic-hypotonic, or (3) unilateral or hemisyndromic. Precht and Beintema, from a study of more than 1500 newborns, found that if clinical examination consistently discloses any one of the three syndromes, the chances are two out of three that by the seventh year the child will be manifestly abnormal neurologically. They found also that certain neurologic signs—such as facial palsy, lack of grasping, excessive floppiness, and impairment of sucking—while sometimes indicative of serious disease of the nervous system, are less dependable; also, being rare, these signs will identify but few brain-damaged infants. It is not the single neurologic sign but groups of them that are held to be the most reliable indices of brain abnormality, and the three syndromes mentioned above are the important ones, even though their anatomic and physiologic bases are not completely known.

In our observations of the neonatal metabolic diseases, we have endeavored to determine whether particular ones consistently manifest themselves by one or another of the three syndromes. We are able to affirm this to some degree. In cases of hypocalcemia-hypomagnesemia, the hyperkinetic-hypertonic syndrome prevails. Although most of the other diseases tend to induce the apathetic-hypotonic state, the hyperactive-hypertonic syndrome may represent the initial phase of the illness and always carries a less ominous prognosis than the apathetic-hypotonic state, which represents a more severe condition regardless of cause. We have been least confident in the recognition of the third putative group of unilateral abnormalities in the metabolic diseases. Even more discouraging has been the frequent overlapping of the two other syndromes and the fact that seizures may occur in all of them. The anatomic correlate for some of these neurologic abnormalities can be observed by MRI. Clearly what is needed is a more definitive neonatal neurologic semiology utilizing numerous stimulus-response tests, including those described by A. Thomas and Dargassies, supplemented by evoked potentials; also needed are ways of accurately quantifying more of the natural activities of this age period. Even the brain death syndrome, in which all brainstem-spinal reflexes are abolished, has not been fully defined in the neonate (Adams et al).

The Neonatal Metabolic Diseases and Their Estimated Frequency

In New England, screening of all newborns for metabolic disorders has been in operation for almost 50 years. Current data on the diseases with neurologic implications have been collated by our colleague, H. L. Levy of Children's Hospital, Boston, and are summarized in Table 37-1. Some of these disorders can be recognized by simple color reactions in the urine; these are listed in Table 37-2.

To this group should be added the inherited hyperammonemic syndromes and vitamin-responsive aminoacidopathies (such as pyridoxine dependency and biotin deficiency) as well as certain nonfamilial metabolic disorders that make their appearance in the neonatal period—hypocalcemia, hypothyroidism and cretinism, hypomagnesemia with tetany, and hypoglycemia.

It is important to note that the three most frequently identified hereditary metabolic diseases—phenylketonuria (PKU), hyperphenylalaninemia, and congenital hypothyroidism—do not be-

Table 37-1

Estimated frequency of metabolic disorders with neurologic implications among newborn infants in New England (1999)

DISORDER	TOTAL SCREENED	TOTAL DETECTED	FREQUENCY
Congenital hypothyroidism	3,105,000	948	1:3,300
Phenylketonuria	4,738,789	336	1:14,000
Atypical PKU	4,738,789	286	1:17,000
Hartnup disorder	1,028,581	46	1:22,000
Histidinemia	1,028,581	38	1:27,000
Methylmalonic acidemia	1,028,581	19	1:54,000
Galactosemia	3,888,716	63	1:62,000
Argininosuccinic acidemia	1,028,581	13	1:80,000
Biotinidase deficiency	1,319,123	14	1:94,000
Homocystinuria	3,300,000	16	1:200,000
Maple syrup urine disease	4,599,373	19	1:240,000
Prolidase deficiency	1,028,581	3	1:350,000
Hyperprolinemia (type II)	1,028,581	2	1:500,000
Short-chain acyl-CoA dehydrogenase deficiency	1,028,581	1	1:1,000,000

come clinically manifest in the neonatal period and are therefore discussed in a later portion of this chapter and in Chap. 40 (in the discussion of congenital hypothyroidism). This is fortunate, for it allows time to introduce preventive measures before the first symptoms appear. A number of others, which can be recognized either by screening or by early signs, are synopsized below.

Vitamin-Responsive Aminoacidopathies Included under this heading is a group of diseases that respond not to dietary restriction of a specific amino acid but to the oral supplementation of a specific vitamin. Some 30 vitamin-responsive aminoacidopathies are known (they are all rare, but the more frequent ones are listed in Table 41-3, on page 1000), and many of them result in injury to the central nervous system (CNS).

Pyridoxine-dependent aminoacidopathy Pyridoxine dependency is the classic example. This is a rare disease, inherited as an autosomal recessive trait. It is characterized by the early onset of convulsions, sometimes occurring in utero; failure to thrive; hypertonia-hyperkinesia; irritability; tremulous movements ("jittery baby"); exaggerated auditory startle (hyperacusis); and later, if untreated, by psychomotor retardation. The specific laboratory abnormality is an increased excretion of xanthurenic acid in response

to a tryptophan load. There are decreased levels of pyridoxal-5-phosphate and gamma-aminobutyric acid (GABA) in brain tissue.

The neuropathology has been studied in only a few cases. One of our patients, a 13 1/2-year-old boy affected in the neonatal period, was left in a state of mental retardation, with pale optic discs and spastic legs; the brain weight was 350 g below normal. There was a decreased amount of central white matter in the cerebral hemispheres and a depletion of neurons in the thalamic nuclei and cerebellum, with gliosis (Lott et al). Most importantly, in pyridoxine deficiency, the administration of 50 to 100 mg of vitamin B₆ suppresses the seizure state, and daily doses of 40 mg permit normal development.

Biopterin Deficiency Some patients with increased concentrations of serum phenylalanine in the neonatal period are unresponsive to measures that lower phenylalanine. They are usually found to have a defect in biopterin metabolism. If this condition is unrecognized and not treated promptly, it leads to seizures of both myoclonic and later grand mal types combined with a poor level of responsiveness and generalized hypotonia. Swallowing difficulty is another prominent symptom. Within a few months, developmental delay becomes prominent. Unlike in PKU, phenylalanine

hydroxylase enzyme levels are normal, but there is a lack of tetrahydrobiopterin, which is a cofactor of phenylalanine hydroxylase. Treatment consists of administration of tetrahydrobiopterin in a dosage of 7.5 mg/kg per day in combination with a low-phenylalanine diet. It is important to recognize this condition early in life by the measurement of urine pterins and to institute appropriate therapy before irreversible brain injury occurs.

Galactosemia Inheritance of this disorder is autosomal recessive. The biochemical abnormality consists of a defect in galactose-1-phosphate uridylyl transferase (GALT), the enzyme that catalyzes the conversion of galactose-1-phosphate to uridine diphosphate galactose. Several forms of galactosemia have been described, based on the degree of completeness of the metabolic block. In the classic (severe) form, the onset of symptoms is in the first days of life, after the ingestion of milk; vomiting and diarrhea are followed by a failure to thrive. Drowsiness, inattention, hypotonia, and diminution in the vigor of neonatal automatisms then become evident. The fontanels may bulge, the liver and spleen enlarge, the skin becomes yellow (in excess of the common neonatal jaundice), and anemia develops. Rarely there is thrombocytopenia with cerebral bleeding. Cataracts may form due to the accumulation of galactitol in the lens. Studies of the outcome of surviving infants have shown retarded psychomotor development (IQ about 85), visual impairment, osteoporosis, ovarian failure, and residual cirrhosis, sometimes with splenomegaly and ascites. This seems to happen even with treatment. However, it is not known whether, in such patients, the treatment is always maintained through a critical developmental period. In one such patient, who died at 8 years, the main change in the brain was slight microcephaly with fibrous gliosis of the white matter and some loss of Purkinje and granule cells in the cerebellum, and also gliosis (Crome). The diagnostic laboratory findings are an elevated blood galactose level, low glucose, galactosuria, and deficiency of GALT in red and white blood cells and in liver cells. The treatment is essentially dietary, using milk substitutes; if this is instituted early, the brain should be protected from injury.

A late-onset neurologic syndrome has also been observed by Friedman and colleagues in galactosemic patients who survived the infantile disease. By late adolescence, they are found to be subnormal intellectually and socially maladjusted; some have shown cerebellar ataxia, dystonia, and apraxia. One of these patients was middle-aged.

Organic Acidurias of Infancy These have been divided into ketotic and nonketotic types. Among the *ketotic types*, the main one is *propionic acidemia*. This is an autosomal recessive disease due to a primary defect in organic acid metabolism that is expressed clinically by episodes of vomiting, lethargy, coma, convulsions, hypertonia, and respiratory difficulty. The onset is in the neonatal or early infantile period; in time, psychomotor retardation becomes evident. Death usually occurs within a few months despite dietary treatment. Propionic acid, glycine, various forms of fatty acids, and butanone are elevated in the serum. As with other ketotic organic acidurias, high protein intake induces ketotic attacks. Marked restriction of dietary protein (specifically leucine) may prevent attacks of ketoacidosis and permit relatively good psychomotor development.

A number of other ketotic acidurias also occur in infancy. The most important of these are *methylmalonic acidemia*, *isovaleric acidemia*, *beta-keto acidemia*, and *lactic acidemia*. Each of these

disorders can present with profound metabolic acidosis and intermittent lethargy, vomiting, tachypnea, tremors, twitching, convulsions, and coma, with early death in about half the patients and developmental retardation in those who survive. Rare subtypes of methylmalonic acidemia respond to vitamin B₁₂. Isovaleric acidemia is characterized by a striking odor of stale perspiration, which has given it the sobriquet "sweaty foot syndrome." Numerous metabolic defects, most commonly of pyruvate decarboxylase and pyruvate dehydrogenase, are responsible for the accumulation of lactic and pyruvic acids. The enzymatic defect of isovaleric acidemia has also been demonstrated in a recurrent form of episodic cerebellar ataxia and athetosis and in a persistent form in mitochondrial encephalopathies (Leigh disease), as described further on in this chapter.

A separate and rare deficiency of aromatic L-amino acid decarboxylase has been described; the chemical signature is of low levels of almost all catecholamines. This defect is associated with a peculiar movement disorder of oculogyric crises, dystonia and athetosis and autonomic failure (see Swoboda et al).

A type II glutaric acidemia has also been observed in the neonatal period and causes episodes of acidosis with vomiting and hyperglycemia. Multiple congenital anomalies of brain and somatic structures and cardiomyopathy are conjoined. A diet low in the specific toxic amino acid and supplements of carnitine and riboflavin are recommended, but the effects are unclear.

In the *nonketotic form of hyperglycinemia*, there are high levels of glycine but no acidosis. The notable diagnostic finding is an elevation of the CSF glycine, several times higher than that of the blood. The effects on the nervous system are more devastating than in the ketotic form. In reported cases (the authors and our colleagues have seen several), the neonate is hypotonic, listless, and dyspneic, with dysconjugate eye movements, opisthotonic posturing, myoclonus, and seizures. A few such neonates survive to infancy but are extremely retarded and helpless. Spongy degeneration of the brain has been reported both in this disease and in the ketotic form (Shuman et al). No treatment has been effective in severe cases. In an atypical milder form, with neurologic abnormalities that appear in later infancy or childhood, reduction of dietary protein and administration of sodium benzoate in doses up to 250 mg/kg per day have been beneficial. The use of dextromethorphan, which blocks glycine receptors, is said to be effective in preventing seizures and coma.

Inherited Hyperammonemias These are a group of six diseases caused by inborn deficiencies of the enzymes of the Krebs-Henseleit urea cycle; they are designated as *N-acetyl glutamate synthetase*, *carbamyl phosphate synthetase* (CPS), *ornithine transcarbamylase* (OTC), *argininosuccinic acid synthetase* (*citrullinemia*), *argininosuccinase deficiency*, and *arginase deficiency*. Hyperornithinemia-hyperammonemia-homocitrullinemia (HHH) and intrinsic protein intolerance are closely related disorders. They are identified by the finding of a persistent or episodic elevation of ammonia levels in the blood. A detailed account of these inherited hyperammonemic syndromes is contained in the review by Brusilow and Horwitz.

The pattern of inheritance of each of these disorders is autosomal recessive except for OTC deficiency, which is X-linked dominant. Their clinical manifestations are a common expression of an accumulation of ammonia or of urea cycle intermediates in the brain; they differ only in severity, in accordance with the degree of completeness of the enzymatic deficiency and with the age of

the affected individual. The one exception is arginase deficiency, which commonly presents during later childhood as a progressive spastic paraparesis with mental retardation. Clinically it has been convenient to divide the hyperammonemias into two groups—one that presents in the neonatal period and another that presents in the weeks or months thereafter. This division is somewhat artificial, the clinical presentation being more in the nature of a continuous spectrum governed by the biologic factors mentioned above and even extending to rare cases that have their first symptoms during adulthood.

In the most severe forms of the hyperammonemic disorders, the infants are asymptomatic at birth and during the first day or two of life, after which they refuse their feedings, vomit, and rapidly become inactive and lethargic, soon lapsing into an irreversible coma. Profuse sweating, focal or generalized seizures, rigidity with opisthotonus, and hypothermia and hyperventilation have been observed in the course of the illness. These symptoms constitute a medical emergency, but even with measures to reduce serum ammonia, the disease is usually fatal.

In less severely affected infants, hyperammonemia develops some months later, when protein feeding is increased. There is a failure to thrive, and attempts to enforce feeding or during periods of constipation (both of which increase ammonia production in the bowel) there may be bouts of vomiting, lethargy, hyperirritability, and screaming. Respiratory alkalosis is a consistent feature. Other manifestations are periods of alternating hypertonia and hypotonia, seizures, ataxia, blurred vision, and of confusion, stupor, and coma. During episodes of stupor, often precipitated by dehydration, an alimentary protein load, or minor surgery, brain edema may be seen by computed tomography (CT) and MRI; with repeated relapses, the brain edema gives way to atrophy, which appears as symmetrical areas of decreased attenuation in the cerebral white matter. Between attacks, some patients with partial deficiency may be normal or show only a slight hyperbilirubinemia (diMagno et al, Rowe et al). With decompensation, the bilirubin rises, as does ammonia, but neither reaches exceedingly high levels. After repeated attacks, signs of developmental delay with motor and mental retardation become evident, and the patient is vulnerable to recurrent infections. Two adult male patients in our care, who were married (but with azoospermia, which is common) and working at technically demanding jobs, came to medical attention because of bouts of visual blurring followed by stupor that evolved over hours (Shih et al). They had displayed an aversion to protein and milk products as children; in later life, after meals high in protein, they became encephalopathic, one with severe brain swelling. There are few phenotypic differences among the late-onset hyperammonemias except for *argininosuccinic aciduria*, in which excessive dryness and brittleness of the hair (trichorrhexis nodosa) are notable features, and the aforementioned *arginase deficiency* with spastic diplegia.

Diagnosis is established by the finding of *hyperammonemia*, often as high as 1500 mg/dL. The precise biochemical diagnosis requires testing of blood and urine for amino acids or assays for specific enzymes in red cells, liver, or jejunal biopsies. The primary hyperammonemias must be distinguished from the organic acidurias, including *methylmalonic aciduria* (see above), in which hyperammonemia can occur as a secondary metabolic abnormality.

In all the neonatal hyperammonemic diseases, the liver is often enlarged and liver cells appear to be inadequate in their metabolic functions, but how the enzymatic deficiencies or other disorders of amino acid metabolism affect the brain remains uncertain. It must

be assumed that in some the saturation of the brain by ammonia impairs the oxidative metabolism of cerebral neurons, and when blood levels of ammonium increase (from protein ingestion, constipation, etc.), episodic coma or a more chronic impairment of cerebral functions occurs—as it does in adults with cirrhosis of the liver and portal-systemic encephalopathy. In the acutely fatal cases the brain is swollen and edematous and the astrocytes are diffusely increased in number and enlarged. The neurons are normal. Astrocytic swelling has been attributed to the accumulation of glutamate secondary to a suppression of glutamate synthetase. These changes have been reproduced in animals by the injection of ammonium chloride. When the hyperammonemia is abrupt in onset and severe, the resulting combination of encephalopathy, brain swelling, and respiratory alkalosis simulates the postinfectious *Reye syndrome* (page 969).

As in all forms of liver disease, valproic acid and other hepatic toxins may cause hepatic coma by further impairing the urea cycle enzymes. Notable are a few cases of inherited hyperammonemia that come to light in childhood or adulthood only after the administration of one of these drugs.

Ornithine Transcarbamylase Deficiency and Argininosuccinic Aciduria These are episodic diseases in which hyperammonemia develops usually later in childhood, but they may become manifest in the neonatal period. The main clinical features are episodic stupor, ataxia, and seizures. Their other features have been mentioned above.

Treatment of the Hyperammonemic Syndromes The treatment of acute hyperammonemic syndromes is directed to the lowering of ammonia levels by hemodialysis, exchange transfusions, and administration of arginine and certain organic acids. With subsidence of the acute symptoms, a systematic form of management should be undertaken, as outlined by Brusilow et al and by Msall et al. Sodium benzoate should be given in doses up to 250 mg/day, supplemented by sodium phenylacetate or sodium phenylbutyrate, which on theoretical grounds should divert nitrogen from the ureagenesis cycle. Arginine (50 to 150 mg/kg) should be added to the diet, since a deficiency of this substance may be responsible for the mental retardation and skin rashes. In more chronic cases, treatment consists of decreasing the ammonium load by the use of dietary protein restriction and by administration of oral antibiotics and lactulose. In infants with inborn errors of ureogenesis, there is a constant danger of recurrent episodes of hyperammonemia and coma, particularly in response to infections. In a few instances, careful management of the metabolic error has resulted in normal psychomotor development.

Liver transplantation may prove to be a therapeutic option.

Branched-Chain Aminoacidopathies (Maple Syrup Urine Disease) These conditions are caused by a deficiency of α -keto acid dehydrogenase, resulting in the accumulation of the branched-chain amino acids leucine, isoleucine, and valine and the corresponding branched-chain α -keto acids. Maple syrup urine disease may be taken as the prototype. The pattern of inheritance is autosomal recessive. With the most severe neonatal type, the infant appears normal at birth, but toward the end of the first week, poor feeding, intermittent hypertonicity, opisthotonus, and respiratory irregularities appear. These are followed by diminished neonatal automatisms, convulsions, severe ketoacidosis, and often coma and death toward the end of the second to fourth week. This disease is one of the causes of the malignant epileptic syndrome of early infancy (Brett). Four milder forms of the disease have been de-

scribed. In these more chronic forms, feeding difficulties begin somewhat later in the early infantile period. They are manifest as recurrent infections, episodic acidosis, coma, and retarded growth and psychomotor development. Some of these patients, toward the end of the first year, may become quadriparetic or ataxic; or there may be only a nonspecific mental retardation. The disease derives its name from the maple syrup odor of the child's urine which tests positively for 2,4-dinitrophenylhydrazine (DNPH).

Other important laboratory findings are increased plasma and urine concentrations of leucine, isoleucine, valine, and keto acids. Secondary accumulation of a derivative of α -hydroxybutyric acid probably accounts for the maple syrup odor. The neuropathologic findings are uncertain. In the first acute case described, only interstitial edema was observed; but in more chronic cases, pallor and loss of myelin and gliosis of parts of the cerebral white matter that myelinate after birth may be found. This can be visualized in CT and MRI scans.

Treatment by restriction of foods containing branched-chain amino acids (leucine, isoleucine, and valine) allows reasonably normal mental development, but only if such restriction is begun in the neonatal period and maintained lifelong. A thiamine-responsive variant with a slightly different pattern of keto acids described by Prensky and Moser responds variably to 30 to 300 mg of thiamine. The acute episodes, which threaten life, may require peritoneal dialysis to remove the putative toxic metabolites; they respond to the administration of glucose amino acid mixtures that are free of branched-chain keto acids.

Other Organic Acidemias In addition to maple syrup urine disease, there are a number of other metabolic disturbances, some of them of mitochondrial origin, that appear in the neonatal period or later and are marked by an organic acidemia. If they are severe, the infant develops a metabolic (lactic) acidosis soon after birth, with lethargy, feeding problems, rapid respirations, and vomiting. Or there may be irritability, jerky limb movements, and hypertonia. Later presentations take the form of feeding difficulties, repeated vomiting, hypotonia, and failure to thrive. With the passage of time, psychomotor retardation and drug-resistant seizures become evident. Metabolic stress—e.g., intercurrent infection or surgical procedures—may precipitate an episode of lactic or ketoacidosis.

Biochemical studies may disclose a biotinidase deficiency, methylmalonic aciduria, glutaric acidemia, methylglutaconic acidemia, or any number of other organic acid abnormalities. The precise abnormality is determined by measuring enzyme activity in white blood cells or cultured skin fibroblasts. As remarked above, some of these enzymes act in conjunction with a specific vitamin cofactor, so that exact diagnosis is imperative. The biotinidase deficiency may respond to 10 mg of biotin per day; the methylmalonic acidemia to 1 to 2 mg of vitamin B₁₂ per day; maple syrup urine disease to 10 to 20 mg of thiamine per day; and glutaric acidemia types I and II to 300 mg of riboflavin per day. The administration of carnitine may increase the elimination of toxic metabolites.

The care of these patients during an acute illness is of extreme importance. See Lyon and colleagues for a more complete description.

Sulfite Oxidase Deficiency with or without Molybdenum Cofactor Deficiency (See also page 804) These are extremely rare autosomal recessive disorders of sulfur metabolism, manifest clinically during the neonatal period by seizures, axial hypotonia, re-

duced level of responsiveness, and spasms with opisthotonus. There may be added dislocation of lenses, blindness, coloboma, and enophthalmos in combination with severe mental retardation and dysmorphic facial features (widely spaced eyes, long face and philtrum, puffy cheeks). There are no differences between pure sulfite oxidase deficiency and that associated with molybdenum cofactor deficiency. With survival into infancy, episodic confusion and stupor give way to seizures, mental retardation, and ataxia. In one of our cases, described by Shih and colleagues, a stroke-like syndrome of hemiplegia and aphasia appeared during a relapse at the age of 4.5 years, and in a Belgian case, subluxation of the lenses and choreoathetosis appeared at 8 months of age.

The biochemical abnormality is the accumulation of sulfite and possibly sulfatase as a result of the enzyme deficiency. Shih and colleagues have identified sulfite, thiosulfite, and S-sulfocysteine in the urine. Cerebral atrophy with loss and destruction of white matter and gray matter (cerebral cortex, basal ganglia, and cerebellar nuclei) has been observed in one postmortem examination. Increasing the intake of molybdenum or lowering the dietary intake of sulfur amino acids are therapeutic possibilities, not yet fully evaluated.

Diagnosis of Neonatal Metabolic Diseases

An important clue, of course, is provided by the history of a neonatal disease or unexplained death earlier in the same sibship or in a male maternal relative. A history that protein foods are rejected by the infant, or even a history among relatives of a dislike of protein or feeding difficulties in infancy, should raise the suspicion of an inherited hyperammonemic disorder or an organic acidemia. Measurements of blood ammonia and lactate and of the urine for ketones and reducing substances are the key laboratory tests. A wide-spectrum screening program may disclose a biochemical abnormality; this is the optimal state of affairs, especially when this type of screening provides the information before symptoms appear.

A number of nonhereditary metabolic diseases must be distinguished from the hereditary ones in this period of life. *Hypocalcemia* is one of the most frequent causes of neonatal seizures; tetany, spasms, and tremulous movements are usually present. Its cause is unknown, but the disorder is easily corrected, with excellent prognosis. Symptomatic *hypoglycemic reactions* are frequent in neonates. Premature infants are the most susceptible. Seizures, tremulousness, and drowsiness occur with blood sugar levels of less than 30 mg/dL in the mature infant and less than 20 mg/dL in the premature. Maternal toxemia and diabetes mellitus also predispose to hypoglycemia. Other causes of hypoglycemia are adrenal insufficiency, galactosemia, an idiopathic pancreatic islet-cell hyperplasia, the treatable fatty-acid beta oxidation disorders, and a congenital deficiency of CSF glucose transport—causing persistent hypoglycorrachia and refractory seizures unless blood glucose levels are kept high. The damaging effects of untreated hypoglycemia have been well documented by Koivisto and colleagues. Also now identified is a disorder of CSF serine transport causing failure to thrive, severe developmental disability with spasticity and intractable epilepsy. The diagnosis is made by measuring CSF amino acids; treatment is with high-dose oral serine. *Cretinism* and *idiopathic hypercalcemia* are other recognizable entities that appear during this age period.

Aicardi has described a neonatal myoclonic syndrome and

Ohtahara, a malignant neonatal seizure disorder. In some of the cases, the neonatal syndrome merged later with the West type of infantile spasm disorder and the Lennox-Gastaut syndrome. Some of the cases had developmental abnormalities of the cerebrum, and severe mental retardation was the outcome. In other cases of this type, a familial coincidence was a feature; a metabolic defect has been suspected in these cases but never proved.

The hereditary metabolic diseases must also be distinguished from a number of other catastrophic disorders that occur at or soon after birth, such as asphyxia, perinatal ventricular hemorrhage with the respiratory distress syndrome of hyaline membrane disease, other hypotensive-hypoxic states, erythroblastosis fetalis with kernicterus, neonatal bacterial meningitis, meningoencephalitis (herpes simplex, cytomegalic inclusion disease, listeriosis, rubella, syphilis, and toxoplasmosis), and hemorrhagic disease of the newborn. These are described in Chap. 38, on the developmental diseases.

THE HEREDITARY METABOLIC DISEASES OF INFANCY

The hallmark of all the hereditary metabolic diseases is *psychomotor regression*. However, those that have their onset in the first year of life pose extraordinary problems in neurologic diagnosis. If the onset is in the first postnatal months, before the infant has had time to develop the normal complex repertoire of behavior, the first signs of disease may take the form of subtle delays in maturation rather than of psychomotor regression. Departures from normalcy include a lack of interest in the surroundings, a lack of visual engagement, poor head control, an inability to sit up at the usual time, poor hand-eye coordination, and persistence of infantile automatisms. Of course, embryologic maldevelopment of the brain may have similar effects, and systemic diseases and other visceral malformations—such as cystic fibrosis, renal disease, biliary atresia and congenital heart disease, chronic infection, malnutrition, and seizures (with drug therapy)—may appear to impede psychomotor development. Diagnosis becomes somewhat easier in the second half of the first year, especially if development in the first half had proceeded normally. Then an observant mother, usually one with older children, can perceive a loss of certain early acquisitions, attesting to the progressive nature of a disease.

The most distinctive members of this category of neurologic disease are the *leukodystrophies* and the so-called *lysosomal storage diseases*. The leukodystrophies are a group of inherited metabolic diseases of the nervous system characterized by progressive, symmetrical, and usually massive destruction of the white matter of the brain and sometimes of the spinal cord; each type of leukodystrophy is distinguished by a particular abnormal product of degeneration of myelinated fibers. In the *lysosomal storage diseases*, there is a genetic deficiency of the enzymes (usually one or more of the acid hydrolases) necessary for the degradation of specific glycosidic or of peptide linkages in the intracytoplasmic lysosomes, causing nerve cells to become engorged with material that they would ordinarily degrade. These metabolites eventually damage the nerve cell or its myelin sheath.

Most of these diseases are classed as *sphingolipidoses*. It was Brady in 1966 who made the observation that in each of these disorders an increased quantity of sphingolipid accumulated in the brain and other tissues. The sphingolipids are a class of intracellular lipids that all have ceramide as their basic structure, but each has a different attached oligosaccharide or phosphorylcholine. The rate

of synthesis of the sphingolipids is normal and their accumulation results from a defect of a specific lysosomal enzyme that normally degrades each of the glycoproteins, glycolipids, and mucopolysaccharides by removing a monosaccharide or sulfate moiety. It is the type of enzyme deficiency and accumulated metabolite, as well as the tissue distribution of the undegradable substrate, that impart a distinctive biochemical and clinical character to each of the diseases in this category.

The concept of lysosomal storage diseases, introduced by Hers in 1965, excited great interest among neurologists at the time because it provided the potential for prenatal diagnosis and the detection of carriers. The diagnosis of this group of diseases has also been facilitated by the use of CT scanning, MRI, and evoked response techniques, which confirm the existence of leukodystrophies, and by the electron microscopic examination of skin, rectal, or conjunctival biopsies, circulating lymphocytes, and cultured amniotic fluid cells, which discloses the lysosomal storage material in nonneuronal cells. The activity of most lysosomal enzymes can be determined by exposing them to artificial chromogenic or fluorogenic substrates.

There are now more than 40 lysosomal storage diseases in which the biochemical abnormalities have been determined. They are listed in Table 37-3, which was adapted originally from the review of Kolodny and Cable and recently updated by our colleague E. Kolodny. In addition to the sphingolipidoses, which are the lysosomal storage diseases most likely to be encountered in the first year of life, the table includes the storage diseases that may not appear clinically until a later age (in childhood and adolescence)—to be considered later in this chapter. The frequency of each of the various types as detected in a comprehensive study of the Australian population is given by Meikle and colleagues and generally accords with the ordering below. A broad perspective on the frequency of the lysosomal disorders can be appreciated from the report of the Australian national referral laboratory. There were 545 cases (75 detected prenatally) over a 16-year period, a calculated frequency of 1 case per 7700 live births. This is close to the estimate in the United States, which is approximately 1 per 5000 births.

The more frequent types of lysosomal storage diseases are as follows:

1. Tay-Sachs disease (GM_2 gangliosidosis) and variants such as Sandhoff disease
2. Infantile Gaucher disease
3. Infantile Niemann-Pick disease
4. Infantile GM_1 generalized gangliosidosis
5. Krabbe globoid-body leukodystrophy
6. Farber lipogranulomatosis
7. Pelizaeus-Merzbacher and other sudanophilic leukodystrophies
8. Spongy degeneration (Canavan-van Bogaert-Bertrand disease)
9. Alexander disease
10. Zellweger encephalopathy
11. Lowe oculorenal-cerebral disease

In the following descriptions, we have summarized the clinical and pathologic features of each of the diseases listed above and have italicized the characteristic clinical signs and corroborative laboratory tests. Leigh disease, which may appear in this age group,

Table 37-3
Lysosomal storage diseases

DISORDER	PRIMARY DEFICIENCY	ACCUMULATED METABOLITE
Sphingolipidoses		
GM ₁ gangliosidosis	β -Galactosidase	GM ₁ ganglioside, galactosyl oligosaccharides, keratan sulfate
GM ₂ gangliosidosis		
Tay-Sachs disease	<i>N</i> -acetylhexosaminidase α subunit	GM ₂ ganglioside
Sandhoff disease	<i>N</i> -acetylhexosaminidase β subunit	GM ₂ ganglioside, oligosaccharides, glycosaminoglycans
Activator deficiency	GM ₂ activator	GM ₂ ganglioside
Metachromatic leukodystrophy	Arylsulfatase A (sulfatidase), sulfatide activator (saposin B)	Galactosylsulfatide, lactosylsulfatide
Krabbe disease	Galactocerebrosidase	Galactosylceramide
Fabry disease	α -Galactosidase A	Ceramide trihexoside
Gaucher disease	Glucocerebrosidase	Glucosylceramide, glycopeptides
Niemann-Pick disease		
Types A and B	Sphingomyelinase	Sphingomyelin, cholesterol
Type C	Cholesterol esterification	Free cholesterol, <i>bis</i> -monoacylglycerophosphate
Farber disease	Ceramidase	Ceramide
Schindler disease	α -Galactosidase B	α -N-acetylgalactosaminyl oligosaccharides and glycopeptides
Neuronal ceroid lipofuscinoses		
Infantile form (Haltia-Santavuori)	Palmitoyl-protein thioesterase	Granular osmiophilic deposits
Late infantile form (Jansky-Bielschowsky)	Tripeptidyl peptidase I	Curvilinear bodies, subunit C of mitochondrial ATP synthase
Juvenile form (Spielmeyer-Sjögren)	438-amino acid membrane protein	Curvilinear and laminated (fingerprint) bodies, subunit C of mitochondrial ATP synthase
Adult form (Kufs disease)	Unknown	Mixed-type osmiophilic deposits and lamellar inclusions
Glycoproteinoses		
Aspartylglycosaminuria	Aspartylglycosaminidase	Aspartylglycosamine
Fucosidosis	α -L-Fucosidase	Fucosyloligosaccharides, fucosylglycosphingolipids
Galactosialidosis	Protective protein (β -galactosidase and α -neuraminidase)	Sialyloligosaccharides, galactosyloligosaccharides
α -Mannosidosis	α -Mannosidase	α -Mannosyl oligosaccharides
β -Mannosidosis	β -Mannosidase	β -Mannosyl oligosaccharides
Mucolipidoses		
Sialidosis (mucolipidosis I)	α -Neuraminidase	Sialyloligosaccharides, sialylglycopeptides
Mucolipidosis II (I-cell disease)	UDP- <i>N</i> -acetylglucosamine: lysosomal enzyme, <i>N</i> -acetylglucosamine-1-phosphotransferase	Sialyloligosaccharides, glycoproteins, glycolipids
Mucolipidosis III (pseudo-Hurler polydystrophy)	Same phosphotransferase as above	Sialyloligosaccharides, glycoproteins, glycolipids
Mucolipidosis IV	Unknown	Gangliosides, phospholipids, mucopolysaccharides
Other lysosomal diseases		
Acid lipase deficiency		
Wolman disease	Acid lipase	Cholesterol esters, triglycerides
Cholesterol ester storage disease	Acid lipase	Cholesterol esters, triglycerides
Glycogenosis type II (Pompe disease)	α -Glucosidase (acid maltase)	Glycogen
Sialic acid storage disease		
Infantile form	Sialic acid transport	Free sialic acid
Salla disease	Sialic acid transport	Free sialic acid
Mucopolysaccharidoses (see Table 37-7).		

is described with the mitochondrial diseases, further on in this chapter.

Tay-Sachs Disease (GM₂ Gangliosidosis, Hexosaminidase A Deficiency)

This is an autosomal recessive disease, mostly of Jewish infants of eastern European (Ashkenazic) background. The first description came from Tay, a British ophthalmologist, in 1881, and Sachs, an American neurologist, in 1887; they called it amaurotic family idiocy. The disease becomes apparent in the first weeks and months of life, almost always by the fourth month. The first manifestations are a regression of motor activity and an abnormal startle to acoustic stimuli, accompanied by listlessness, irritability, and poor reactions to visual stimuli. These are followed by a progressive *delay in psychomotor development* or regression (by 4 to 6 months), with inability to roll over and sit. At first, axial hypotonia is prominent, but later spasticity and other corticospinal tract signs and visual failure become evident. Degeneration of the macular cells exposes the underlying red vascular choroid surrounded by a whitish gray ring of retinal cells distended with ganglioside. The resulting appearance is of the *cherry-red spot* with optic atrophy (Fig. 37-1). These are observed in the retinas in more than 90 percent of patients (but are also characteristics of other storage diseases—see Table 37-4). In the second year, there are tonic-clonic or minor motor seizures and an increasing size of the head and diastasis of sutures with relatively normal-sized ventricles; in the third year, the clinical picture is one of dementia, decerebration, and blindness. Cachexia becomes increasingly severe and death occurs at 2 to 4 years. The electroencephalogram (EEG) becomes abnormal in the early stages (paroxysmal slow waves with multiple spikes). Occasionally one can find basophilic granules in leukocytes and vacuoles in lymphocytes. There are no visceral, skeletal, or bone marrow abnormalities by light microscopy.

The basic enzymatic abnormality is a *deficiency of hexosaminidase A*, which normally cleaves the *N*-acetylgalactosamine from gangliosides. As a result of this deficiency, GM₂ ganglioside accumulates in the cerebral cortical neurons, Purkinje cells, retinal ganglion cells, and, to a lesser extent, larger neurons of the brain-

Table 37-4
Diseases displaying a cherry-red macular spot

Niemann-Pick disease types A to D (not E and F); ring may be diffuse and indistinct
Farber lipogranulomatosis
Metachromatic leukodystrophy
Neuronal ceroid lipofuscinosis, late infantile form ("bull's eye" maculopathy, not true cherry-red spot)

stem and spinal cord. The enzymatic defect can be found in the serum, white blood cells, and cultured fibroblasts from the skin or amniotic fluid, the latter giving parents the option of abortion to prevent a presently untreatable and fatal disease. Testing for hexosaminidase A also permits the detection of heterozygote carriers of the gene defect. Detection of this enzyme defect is complicated by the fact that more than 50 mutations of the alpha subunit of the beta hexosaminidases have been isolated and the enzyme itself is normal in one form of activator enzyme deficiency. Fortunately, only three mutations account for 98 percent of the form that is common in Jews.

The brain is large, sometimes twice the normal weight. In addition, there is a loss of neurons and a reactive gliosis; remaining nerve cells throughout the CNS are distended with glycolipid. Biopsies of the rectal mucosa disclose glycolipid distention of the ganglion cells of the Auerbach plexus, but the need for this procedure has been obviated by enzyme analysis of white blood cells. Under the electron microscope, the particles of stored material appear as membranous cytoplasmic bodies. Retinal ganglion cells are distended with the same material and, together with fat-filled histiocytes, cause the whitish gray rings around the fovea, where there are no nerve cells, as noted above.

The same neuropathologic process has been found in a few congenital cases in which there was a rapidly progressive decline of a microcephalic infant. Kolodny and Raghavan have described two other, probably allelic variants of the hexosamine A defect. One presents as a childhood spinocerebellar degeneration, the other as a progressive spinal muscular atrophy in juveniles and young adults, due presumably to widespread involvement of spinal motor neurons (see further on).

Tay-Sachs disease is untreatable but can be prevented by testing all individuals of Jewish origin for the recessive trait. Since this screening was instituted at the E. K. Shriver Center in 1968 and adopted throughout the state, it is essentially unknown in Massachusetts.

In *Sandhoff disease*, which affects non-Jewish infants, there is a deficiency of both hexosaminidase A and B, moderate hepatosplenomegaly, and coarse granulations in bone marrow histiocytes. The clinical and pathologic picture is the same as in Tay-Sachs disease except for the additional signs of visceral lipid storage. Occasionally these visceral organs are not enlarged.

In recent years numerous variants of hexosaminidase A and B deficiency have been identified. They differ clinically from Tay-Sachs disease in having a later onset, less extensive brain involvement (cortical neurons relatively spared and intense affection of basal ganglia as well as cerebellar and spinal neurons). Accordingly, the clinical expression of the variants appearing in childhood,

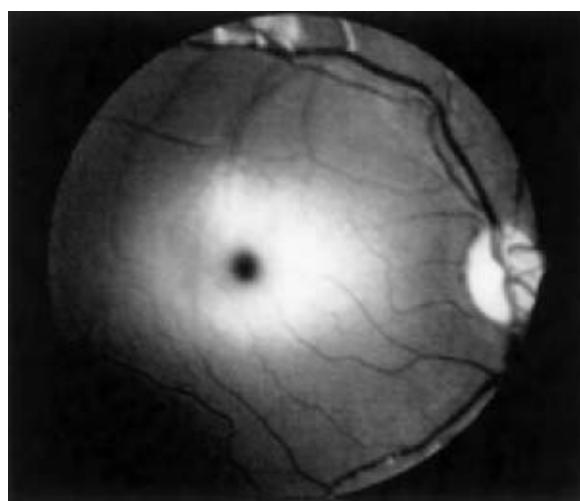

Figure 37-1. Retinal cherry-red spot in a patient with Tay-Sachs disease. The whitish ring surrounds the dark macula. (Reproduced by permission from Lyon et al.)

adolescence, and adult life take the form of athetosis, dystonia, ataxia, and motor neuron paralysis; mental function can be normal.

Infantile Gaucher Disease (Type II) Neuronopathic Form, Glucocerebrosidase Deficiency

This is an autosomal recessive disease without ethnic predominance, first described by Gaucher in 1882. The onset of the neuronopathic form is usually before 6 months and frequently before 3 months. The clinical course is more rapid than that of Tay-Sachs disease (most patients with infantile Gaucher disease do not survive beyond 1 year and 90 percent not beyond 2 years). Oculomotor apraxia and bilateral strabismus are early signs and are accompanied by rapid loss of head control, of ability to roll over and sit, and of purposeful movements of the limbs—along with apathy, irritability, frequent crying, and difficulty in sucking and swallowing. In some cases progression is slower, with acquisition of single words by the first year, bilateral corticospinal signs (Babinski signs and hyperactive tendon reflexes), *persistent retroflexion of the neck*, and *strabismus*. Laryngeal stridor and trismus, diminished reaction to stimuli, smallness of the head, rare seizures, normal optic fundi, *enlarged spleen* and slightly enlarged liver, poor nutrition, yellowish skin and scleral pigmentation, osteoporosis, vertebral collapse and kyphoscoliosis, and sometimes lymphadenopathy complete the clinical picture. The CSF is normal; the EEG is abnormal but nonspecifically so.

The important laboratory findings are an *increase in serum acid phosphatase and characteristic histiocytes (Gaucher cells)* in marrow smears and liver and spleen biopsies. A deficiency of *glucocerebrosidase* in leukocytes and hepatocytes is diagnostic; glucocerebroside accumulates in the involved tissues. The characteristic pathologic feature is the Gaucher cell, 20 to 60 μm in diameter, with a wrinkled appearance of the cytoplasm and eccentricity of the nucleus. These cells are found in the marrow, lungs, and other viscera; neuronal storage is seldom evident. In the brain, the main abnormality is a loss of nerve cells—particularly in the bulbar nuclei but also in the basal ganglia, cortex, and cerebellum—and a reactive gliosis that extends into the white matter.

In contrast to the type II form described above, type I Gaucher disease is a nonneuronopathic and relatively benign form. A less frequent type III Gaucher disease is neuronopathic. It expresses itself in late childhood or adolescence by a slowly progressive mental decline, seizures, and ataxia, and, later, by spastic weakness and splenomegaly. Vision and retinæ remain normal. Highly diagnostic is the defect in voluntary lateral gaze, with full movements on the oculocephalic (“doll’s-head”) maneuver. These signs help to differentiate Gaucher from Niemann-Pick disease, in which vertical eye movements are lost (see below). The nucleotide sequence of the cloned glucocerebrosidase of type I Gaucher disease was found by Tsuji and associates to be different from that of types II and III. There is no treatment for the latter types.

Infantile Niemann-Pick Disease (Sphingomyelinase Deficiency)

This is also an autosomal recessive disease. Two-thirds of the affected infants have been of Ashkenazi Jewish parentage. The onset of symptoms in the usual type A disease is between 3 and 9 months of age, frequently beginning with marked *enlargement of liver, spleen, and lymph nodes and infiltration of the lungs*; rarely there

is jaundice and ascites. Cerebral abnormalities are definite by the end of the first year, often earlier. The usual manifestations are loss of spontaneous movements, lack of interest in the environment, axial hypotonia with bilateral corticospinal signs, blindness and amaurotic nystagmus, and a macular cherry-red spot (in about one-quarter of the patients). Seizures may occur but are relatively late. There is no acoustic-induced startle or myoclonus, and head size is normal or slightly reduced. Loss of tendon reflexes and slowed conduction in peripheral nerves have been recorded but are rare. Protruberant eyes, mild hypertelorism, slight yellowish pigmentation of oral mucosa, and dysplasia of dental enamel have also been reported but are rare. Most patients succumb to an intercurrent infection by the end of the second year.

Vacuolated histiocytes (“foam cells”) in the bone marrow and vacuolated blood lymphocytes are the important laboratory findings. A deficiency of sphingomyelinase in leukocytes, cultured fibroblasts, and hepatocytes is diagnostic. Pathologic examination reveals a decrease in the number of neurons; many of the remaining ones are pale and ballooned and have a granular cytoplasm. The most prominent neuronal changes are seen in the midbrain, spinal cord, and cerebellum. The white matter is little affected. The retinal nerve cell changes are similar to those in the brain. The foamy histiocytes (Niemann-Pick cells) that fill the viscera contain sphingomyelin and cholesterol; the distended nerve cells contain mainly sphingomyelin.

There are also less severe late infantile and juvenile forms of Niemann-Pick disease types C and D. These are discussed in a later section of this chapter.

Infantile Generalized GM₁ Gangliosidosis (Type I, β -Galactosidase Deficiency, Pseudo-Hurler Disease)

This is probably an autosomal recessive disease without ethnic predominance. The infants appear abnormal at birth. They have *dysmorphic facial features*, like those of the mucopolysaccharidoses: depressed and wide nasal bridge, frontal bossing, hypertelorism, puffy eyelids, long upper lip, gingival and alveolar hypertrophy, macroglossia, and low-set ears. These features, with the bone changes mentioned below, account for the term *pseudo-Hurler*. Other indications of the disease are the onset of impaired awareness and reduced responsivity in the first days or weeks of life; lack of *psychomotor development* after 3 to 6 months; hypotonia, and later hypertonia with lively tendon reflexes and Babinski signs. Seizures are frequent. The head size is variable (microcephaly more often than macrocephaly). *Loss of vision, coarse nystagmus and strabismus, macular cherry-red spots* (in half the cases), flexion pseudo-contractures of elbows and knees, kyphoscoliosis, and enlarged liver and sometimes enlarged spleen are the other important clinical findings. Radiographic abnormalities include subperiosteal bone formation, midshaft widening and demineralization of long bones, and hypoplasia and beaking of the thoracolumbar vertebrae. Vacuoles are seen in 10 to 80 percent of blood lymphocytes and foam cells in the urinary sediment.

A partial or complete deficiency of β -galactosidase and accumulation of GM₁ ganglioside in the viscera and in neurons and glial cells throughout the CNS are the specific biochemical abnormalities. In addition, the epithelial cells of renal glomeruli, histiocytes of the spleen, and liver cells contain a modified keratan sulfate and a galactose-containing oligosaccharide. The changes in the bone are also like those in the Hurler form of mucopolysac-

charidosis. The disease should be suspected in an infant having the facial features of mucopolysaccharidosis and severe early-onset neurologic abnormalities.

A remarkably benign variant, also inherited as an autosomal recessive trait, begins later in childhood but may advance so slowly as to allow attainment of adult life. Dystonia, myoclonus, seizures, visual impairment, and macular red spots were features of the two cases described by Goldman and coworkers.

Globoid Cell Leukodystrophy (Krabbe Disease, Galactocerebrosidase Deficiency)

This is an autosomal recessive disease without ethnic predilection, first described by Krabbe, a Danish neurologist, in 1916. The onset is usually before the sixth month and often before the third month (10 percent after 1 year). Early manifestations are *generalized rigidity*, loss of head control, diminished alertness, frequent vomiting, irritability and bouts of inexplicable crying, and spasms induced by stimulation. With increasing muscular tone, *opisthotonic* recurvature of the neck and trunk develops. Later signs are adduction and extension of the legs, flexion of the arms, clenching of the fists, hyperactive tendon reflexes, and Babinski signs. Later still, the tendon reflexes are depressed or lost but Babinski signs remain, an indication that *neuropathy* is added to corticospinal damage. This finding, shared with some of the other leukodystrophies, is of diagnostic value. Blindness and optic atrophy supervene. Convulsions occur but are rare and difficult to distinguish from tonic spasms. Myoclonus in response to auditory stimuli is present in some cases. The head size is normal or, rarely, slightly increased. In the last stage of the disease, which may occur from one to several months after the onset, the child is blind and usually deaf, opisthotonic, irritable, and cachectic. Most patients die by the end of the first year and survival beyond 2 years is unusual, although a considerable number of cases of later onset have been reported (see below).

The EEG shows nonspecific slowing without spikes, and the CSF protein is usually elevated (70 to 450 mg/dL). CT scanning and MRI reveal symmetrical nonenhancing areas of increased density in the internal capsules and basal ganglia. As the disease advances, more of the cerebral white matter and brainstem become involved (Fig. 37-2). Neuropathy is a feature in most cases, but clinical signs may be difficult to detect except for a decrease or loss of tendon reflexes; however, there is *electromyographic (EMG) evidence of denervation and slowed motor and sensory nerve conduction velocities*, reflecting a demyelinating type of polyneuropathy.

The deficient lysosomal enzyme in Krabbe disease is *galactocerebrosidase* (also called galactosylceramide β -galactosidase, or GALC); it normally degrades galactocerebroside to ceramide and galactose. The deficiency results in the accumulation of galactocerebroside; a toxic metabolite, psychosine, leads to the early destruction of oligodendrocytes and depletion of lipids in the cerebral white matter. The globoid cell reaction, however, indicates that impaired catabolism of galactosylceramide is also important. Gross examination of the brain discloses a marked reduction in the cerebral white matter, which feels firm and rubbery. Microscopically, there is widespread myelin degeneration, absence of oligodendrocytes, and astrocytic gliosis in the cerebrum, brainstem, spinal cord, and nerves. The characteristic globoid cells are large histiocytes containing the accumulated metabolite. Schwann cells have tubular or crystalloid inclusions under electron microscopy.

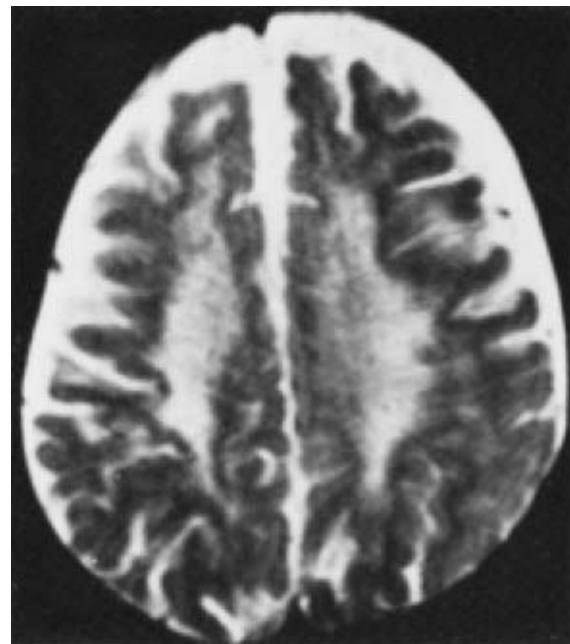

Figure 37-2. Krabbe disease. T2-weighted MRI in the axial plane demonstrating an abnormal high signal in the periventricular white matter. Arcuate fibers are spared. The patient was a 14-month-old boy with severe generalized rigidity. Diagnosis was proved postmortem (4 months after the MRI). (Reproduced by permission from Lee SH, Rao K, Zimmerman RA: *Cranial MRI and CT*, 3rd ed. New York, McGraw-Hill, 1992.)

About a dozen variants of globoid cell leukodystrophy have been reported, many of them allowing survival for years. In these, neurologic regression begins in the 2- to 6-year period. Visual failure with optic atrophy and a normal electroretinogram is an early finding. Later there is ataxia as well as spastic weakness of the legs, mental regression, and finally decerebration. In three patients observed by R. D. Adams, a progressive quadriplegia with mild pseudobulbar signs, slowly progressive impairment of memory and other mental functions, dystonic posturing of the arms, and preserved sphincteric control constituted the clinical picture. The patients were alive at ages 9, 12, and 16 years. We have observed another rare variant, beginning in adult years, with spastic quadriplegia (asymmetrical) and optic atrophy. Mentation was essentially normal and, on CT scanning and MRI, the cerebral lesion was restricted. Unlike typical Krabbe disease, these CNS abnormalities are unaccompanied by any change in the spinal fluid. The nerve conduction velocities in the late-onset form may be either normal or abnormal.

Kolodny and colleagues have reported 15 cases of even later onset (ages 4 to 73 years); pes cavus, optic pallor, progressive spastic quadriplegia, a demyelinating sensorimotor neuropathy, and symmetrical parieto-occipital white matter changes (on imaging studies) were the main features. Galactocerebrosidase levels were not as much reduced as in the infantile form; possibly these late-onset variants represent a structural mutation of the enzyme (see Farrell and Swedberg).

In this disease, as well as others described in this chapter, it has become clear that different mutations involving the same enzyme or metabolic pathway can produce strikingly different phenotypes and that there is a wide range in the age of onset in what had been considered, until relatively recently, a disease confined to infancy and early childhood.

Lipogranulomatosis (Farber Disease, Ceramidase Deficiency)

This is a rare disorder that is probably genetic, affecting both sexes and without a particular racial predilection. The onset is in the first weeks of life, with a hoarse cry due to fixation of laryngeal cartilage, respiratory distress, and sensitivity of the joints, followed by characteristic *periarticular and subcutaneous swellings and progressive arthropathy*, leading finally to ankylosis. Usually there is severe psychomotor retardation, but a few patients have appeared neurologically normal. Inanition and recurrent infections lead to death in the first 2 years. The diagnostic abnormality is a *deficiency of ceramidase*, leading to accumulation of ceramide. There is widespread lipid storage in neurons, granulomas of the skin, and accumulation of periodic acid-Schiff (PAS)-positive macrophages in periarticular and visceral tissues.

Sudanophilic Leukodystrophies and Pelizaeus-Merzbacher Disease

These are a heterogeneous group of disorders that have in common a defective myelination of the cerebrum, brainstem, cerebellum, spinal cord, and peripheral nerves. Morphologic peculiarities and genetic features separate a certain group called *Pelizaeus-Merzbacher disease*; other types have been artificially delineated; as a result, a relatively meaningless terminology has been introduced.

Pelizaeus-Merzbacher Disease This is predominantly an X-linked disease of infancy, childhood, and adolescence and includes other closely related pathologic entities with different modes of inheritance. The affected gene encodes proteolipid protein (PLP), one of the two myelin basic proteins. Koeppen and associates have offered evidence of a defective synthesis of this protein. While one group of PLP mutations causes Pelizaeus-Merzbacher disease, another set causes an infantile spastic paraparesis.

The onset of symptoms is most often in the first months of life; other cases begin later in childhood. The first signs are *abnormal movements of the eyes* (rapid, irregular, often asymmetrical pendular nystagmus), jerk nystagmus on extremes of lateral movements, upbeat nystagmus on upward gaze, and hypometric saccades (Trobe et al). There is spastic weakness of the limbs, optic atrophy (often with unexplained retention of pupillary light reflex), ataxia of limb movement and intention tremor, choreiform or athetotic movements of the arms, and slow psychomotor development with delay in sitting, standing, and walking. Seizures occur occasionally. In later-developing cases, pendular nystagmus, choreoathetosis, corticospinal signs, dysarthria, cerebellar ataxia, and mental deterioration are the major manifestations. There are milder cases of later onset with behavioral peculiarities and loss of tendon reflexes and, rarely, pure spastic paraparesis.

CT scanning and MRI confirm the extensive and symmetrical white matter involvement. In the most severe cases, Seitelberger has observed an absence of oligodendrocytes and myelinated fibers. It is hypothesized that proteolipids accumulate in the endoplasmic reticulum of the oligodendrocytes, resulting in apoptosis. Patients may survive to the second and third decades. One group of cases resembles the Cockayne syndrome (page 824), with photosensitivity of skin, dwarfism, cerebellar ataxia, corticospinal signs, cataracts, retinitis pigmentosa, and deafness. Pathologically, islands of preserved myelin impart a tigroid pattern of degenerated and

intact myelin in the cerebrum. Seitelberger has obtained pathologic verification of this lesion in cases beginning as late as adult years. *This disease and Cockayne syndrome are the only leukodystrophies in which nystagmus has been an invariable finding.*

Koeppen and Robitaille, in a current and thorough review of the subject, summarize the present-day understanding of the pathogenesis, based on misfolding of myelin proteins.

Unclassifiable Sporadic and Familial Sudanophilic Leukodystrophies There are two types of such disorder, one with early and the other with late onset. In the former, onset is before 3 months, with survival of less than 2 years; in the latter type, onset is from 3 to 7 years and the course is chronic. *Psychomotor regression; spastic paralysis; incoordination; blindness and optic atrophy; seizures (rare); severe microcephaly; and absence of skeletal, visceral, and hematologic evidence of the metabolic abnormality* are the main features. No characteristic laboratory abnormalities are known. Diffuse degeneration of myelinated fibers with phagocytosis of *sudanophilic degeneration products of myelin* (visible by MRI) and gliosis are the major changes. In two cases followed by R. D. Adams and T. Rabinowicz, a brother and sister living to adolescence, the destroyed white matter was widely cavitated.

Spongy Degeneration of Infancy (Canavan-van Bogaert-Bertrand or Canavan Disease)

This is an autosomal recessive disease described in 1931 by Canavan as a form of Schilder disease (see Chap. 36) but later categorized as a spongy degeneration of the brain by van Bogaert and Bertrand. Of 48 affected families reported by Banker and Victor, 28 were Jewish. Onset is early, usually recognizable in the first 3 months of life and sometimes in the first neonatal weeks. There is either a lack of development or rapid *regression of psychomotor function, loss of sight and optic atrophy*, lethargy, difficulty in sucking, irritability, reduced motor activity, hypotonia followed by spasticity of the limbs with corticospinal signs, and an *enlarged head* (macrocephaly). There are no visceral or skeletal abnormalities, but a variable sensorineural hearing loss has been found (Ishiyama et al). Seizures occur in some cases. An interesting but unexplored aspect of the disease is the occurrence of blond hair and light complexion in affected members, in contrast to the darker hair and complexion of their normal siblings (Banker and Victor).

The CSF is usually normal, but the protein is slightly elevated in some cases. The disease is characterized by an increased urinary excretion of *N-acetyl-L-aspartic acid (NAA)*, which may be used as a biochemical marker. It reflects the basic enzyme abnormality, a deficiency of aminocyclase II, which catalyzes the breakdown of NAA (Matalon et al). On CT scans there is *attenuation of cerebral and cerebellar white matter in an enlarged brain with relatively normal-sized ventricles*. The MRI appearance (Fig. 37-3) is that of diffuse, somewhat uneven, high signal intensity on T2-weighted images. A leukodystrophy with behavioral regression, an enlarging head, a characteristic MRI abnormality, and a marked elevation of urinary NAA should leave little doubt about the diagnosis.

The characteristic pathologic changes are an increase in brain volume (and weight), spongy degeneration in the deep layers of the cerebral cortex and subcortical white matter, widespread depletion of myelin involving the convolutional more than the central white matter, loss of Purkinje cells, and hyperplasia of Alzheimer

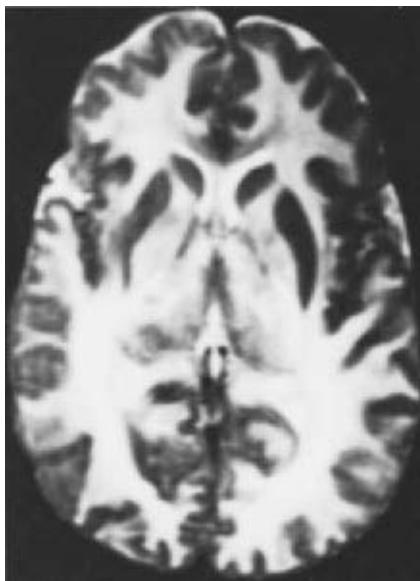

Figure 37-3. Spongy degeneration of infancy (Canavan-van Bogaert-Bertrand disease). T2-weighted axial MRI from an infant with a positive urine assay for *N*-acetyl-L-aspartic acid. The abnormal white matter appears hyperintense and extends to the cortex without sparing of the arcuate fiber. (Reproduced by permission from Lee SH, Rao K, Zimmerman RA: *Cranial MRI and CT*, 3rd ed. New York, McGraw-Hill, 1992.)

type II astrocytes throughout the cerebral cortex and basal ganglia. Adachi and coworkers have demonstrated an abnormal vacuolar accumulation of fluid in astrocytes and between split myelin lamellae; they have suggested that the loss of myelin is secondary to these changes.

The enlargement of the brain in this disease must be distinguished clinically from GM₂ gangliosidosis, Alexander disease, Krabbe disease, and nonprogressive megalcephaly and pathologically from a variety of disorders characterized by vacuolation of nervous tissue. There is no treatment.

Alexander Disease

This distinctive disease shares certain features with the leukodystrophies and also with gray matter diseases (poliodystrophies), both clinically and pathologically. The onset is in infancy with a *failure to thrive, psychomotor retardation, spasticity of the craniospinal musculature, and seizures*. An early and *progressive macrocephaly* has been a consistent feature. Alexander was the first to call attention to the enlargement of the brain, the extensive loss of cerebral white matter, and highly characteristic inclusions (the so-called Rosenthal fibers noted below) in astrocytes, and subpial and periventricular regions.

Pathologically, there are severe destructive changes in the cerebral white matter, most intense in the frontal lobes. Distinctive eosinophilic hyaline bodies, most prominent just below the pia and around blood vessels, are seen throughout the cerebral cortex, brainstem, and spinal cord. These have been identified as *Rosenthal fibers* and probably represent glial degradation products.

The astrocytic changes have been traced to a mutation in the glial fibrillary protein, according to Gorospe et al. This gene abnormality gives rise to the intermediate filament protein in astrocytes and, presumably, to the Rosenthal fiber inclusions. On the

basis of this and related gene mutations, apparent milder forms of Alexander disease have been reported in juveniles and adults. They differed clinically in lacking the cerebral leukoencephalopathy. Instead, after a long period of constipation, sleep disorder, and orthostatic hypotension during adolescence, bulbar symptoms (dysarthria, dysphonia, and dysphagia), seizures, and in some cases ataxia gradually emerged during adult years. The myelin changes and atrophy of the medulla seen in MRI were confirmed by postmortem examination and the Rosenthal fibers; GFAP fibers were present in two autopsied cases.

Stumpf and colleagues advanced the idea that the glial and GFAP changes relate the cases in the large kindred they studied to a variant of Alexander disease.

Alpers Disease This is a progressive disease of the cerebral gray matter, known also as *progressive cerebral poliodystrophy or diffuse cerebral degeneration in infancy*. A familial form (probably autosomal recessive) as well many sporadic cases has been reported. In both groups there is a certain uniformity of clinical features—loss of smile and disinterest in the surroundings, sweating attacks, *seizures and diffuse myoclonic jerks* beginning in early infancy and followed by incoordination of movements; progressive spasticity of limb, trunk, and cranial muscles; blindness and optic atrophy; growth retardation and *increasing microcephaly*; and finally virtual decortication. In some instances, the late onset of jaundice and fatty degeneration or cirrhosis of the liver have been described (Alpers-Huttenlocher syndrome); the hepatic changes are distinctive and probably not related to the use of anticonvulsant drugs, as had been hypothesized (Harding et al). By the age of 4 years, these patients are hypotonic, anemic, and thrombopenic. They also show hair changes (trichorrhexis).

The nature of this combined hepatic-cerebral degeneration remains unexplained, but some instances have been connected to the mitochondrial disorders, as noted below. EEG abnormalities, progressive atrophy (particularly occipital) on the CT scan, loss of visual evoked potentials, and abnormal liver function tests are diagnostically useful. Neuropathologic examination shows marked atrophy of the cerebral convolutions and cerebellar cortex, with loss of nerve cells and fibrous gliosis (“walnut brain”). The cerebral white matter and basal ganglia are relatively preserved. In some cases, the spongiform vacuolization of the gray matter of the brain resembles that seen in Creutzfeldt-Jakob disease. Hypoglycemic, hypoxic, and hypotensive encephalopathies must always be considered in the diagnosis but can usually be eliminated by knowledge of the clinical circumstances at the onset of the illness.

A number of biochemical abnormalities have been identified in patients with Alpers disease, including pyruvate dehydrogenase deficiency, decreased pyruvate utilization, dysfunction of the citric acid cycle, and decreased cytochromes *a* and *aa₃*. The biochemical and pathologic changes suggest a relationship to Leigh encephalomyopathy and a mitochondrial transmission. Many authoritative texts classify it with the mitochondrial diseases, but its nosologic status is in our opinion still uncertain (see Shaffner and Wallace).

Congenital Lactic Acidosis

This uncommon disease of the neonatal period or early infancy has many biochemical etiologies. The symptoms have consisted of *psychomotor regression and episodic hyperventilation, hypotonia*, and

convulsions, with intervening periods of normalcy. *Choreoathetosis* has been observed in a few cases. Death often occurs before the third year. The important laboratory findings are *acidosis with an anion gap and high serum lactate levels* and hyperalaninemia. Defects can be found in the pyruvate dehydrogenase complex of enzymes and the electron transport chain complexes, which function in the oxidative decarboxylation of pyruvate to acetyl CoA, relating the disease to defects in the mitochondrial respiratory chain enzymes. Indeed, lactic acidosis is a feature of several of the mitochondrialopathies discussed later in this chapter. Cases examined postmortem have shown necrosis and cavitation of the globus pallidus and cerebral white matter. Possibly this is a variant of Leigh disease (page 843). It must be distinguished from the several diseases of infancy that are complicated secondarily by lactic acidosis, especially the organic acidopathies. Cases of benign transient infantile lactic acidosis have been reported, but their etiology is unclear.

Cerebrohepatorenal (Zellweger) Disease (Peroxisomal Disorder)

This disease, estimated to occur once in every 100,000 births, is inherited as an autosomal recessive trait. It has its onset in the neonatal period or early infancy and as a rule leads to death within a few months. Motor inactivity and hypotonia, *dysmorphic alterations of the skull and face* (high forehead, shallow orbits, hypertelorism, high arched palate, abnormal helices of ears, retrognathia), poor visual fixation, multifocal seizures, swallowing difficulties, fixed flexion posture of the limbs, cataracts, abnormal retinal pigmentation, optic atrophy, cloudy corneas, hepatomegaly, and hepatic dysfunction are the usual manifestations. *Stippled, irregular calcifications of the patellae and greater trochanters are highly characteristic.* Pathologically, there is dysgenesis of the cerebral cortex and degeneration of white matter as well as a number of visceral abnormalities—cortical renal cysts, hepatic fibrosis, intrahepatic biliary dysgenesis, agenesis of the thymus, and iron storage in the reticuloendothelial system.

As to the biochemical abnormality, A. B. Moser and coworkers have demonstrated a fivefold increase of very-long-chain fatty acids, particularly hexacosanoic acid, in the plasma and cultured skin fibroblasts from 35 patients with Zellweger disease. A similar abnormality was found in cultured amniocytes of women at risk of bearing a child with Zellweger disease, thus permitting prenatal diagnosis. The findings of Moser and colleagues are in keeping with current notions about the basic abnormality in Zellweger syndrome—namely, that it is due to a lack of liver peroxisomes (oxidase-containing, membrane-bound cytoplasmic organelles), in which the very-long-chain fatty acids are normally oxidized (Goldfischer et al).

Currently, a spectrum of at least 12 disorders of peroxisomal function is recognized, all of them characterized by deficiencies in the peroxisomal enzyme of fatty-acid oxidation—a veritable peroxisomal assembly. The most widely recognized are neonatal adrenoleukodystrophy and infantile Refsum disease, but the Zellweger cerebrohepatorenal syndrome can be considered the prototype. Each variant can be identified by its characteristic profile of elevated long- and very-long-chain fatty acids, and the specific diagnosis can be confirmed by enzymology of cultured fibroblasts or amniocytes. Several of them become manifest at a later age and are discussed further on. For an authoritative discussion of peroxisomal biogenesis, the reader is referred to the article by Gould and Valle.

The Oculocerebrorenal (Lowe) Syndrome

Here the mode of inheritance is probably X-linked recessive, although sporadic cases have been reported in girls. The abnormal gene is located on chromosome Xq25.26. The clinical abnormalities comprise *bilateral cataracts* (which may be present at birth), glaucoma, large eyes with megalocornea and buphthalmos, corneal opacities and blindness, pendular nystagmus, hypotonia and absent or depressed tendon reflexes, corticospinal signs without paralysis, slow movements of the hands, tantrums and aggressive behavior, high-pitched cry, occasional seizures, and psychomotor regression. Later the frontal bones become prominent and the eyes sunken. The characteristic biochemical abnormality is a *renal tubular acidosis*, and death is usually from *renal failure*. Additional laboratory findings include demineralization of bones and typical rachitic deformities, anemia, metabolic acidosis, and generalized aminoaciduria. The neuropathologic changes are nonspecific; inconstant atrophy and poor myelination have been described in the brain and tubular abnormalities in the kidneys. The primary genetic defects are in the gene encoding inositol polyphosphate phosphatase of the Golgi complex. The main diagnostic distinction is from Zellweger disease. Treatment programs include anticonvulsant medication, correction of electrolyte disorders, and removal of cataracts.

Menkes Disease (Kinky- or Steely-Hair Disease; Trichopoliodystrophy)

This is a rare disorder, inherited as a sex-linked recessive trait. In most of the cases known to us, birth was premature. Poor feeding and failure to gain weight, instability of temperature (mainly *hypothermia*), and seizures become apparent in early infancy. The hair is normal at birth, but the secondary growth is lusterless and depigmented and feels like steel wool; hairs break easily and under the microscope they appear twisted (*pili torti*). Radiologic examination shows *metaphysial spurring*, mainly of the femurs, and subperiosteal calcifications of the bone shafts. Arteriography discloses *tortuosity and elongation of the cerebral and systemic arteries* and occlusion of some. The combination of intracerebral hemorrhage and metaphysial bone spurs, which may be interpreted as “corner fractures,” has led in some cases to the erroneous diagnosis of child abuse. There is no discernible neurologic development, and rarely does the untreated child survive beyond the second year. Treated with copper histidine, patients may survive to adolescence, but they remain profoundly impaired and hypotonic and require gastric feeding; the seizures may abate. Three of our cases have been examined postmortem (Williams et al). There was a diffuse loss of neurons in the relay nuclei of the thalamus, the cerebral cortex, and the cerebellum (granule and stellate cells) and of dendritic arborizations of residual neurons of the motor cortex and Purkinje cells.

The manifestations of this disease are attributable to a deficiency of several copper-dependent enzymes, including cytochrome oxidase, resulting in a *failure of absorption of copper from the gastrointestinal tract* and a profound deficiency of tissue copper (Danks et al). Further, since copper fails to cross the placenta, a severe reduction of copper in the brain and liver is evident from birth. In this sense, the abnormality of copper metabolism is the opposite of that in Wilson disease. A relationship between Wilson and Menke disease is nonetheless evident at a genetic level since they arise from genes encoding two different copper-transporting proteins that are both ATPases. Parenteral administration of cupric

salts restores the serum and hepatic copper but does not materially influence the neurologic symptoms, as noted above.

Diagnosis of Inherited Metabolic Diseases of Infancy

It will be recognized from the foregoing synopses that many of the neurologic manifestations of the inherited metabolic diseases of infancy are nonspecific and are common to most or all of the diseases in this group. In general, in the early stages of all these diseases, there is a loss of postural tone and a paucity of movement without paralysis or loss of reflexes; later there is spasticity with hyperreflexia and Babinski signs. Equally nonspecific are features such as irritability and prolonged crying; poor feeding, difficulty in swallowing, inanition, and retarded growth; failure of fixation of gaze and following movements of the eyes (often misinterpreted as blindness); and tonic spasms, clonic jerks, and focal and generalized seizures.

The differentiation of the inherited metabolic diseases of in-

fancy rests essentially upon four types of data: (1) a few highly characteristic neurologic and ophthalmic signs; (2) the presence of an enlarged liver and/or spleen; (3) special dysmorphic features of the face; and (4) the results of several relatively simple laboratory tests, such as radiographs of the thoracolumbar spine, hips, and long bones; smears of the peripheral blood and bone marrow; CSF examination; and certain urinary tests and other biochemical estimations (serum lactate, glucose, ammonia, and urinary ketones, amino acids, and organic acids). For purposes of differential diagnosis, we have found the flowcharts constructed by our colleague E. Kolodny to be most serviceable. One such schematic, illustrated in Fig. 37-4, is based on the subdivision of patients into three groups: (1) dysmorphic, (2) visceromegalic, and (3) purely neurologic. Only rarely does an inherited metabolic disease fall into more than one of these categories. There is also considerable value in beginning the diagnostic process by classifying the syndrome as a leukodystrophy or a poliodystrophy (disease predominantly affecting neurons, see further on), although this distinction is easier to make in the older child.

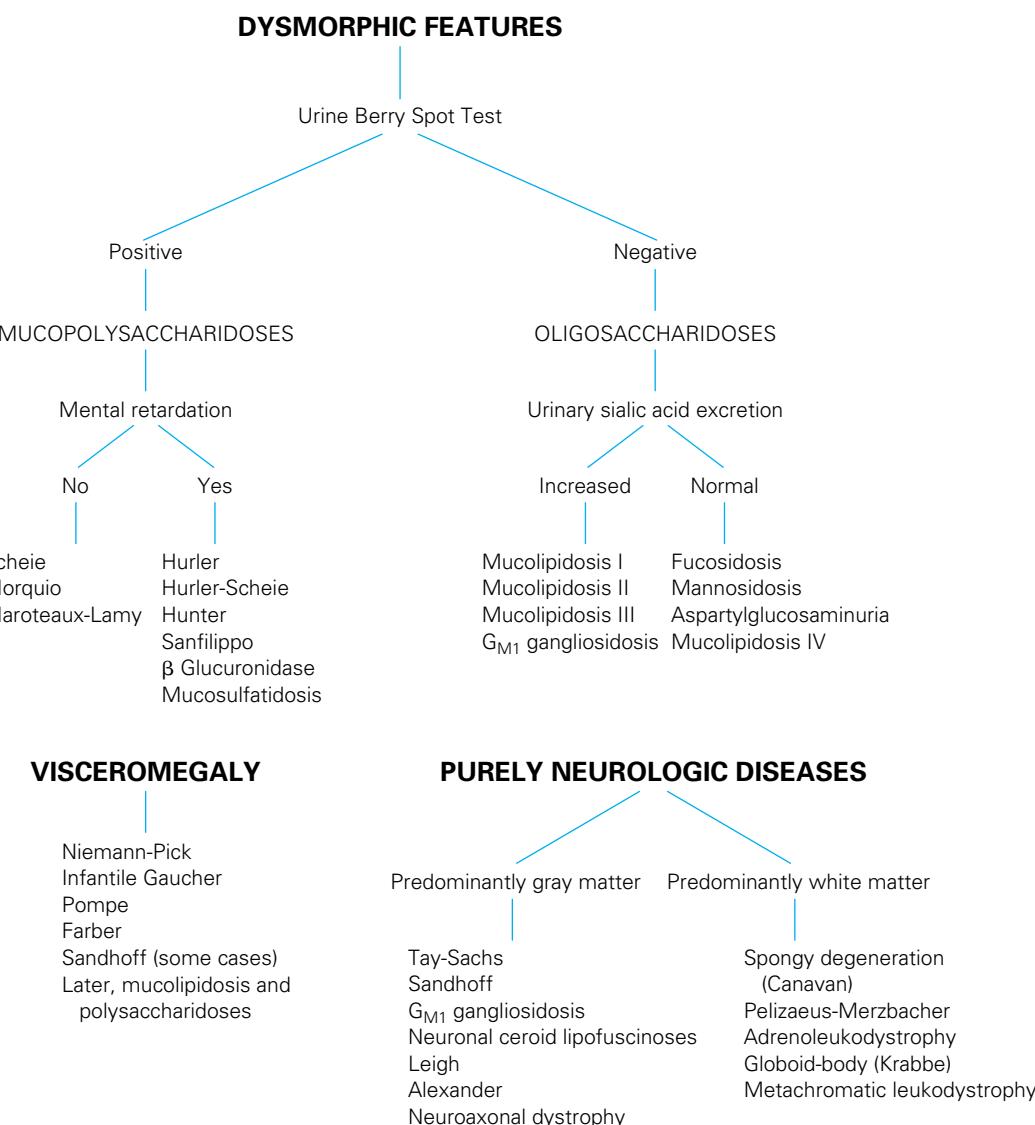

Figure 37-4. A schematic for diagnosis of the inherited metabolic diseases of infancy. (Courtesy of Dr. Edwin Kolodny.)

Once the patient is placed in one of these major categories, correct diagnosis then depends on the recognition of particular clinical and laboratory features, tabulated below (see also Tables 37-5 and 37-6).

Neurologic signs that are more or less specific for certain metabolic diseases are as follows:

1. Acousticomotor obligatory startle: Tay-Sachs disease
2. Abolished tendon reflexes with definite Babinski signs: globoid cell (Krabbe) leukodystrophy, occasionally Leigh disease, and (beyond infancy) metachromatic leukodystrophy
3. Peculiar eye movements, pendular nystagmus, and head rolling: Pelizaeus-Merzbacher disease, Leigh disease; later, hyperbilirubinemia and Lesch-Nyhan hyperuricemia (see below)
4. Marked rigidity, opisthotonus, and tonic spasms: Krabbe,

- Alpers disease, or infantile Gaucher disease (classic triad: trismus, strabismus, opisthotonus)
5. Intractable seizures and generalized or multifocal myoclonus: Alpers disease
6. Intermittent hyperventilation: Leigh disease and congenital lactic acidosis (also nonprogressive familial agenesis of vermis)
7. Strabismus, hypotonia, seizures, lipodystrophy: carbohydrate-deficient glycoprotein syndrome

Ocular abnormalities of specific diagnostic value in this age group are as follows:

1. Rapid pendular nystagmus: Pelizaeus-Merzbacher disease, rarely Krabbe leukodystrophy, Cockayne syndrome (later age)

Table 37-5
Differential diagnosis of poliodystrophies of infancy

	TAY-SACHS	NIEMANN-PICK	GAUCHER	ALPERS	SUBACUTE NECROTIZING ENCEPHALOPATHY
<i>Age of onset</i>	4–6 months	Under 6 months	Under 6 months	Under 1 year	Under 1 year, rarely late childhood

2. Macular cherry-red spots: Tay-Sachs disease and Sandhoff variant, some cases of infantile Niemann-Pick disease, and rarely lipofuscinosis (see Table 37-4)
3. Corneal opacification: Lowe disease, infantile GM₁ gangliosidosis; later, the mucopolysaccharidoses
4. Cataracts: galactosemia, Lowe disease, Zellweger disease (also congenital rubella)

Several other medical findings are of specific diagnostic value:

1. Dysmorphic facies: generalized GM₁ gangliosidosis, Lowe and Zellweger syndromes, and some early cases of mucopolysaccharidosis and mucolipidoses

2. Enlarged liver and spleen: infantile Gaucher disease and Niemann-Pick disease; one type of hyperammonemia; Sandhoff disease; later, the mucopolysaccharidoses and mucolipidoses
3. Enlarging head without hydrocephalus (macrocephaly): Canavan spongy degeneration of infancy, some cases of Tay-Sachs disease, Alexander disease
4. Beaking of vertebral bodies in radiographs: GM₁ gangliosidosis (and, at a more advanced age, the mucopolysaccharidoses, fucosidosis, mannosidosis, and the mucolipidoses)
5. Multiple arthropathies and raucous dysphonia: Farber disease
6. Storage granules and vacuolated lymphocytes: Niemann-Pick disease, generalized GM₁ gangliosidosis

7. Abnormal histiocytes in marrow smears: Gaucher cells, foamy histiocytes in Niemann-Pick disease, generalized GM₁ gangliosidosis and closely related diseases, Farber disease
8. Colorless, friable hair: Menkes disease

INHERITED METABOLIC DISEASES OF EARLY CHILDHOOD

Included here are the diseases that become manifest between the ages of 1 and about 4 years. Diagnosis is less difficult than in the neonate and young infant. A pathologic process in the nervous system is reliably ascertained by the obvious progression of a neurologic disorder, such as a loss of ability to walk and to speak, which usually parallels a regression in other high-level (quasi-intellectual) functions. Embryologic anomalies, prenatal diseases, and birth injuries can be excluded with relative certainty if psychomotor development was normal in the first year or two. Diseases characterized by seizures and myoclonus may prove more difficult to interpret, for the seizures may occur at any age from a variety of distant or immediate neurologic causes and, if frequent, may cause a significant impairment of psychomotor function. The effects of anticonvulsant medications may add to the impairment of cortical function. Unfortunately, most of the slowly advancing metabolic diseases of the second year may be so subtle in their effects that for a time the physician cannot be sure whether a regression of intellectual functions is taking place or mental retardation or autism is becoming apparent for the first time. An added difficulty arises when, for a number of years, the hereditary metabolic abnormality merely slows development. To distinguish metabolic disease from developmental retardation is more difficult if the parents have been unobservant. Repeated examinations and testing will usually settle the matter. Suspicion of a progressive encephalopathy is heightened by the presence of certain ocular, visceral, and skeletal abnormalities, as described below.

Once a neurologic syndrome is clearly established, there is a particular advantage in determining whether its main characteristics reflect a disorder of the cerebral white matter (oligodendrocytes and myelin) or of gray matter (neurons). Indicative of predominantly white matter affection (*leukodystrophy* or leukoencephalopathy) are early onset of spastic paralysis of the limbs, with or without ataxia, and visual impairment with optic atrophy but normal retinae. Seizures and intellectual deterioration are late events. MRI usually confirms the involvement of white matter. Indicative of gray matter disease (*poliodystrophy* or *polioencephalopathy*) are the early onset of seizures, myoclonus, blindness with retinal changes, and mental regression. Choreoathetosis and ataxia, spastic paralysis, and signs of sensorimotor tract involvement occur later. On MRI, only a generalized atrophy and ventricular enlargement may be seen.

Neuronal storage diseases, such as those described in the previous section, as well as neuroaxonal dystrophy and the lipofuscinoses, conform to the pattern of gray matter diseases (Table 37-5). Metachromatic globoid-body (Krabbe) disease, sudanophilic leukodystrophy, and spongy degeneration of infancy (Canavan disease) exemplify white matter diseases (Table 37-6). Although this mode of categorization is helpful, there is some degree of overlap; for example, Tay-Sachs disease, a poliodystrophy, also causes white matter changes, and metachromatic leukodystrophy may be accompanied by some degree of neuronal storage.

The following are inherited metabolic diseases that become evident clinically in late infancy and early childhood:

1. Many of the milder disorders of amino acid metabolism
2. Metachromatic and other leukodystrophies
3. Late infantile GM₁ gangliosidosis
4. Late infantile Gaucher disease and Niemann-Pick disease
5. Neuroaxonal dystrophy
6. The mucopolysaccharidoses
7. The mucolipidoses
8. Fucosidosis
9. The mannosidoses
10. Aspartylglycosaminuria
11. Ceroid lipofuscinosis (Jansky-Bielschowsky disease)
12. Cockayne syndrome

The Aminoacidopathies (Aminoacidurias)

In a group of 48 inherited aminoacidopathies tabulated by Rosenberg and Scriver, at least one-half were associated with recognizable neurologic abnormalities. Twenty other aminoacidopathies result in a defect in the renal transport of amino acids, some of which secondarily damage the nervous system. Usually, when the nervous system is involved, the only clinical manifestation is simply a lag in psychomotor development, which, if mild, does not become apparent until the second and third years or later. Like other inherited metabolic disorders, the aminoacidurias do not impair growth, development, or maturation in utero or interfere with parturition. (This is the result of the maternal blood supply, which defines the amino acid balance in utero.) No physical sign betrays their presence in the early months of life. The only possible means of detection is by the screening of all newborns. The relative frequency of these diseases is indicated in Table 37-1, and the practical tests for their identification are summarized in Table 37-2.

Three aminoacidopathies of the late infantile and early childhood period—phenylketonuria (PKU), tyrosinemia, and Hartnup disease—are described here because of their clinical importance and because they exemplify different types of biochemical defect. Reference is also made to certain other aminoacidurias, described in the first part of this chapter, which, like Hartnup disease, are associated with intermittent ataxia. Only passing comments are made about the other aminoacidurias, which are exceedingly rare or have only an uncertain effect on the nervous system. A detailed and relatively current account of these disorders can be found in the monograph of Scriver and coworkers.

The Phenylketonurias (PKU, Phenylalanine Hydroxylase Deficiency) Apart from being the most frequent of the aminoacidurias, this entity has a special historical significance. Since its discovery by Følling in 1934, it has remained the classic example of an aminoaciduria and illustrates three principles of medical genetics: first, it is inherited as an autosomal recessive trait; second, it exemplifies Garrod's cardinal principle of gene action, in which genetic factors specify chemical reactions as well as biochemical individuality; third, PKU is expressed only in an environment that contains an abundance of L-phenylalanine. Thus, as predicted by Galton, the ultimate phenotype is a product of "nature and nurture" (Scriver and Clow).

One must refer to the phenylketonurias in the plural, for there are (1) the usual type and several mild and severe variants thereof,

in all of which mental retardation is invariable if the disease is not treated early in life, (2) other types, presumably allelic mutations, in which there is hyperphenylalaninemia without PKU and without effect on the nervous system, and (3) a rare adult type with a progressive spastic paraparesis or without neurologic manifestations. Also there are a small number of patients (3 percent in our series) in whom a lowering of the hyperphenylalaninemia does not prevent the progression of the neurologic lesion.

At birth, the typical PKU infant is believed to have a normal nervous system. The disease appears later, only after long exposure of the nervous system to phenylalanine (PA), because the homozygous infant lacks the means of protecting the nervous system. However, if the mother is homozygous with high PA levels in the blood during pregnancy, the CNS is damaged in utero and the heterozygous infant is mentally defective from birth.

In the classic form of PKU, the *impairment of psychomotor development* can usually be recognized in the latter part of the first year, when expected performance lags. By 5 to 6 years in an untreated child, when the IQ can be estimated, it is usually less than 20, occasionally 20 to 50, and exceptionally above 50. *Hyperactivity*, aggressivity, self-injurious behavior—including severe injury to the eyes, clumsy gait, fine tremor of the hands, poor coordination, odd posturings, *repetitious digital mannerisms* and other so-called rhythmias, and slight corticospinal tract signs stand out as the main clinical manifestations. Athetosis, dystonia, and frank cerebellar ataxia have been described but must be exceedingly rare. Also, seizures are said to occur in 25 percent of severely retarded patients, taking the form at first of flexor spasms and later of absence and grand mal attacks. However, of more than 30 of PKU patients at the Fernald School, a number of which we have followed clinically, none had seizures or extrapyramidal signs. The majority are blue-eyed and fair in skin and hair color, and their skin is rough and dry and subject to eczema. A musty body odor (due to phenylacetic acid excretion) can often be detected. Two-thirds are slightly microcephalic. The fundi are normal, and there is no visceral enlargement or skeletal abnormality.

There are individuals living in the community with asymptomatic PKU and normal intelligence. Instances of PKU in which the symptoms are of adult onset are rare but of interest because of the entirely unexpected diagnosis. The few such cases reported and summarized by Kassim and colleagues, with a case of their own, have developed a progressive spastic paraparesis, some with mild dementia. The phenylalanine levels have been at values that reflect total or partial enzyme deficiency.

The finding of *high levels of serum phenylalanine* (above 15 mg/dL) and of *phenylpyruvic acid in the blood, CSF, and urine* are diagnostic of PKU. The level is normal at birth and rises only after the first few days. But screening by the Guthrie (ferric chloride) test will reliably identify the patient at risk. The addition of 3 to 5 drops of 10% ferric chloride to 1 mL of urine is a simple and informative test. It yields an emerald-green color that reaches a peak intensity in 3 to 4 min and fades in 20 to 40 min. In contrast, the green-brown color in the urine of patients with histidinemia is permanent. In maple syrup urine disease, the ferric chloride test gives a navy-blue color; propionic and methylmalonic acidemia and either ketones or salicylates in the urine yield a purple color.

The fundamental biochemical abnormality is a deficiency of the hepatic enzyme PA hydroxylase; the failure of conversion of PA to tyrosine results in the excretion of phenylpyruvic acid by affected individuals. The precise step that is faulty in the complex phenylalanine hydroxylating reaction is still unknown.

Pathologic examination shows poor staining of myelin in the cerebral hemispheres. This can be visualized by MRI in untreated children. Another curious feature is that the usually pigmented nuclei (substantia nigra, locus ceruleus, dorsal vagal motor) fail to acquire dark coloration because of a block in the production of melanin. Reduction in size of cortical neurons and their dendritic arborizations is said to be demonstrable in some cases.

Treatment If instituted in infancy, diets low but not totally lacking in PA can improve intellectual development (blood level should be maintained at 5 to 10 mg/dL). Once the neurologic picture unfolds, diet has little or no effect on the mental status but may improve behavior. Prolonged dietary treatment has many untoward effects and should be supervised by physicians and nutritionists experienced in its use; if too restricted, it may retard growth. This is particularly important, since it has been shown that intellectual impairment is greatest among children who were the earliest to abandon their diets, permitting the PA concentration to rise above 15 mg/dL, and least in children who maintained dietary control the longest (Holtzman et al). Continued dietary treatment is necessary. With the widespread screening for PKU and the initiation of dietary control during early postnatal life, this metabolic brain disease has virtually disappeared in the New England states. Treated women who reach childbearing age should be particularly careful about dietary restriction, since high levels of phenylalanine are harmful to the normal fetus. Mild cases of PKU have been successfully treated with the cofactor tetrahydrobiopterin (Muntau et al).

The late forms of maple syrup urine disease, histidinemia, and hydroxyprolinemia evolve in much the same fashion as PKU and raise similar problems in diagnosis and therapy.

A small number of infants have a variant of PKU in which a restricted PA diet does not prevent neurologic involvement. In some such infants, a dystonic extrapyramidal rigidity ("stiff-baby syndrome") has appeared as early as the neonatal period, and, according to Allen and coworkers, it responds to biopterin. Such infants have normal levels of PA hydroxylase in the liver. The defect is a failure to synthesize the active cofactor tetrahydrobiopterin, because of either an insufficiency of dihydropteridine reductase or an inability to synthesize biopterin (see page 801). The urinary metabolites of catecholamines and serotonin are reduced and are not responsive to low-PA diets. There is some evidence that the underlying neurotransmitter fault can be corrected by L-dopa and by 5-hydroxytryptophan (Scriver and Clow).

Heredity Tyrosinemia (Oculocutaneous Tyrosinemia; Richner-Hanhart Disease) This is a rare, predominantly dermatologic aminoacidopathy, but in approximately one-half of the infants there is a mild to moderate degree of mental retardation. Also, as in some other aminoacidopathies, there may be self-mutilation and incoordination of limb movements. Language defects are prominent. Toward the end of the first or second year of life, lacrimation, photophobia, and redness of the eyes (due to corneal erosions) appear. Neovascularization of the corneas and opacification follow. Palmar and plantar keratosis with hyperhidrosis and pain are frequently present as a result of an inflammatory reaction to deposits of crystalline tyrosine (also the cause of the corneal changes). Elevated tyrosine in the blood ($>0.18 \text{ mM}$) and urine are diagnostic. The disease is due to a gene defect on chromosome 15 that codes for the enzyme fumarylacetoacetate hydrolase, a deficiency of which results in the accumulation of tyrosine and its metabolites.

A low-tyrosine and low-PA diet, optimized to allow growth

and development, has resulted in rapid amelioration of symptoms but must be started early. Retinoids given orally improve the skin lesions. Neonatal tyrosinemia can cause liver failure and early death. This disease can be distinguished from the Cross syndrome (albinism with mental retardation, growth impairment, spastic weakness, and alkalosis) and from the Waardenberg ocular albinism syndrome (white forelock, hypertelorism, deafness). For a detailed discussion of the albinism syndromes, see the article by Oetting and King.

Tyrosine Hydroxylase Deficiency This relatively recently described disease causes a progressive infantile encephalopathy; it is of special interest because tyrosine is the precursor of L-dopa and the other catecholamines. Levels of these chemical substances in the brain are greatly reduced. As a result, the encephalopathy takes the form mainly of fluctuating extrapyramidal signs in combination with ocular and vegetative symptoms. L-Dopa causes some improvement in the motor symptoms (see Hoffmann et al). This disease has implications for juvenile dopa-responsive dystonia, which is exquisitely sensitive to L-dopa treatment (as discussed on page 930) and is contrasted with the deficiency of L-amino decarboxylase, described above, which also causes low levels of catecholamines and a movement disorder.

Hartnup Disease This amino acid disorder, named after the family in which it was first observed, is probably transmitted in an autosomal recessive pattern. Women carrying this trait deliver babies who are normal at birth. The onset of symptoms is in late infancy or early childhood. The clinical features consist of an *intermittent red, scaly rash over the face, neck, hands, and legs*, resembling that of pellagra. It is often combined with an episodic personality disorder in the form of *emotional lability*, uncontrolled temper, and confusional-hallucinatory psychosis; *episodic cerebellar ataxia* (unsteady gait, intention tremor, and dysarthria); and occasionally spasticity, vertigo, nystagmus, ptosis, and diplopia. Attacks of disease are triggered by exposure to sunlight, emotional stress, and sulfonamide drugs and last for about 2 weeks, followed by variable periods of relative normalcy. The frequency of attacks diminishes with maturation, but some children suffer retarded growth and development with a mild persistent mental retardation.

The metabolic faults are due to a transport error of neutral amino acids across renal tubules, with excretion of greatly increased amounts of these amino acids in the urine and feces. In particular, there is the excretion of large amounts of indicans, mainly indoxyl sulfate, particularly after oral L-tryptophan loading, and an abnormally high excretion of nonhydroxylated indole metabolites. Impaired intestinal transport of tryptophan and loss in the urine reduces its availability for the synthesis of niacin and accounts for the pellagrous skin changes. The pathologic basis of the disease is undetermined. It must be differentiated from the large number of intermittent and progressive cerebellar ataxias of childhood, described below.

Treatment consists of avoiding exposure to sunlight and to sulfonamide drugs. Because of the similarities between pellagra and Hartnup disease, the usual practice is to give nicotinamide in doses of 50 to 300 mg daily. The skin lesions disappear and there are reports of subsidence of ataxia and psychotic behavior. However, the results of treatment are inconsistent. Possibly a better response is obtained by the administration of L-tryptophan ethyl ester in doses of 20 mg/kg thrice daily.

Other Metabolic Diseases with Episodic or Persistent Ataxia, Seizures, and Mental Retardation In addition to Hartnup disease, a number of other metabolic diseases give rise to intermittent episodes of ataxia during early childhood. These are (1) mild forms of maple syrup urine disease and the congenital hyperammonemias (type II hyperammonemia, citrullinemia, argininosuccinic aciduria, hyperornithinemia), described in an earlier part of the chapter; (2) necrotizing encephalomyopathy (Leigh disease), described further on; (3) hyperalaninemia and hyperpyruvic acidemia (Lonsdale et al, Blass et al); and (4) autosomal dominant, acetazolamide-responsive ataxia that may have its onset in childhood but usually appears later (page 827).

In all these conditions the ataxia, which is of cerebellar type, is highly variable from time to time and may follow a burst of seizures (such as occur in argininosuccinic aciduria). The seizures are treated with anticonvulsant drugs, which may at first be held responsible for the ataxia. In time, however, it becomes apparent that the ataxia lasts a week or two and bears no relation to the anticonvulsant therapy. Indeed, seizures and ataxia are both due to the common biochemical abnormality. Between attacks, in all the intermittent ataxias, the patient's movements are relatively normal, but most of the affected children are slow in learning and remain backward mentally to a varying degree.

The Problem of Progressive Cerebellar Ataxia of Early Childhood

The differentiation of the childhood ataxias is difficult. The problem is twofold—first, to be certain that ataxia exists, and, second, to differentiate cerebellar ataxia from the sensory ataxia of peripheral nerve disease and from generalized tremor and polymyoclonus. Since cerebellar ataxia is more a disorder of voluntary than of postural movements, its presence usually cannot be determined with certainty until intentional (projected) movements become part of the child's repertoire of motor activity. As indicated in Chap. 28, the earliest signs become manifest in the arms when the infant reaches for an object and brings it to his mouth or transfers it from hand to hand. A jerky, wavering, tremulous movement then appears; in sitting, a titubation of the head and a tremor of the trunk may be apparent. Once walking begins, apart from the usual clumsiness of the toddler, there is a similar incoordination of movement. Sensory ataxia is always difficult to distinguish but is rare at this age and usually accompanied by weakness and absence of tendon reflexes. By the fourth or fifth year, when more detailed sensory testing becomes possible, the presence or absence of a proprioceptive disturbance and a Romberg sign can be demonstrated.

The group of persistent and progressive cerebellar ataxias is heterogeneous and of varied etiology; some of them merge with Friedreich ataxia, Levy-Roussy neuropathy, and other adolescent-adult degenerative hereditary ataxias. These disorders are discussed in Chap. 39 on degenerative diseases, since, apart from their hereditary nature, neither their cause nor their pathogenesis is known. There are many other childhood ataxias that probably belong in the category of degenerative disease, some in which cerebellar ataxia is the most prominent disorder and in which other neurologic abnormalities are more prominent. To describe each in detail would be impractical in a book on the principles of neurology; therefore, the non-Friedreich ataxias are only tabulated here.

1. The disequilibrium and dyssynergia syndrome of Hagberg

and Janner: early-life onset of relatively pure cerebellar ataxia, with psychomotor retardation.

2. Cerebellar ataxia with diplegia, hypotonia, and mental retardation (also called *ataxic diplegia* of Foerster); this is either a fetal disease or birth (cerebral palsy).
3. Agenesis of the cerebellum: early cerebellar ataxia (with or without mental retardation) and episodic hyperventilation (Norman's family with granule-cell degeneration falls into this category).
4. Cerebellar ataxia with cataracts and oligophrenia: onset from childhood (mainly) to as late as adult years (Marinesco-Sjögren disease).
5. Familial cerebellar ataxia and retinal degeneration (Behr).
6. Familial cerebellar ataxia with cataracts and ophthalmoplegia or with cataracts and mental as well as physical retardation.
7. Familial cerebellar ataxia with mydriasis.
8. Familial cerebellar ataxia with deafness and blindness and a similar combination, called retinocochleodentate degeneration, involving the loss of neurons in these three structures.
9. Familial cerebellar ataxia with choreoathetosis, corticospinal tract signs, and mental and motor retardation.

In none of the syndromes mentioned above has a biochemical abnormality been established, so their metabolic nature is a matter of speculation. However, disorders of the electron transport chain can, on occasion, present as the Marinesco-Sjögren phenotype, mentioned above.

The persistent cerebellar ataxias of childhood in which a metabolic fault or gene defect has been demonstrated are as follows:

1. Refsum disease
2. Abetalipoproteinemia (Bassen-Kornzweig syndrome)
3. Ataxia-telangiectasia
4. Galactosemia
5. Possibly Friedreich ataxia

Refsum disease is discussed with the hereditary polyneuropathies (page 1157).

The Bassen-Kornzweig syndrome has its onset more often in late than in early childhood and is more appropriately described in the following section of this chapter. Ataxia-telangiectasia is described below. Galactosemia has been described on page 802 and Friedreich ataxia on page 949. Generally, it is not difficult to differentiate these diseases from the acquired postinfectious variety that occurs predominantly in children.

Ataxia-Telangiectasia This disease, sometimes referred to as the *Louis-Bar syndrome*, was first described by Sylaba and Henner in 1926, long before Louis-Bar's report in 1941. It combines a progressive ataxia with humoral immune deficiency and telangiectasias. Like xeroderma pigmentosum and the Cockayne syndrome, ataxia-telangiectasia has been attributed to defective repair of DNA. The inheritance pattern is autosomal recessive.

The disorder first presents as an ataxic-dyskinetic syndrome in children who appear to have been normal in the first few years of life. The onset of the disease coincides more or less with the acquisition of walking, which is awkward and unsteady. Later, by the age of 4 to 5 years, the limbs become ataxic, and choreoathetosis, grimacing, and dysarthric speech are added. The eye movements become jerky, with slow and long-latency saccades, and there is also apraxia for voluntary gaze (the patient turns the head

but not the eyes on attempting to look to the side). Optokinetic nystagmus is lost. By the age of 9 to 10 years, slight intellectual decline sets in and signs of mild polyneuropathy are evident. Muscle power is reduced little if at all until late in the illness, but tendon reflexes may disappear. The characteristic telangiectatic lesions, which are mainly transversely oriented subpapillary venous plexuses, appear at 3 to 5 years of age or later and are most apparent in the outer parts of the bulbar conjunctivae (Fig. 37-5), over the ears, on exposed parts of the neck, on the bridge of the nose and cheeks in a butterfly pattern, and in the flexor creases of the forearms. Vitiligo, café-au-lait spots, loss of subcutaneous fat, and premature graying of hair are observed in some patients. Many of the patients have endocrine alterations (absence of secondary sexual development, glucose intolerance). The disease is progressive, and death usually occurs in the second decade from intercurrent bronchopulmonary infection or neoplasia—usually lymphoma, less often glioma (Boder and Sedgwick).

The significant abnormalities in the CNS are severe degeneration in the cerebellar cortex (visible in MRI scans); loss of myelinated fibers in the posterior columns, spinocerebellar tracts, and peripheral nerves; degenerative changes in the posterior roots and cells of the sympathetic ganglia; and loss of anterior horn cells at all levels of the spinal cord. In a few cases, vascular abnormalities, like the mucocutaneous ones, have been found scattered diffusely in the white matter of the brain and spinal cord, but they are of questionable significance. Also, there may be a loss of pigmented cells in the substantia nigra and locus ceruleus (a feature shared with PKU), and cytoplasmic inclusions (Lewy bodies) in the cells that remain (Agamanolis and Greenstein). During early development there are abnormalities of Purkinje cell migration and variations in nuclear size. Intracellular inclusions and bizarre nuclear formations have also been found in the satellite cells (amphicytes) of dorsal root ganglion neurons (Strich).

There is an absence or decrease in several immunoglobulins—IgA, IgE and isotypes, IgG₂, IgG₄—in practically every patient.

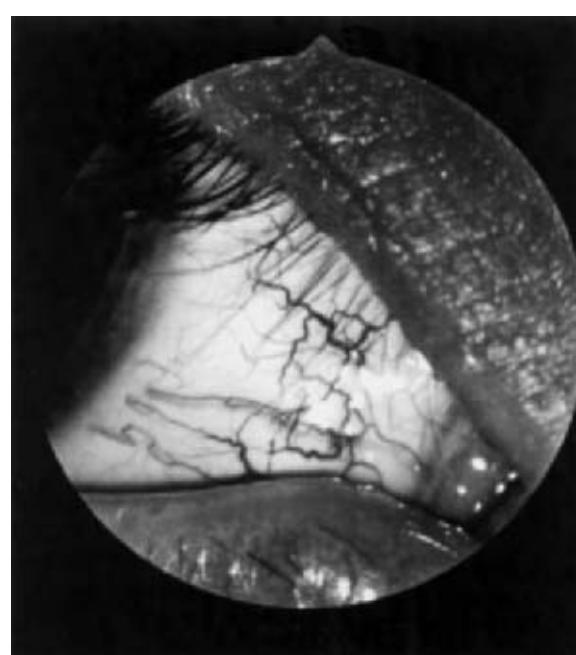

Figure 37-5. Ocular appearance of ataxia-telangiectasia. (Reproduced by permission from Lyon et al.)

These deficiencies, shown by McFarlin and associates to be due to decreased synthesis, are associated with hypoplasia of the thymus, loss of follicles in lymph nodes, failure of delayed hypersensitivity reactions, lymphopenia, and slow formation of circulating antibodies. Probably this immunodeficient state accounts for the striking susceptibility of these patients to recurrent pulmonary infections and bronchiectasis. Transplantation of normal thymus tissue into the patient and administration of thymus extracts have been of no therapeutic value.

The defective gene (designated ATM) is a kinase that mediates DNA repair by halting the cell cycle after DNA damage. For this reason, there is faulty repair of DNA after radiation and a greatly increased risk of lymphomas, leukemias, and other tumors.

The only therapy centers on the control of infections. Free radical scavengers such as vitamin E have been recommended without proof of their effectiveness. Because of radiation sensitivity, even conventional diagnostic tests (dental, chest x-ray) should be avoided unless there is a compelling reason for them.

Metachromatic Leukodystrophy (MLD, Arylsulfatase Deficiency)

This is another of the lysosomal (sphingolipid) storage diseases (Table 37-3). The basic abnormality, localized in chromosome 22, is the absence of the gene for enzyme arylsulfatase A, a deficiency of which prevents the conversion of sulfatide to cerebroside (a major component of myelin) and results in an accumulation of the former. The disease is transmitted as an autosomal recessive trait and usually becomes manifest between the first and fourth years of life (variants have their onset in the congenital period, in late childhood, and even in adult life). Variability of gene mutation accounts for the different forms. The so-called "O" type mutation causes a lack of active gene product and of the corresponding enzyme; the "R" type mutation results in low levels. The infantile form is associated with two copies of the O gene, the juvenile form, with either O or R, and the adult form is usually from two copies of R. Another genetic classification system denominates "I" and "A" alleles and differentiates the types of disease by age of onset and residual enzyme activity.

The disease in this age group is characterized clinically by progressive impairment of motor function (gait disorder, spasticity) in combination with reduced output of speech and mental regression. At first the tendon reflexes are usually brisk, but later, as the peripheral nerves become more involved, the tendon reflexes are decreased and eventually lost. Or, there may be variable hypotonia and areflexia from the beginning, or spasticity may be present throughout the illness, but with hyporeflexia and slowed conduction velocities. Signs of mental regression may be apparent from the onset or appear after the motor disorder has become established. Later there is impairment of vision, sometimes with squint and nystagmus; intention tremor in the arms and dysarthria; dysphagia and drooling; and optic atrophy (one-third of patients), sometimes with *grayish degeneration around the maculae*. Seizures are rare, and there are no somatic abnormalities. The head size is usually normal, but rarely there is macrocephaly. Progression to a bedridden quadriplegic state without speech or comprehension occurs over a 1- to 3-year period, somewhat more slowly in late-onset types. The CSF protein is elevated.

There is widespread degeneration of myelinated fibers in the cerebrum (Fig. 37-6), cerebellum, spinal cord, and peripheral nerves. The presence of metachromatic granules in glial cells and engorged macrophages is characteristic and enables the diagnosis

Figure 37-6. Metachromatic leukodystrophy. T2-weighted axial MRI of a 3-year-old boy. Abnormal high signal intensity involves the entire centrum ovale but spares the subcortical arcuate fibers. (Reproduced by permission from Lee SH, Rao K, Zimmerman RA: *Cranial MRI and CT*, 3rd ed. New York, McGraw-Hill, 1992.)

to be made from a biopsy of a peripheral nerve. The stored material, *sulfatide*, stains brown-orange rather than purple with aniline dyes. Sulfatides are also PAS-positive in frozen sections.

The diagnostic laboratory findings, in addition to the MRI and histologic changes, are the *elevated CSF protein* (75 to 250 mg/dL) and a *marked increase in sulfatide in urine and an absence of arylsulfatase A* in white blood cells, in serum, and in cultured fibroblasts. Assays of arylsulfatase A activity in cultured fibroblasts and amniocytes permit the identification of carriers and prenatal diagnosis of the disease, but a pseudodeficiency of the enzyme is known. In this condition, measured enzyme activity is 10 percent of normal, but no clinical manifestations result.

Treatment with enzyme replacement or bone marrow transplantation is being tried. Marrow transplant appears to be of less benefit once the patient becomes symptomatic, but it may be useful early in the disease and in the treatment of an asymptomatic sibling of an index case.

The differential diagnosis of this leukodystrophy is from neuroaxonal dystrophy (see below), cases of early-onset inherited polyneuropathy, late-onset Krabbe disease, and childhood forms of Gaucher disease and Niemann-Pick disease. A *variant of metachromatic leukoencephalopathy*, due to a deficiency of the isoenzymes of arylsulfatase A, B, and C, was described by Austin in 1973. He called it *multiple sulfatase deficiency*. The neurologic manifestations resemble those of metachromatic leukodystrophy, but, in addition, there are facial and skeletal changes similar to those of a mucopolysaccharidosis. Deafness, hepatic enlargement, ichthyosis, and beaking of lumbar vertebrae are additional findings

in some cases. Metachromatic material is found in the urinary sediment. Pathologically, in addition to metachromasia of degenerating white matter in cerebrum and peripheral nerve, there may be storage material (sulfated glycolipids), like that found in the gangliosidoses in neurons as well as in liver, gallbladder, and kidney. Granules are demonstrable in neutrophilic leukocytes. There has also been described a state of "arylsulfatase pseudodeficiency," which exists as a polymorphism in about 7 percent of Europeans and makes the point that low enzyme levels alone are insufficient to be expressed as a phenotype of metachromatic leukodystrophy.

Forms of metachromatic leukodystrophy developing in adult years are discussed further on.

Neuroaxonal Dystrophy (Degeneration)

This is a rare disease, inherited as an autosomal recessive trait. In the largest group of cases (77 collected by Aicardi and Castelein), the onset was near the beginning of the second year in 50 patients and before the third year in all instances. The clinical constellation comprised psychomotor deterioration (loss of ability to sit, stand, and speak), marked hypotonia but brisk reflexes and Babinski signs, and progressive blindness with optic atrophy but normal retinæ. Seizures, myoclonus, and extrapyramidal signs were rare. Loss of sensation was found later in some cases. Terminally, bulbar signs, spasticity, and decerebrate rigidity often supervened. The course was relentlessly progressive, with fatal issue in a decorticate state in 3 to 8 years. There were no abnormalities of the liver and spleen and no facial or skeletal changes.

Pathologic examination reveals eosinophilic spheroids of swollen axoplasm in the posterior columns and nuclei of Goll and Burdach and in Clarke's column, substantia nigra, subthalamic nuclei, central nuclei of brainstem, and cerebral cortex. There is cerebellar atrophy, affecting the granule cell layer predominantly, and increased iron-containing pigment in the basal ganglia (like that observed in Hallervorden-Spatz disease).

The CT scans and CSF are normal, and there are no biochemical or blood cell abnormalities. After the age of 2 years, however, the EEG shows characteristic high-amplitude fast rhythms (16 to 22 Hz). Evoked responses may be abnormal. Nerve conduction velocities are normal despite EMG evidence of denervation. The diagnosis can be reliably established during life by electron microscopic examination of skin and conjunctival nerves, which show the characteristic spheroids within axons.

There is a later-onset form of the disease in which the course is more protracted and the neurologic manifestations (rigidity and spasticity, cerebellar ataxia, and myoclonus) are more pronounced. In these cases the mental regression is slow. Vision may be retained, but retinal degeneration has been documented. Some of the late-onset cases are indistinguishable from Hallervorden-Spatz disease (page 832).

The primary mutation in most cases is unknown. In early infantile forms there is a mutation in a lysosomal hydrolase.

Late Infantile and Early Childhood Gaucher Disease

As stated earlier, Gaucher disease usually develops in early infancy, but some cases, so-called Gaucher disease type III, may begin in childhood, between 3 and 8 years of age. The clinical picture is variable and combines features of infantile Gaucher disease—such as abducens palsies, dysphagia, trismus, rigidity of the limbs, and dementia—with features of the late childhood–early adult form,

such as palsies of horizontal gaze, diffuse myoclonus, generalized seizures, and a chronic course (Winkelmann et al). The diagnosis is established by the finding of splenomegaly, Gaucher cells, glucocerebroside storage, and deficient activity of glucocerebrosidase in leukocytes or cultured fibroblasts.

Late Infantile–Early Childhood Niemann-Pick Disease

A number of cases of subacute or chronic neurovisceral storage diseases with early signs of hepatosplenomegaly and later signs (2 to 4 years) of neurologic involvement have been described. Crocker and Farber classified them as types III and IV Niemann-Pick disease. Others have classified them as types C and D, although it is now generally agreed that they are best considered a single entity.

The neurologic disorder consists of progressive dementia, dysarthria, ataxia, rarely extrapyramidal signs (choreoathetosis), and *paralysis of horizontal and vertical gaze*, the latter being a distinguishing feature. On attempting to look to the side, some of the patients make head-thrusting movements of the same type that one observes in ataxia-telangiectasia and the oculomotor apraxia of Coogan (page 873). Lateral eye movements are full on passive movement of the head (oculocephalic maneuver). Convergence is also deficient. A special syndrome called *juvenile dystonic lipidosis* is characterized by extrapyramidal symptoms and paralysis of vertical eye movements. The syndrome of the "sea-blue histiocyte" (liver, spleen, and bone marrow contain histiocytes with sea-blue granules)—in which there is retardation in mental and motor development, grayish macular degeneration, and, in one of our cases, posterior column and pyramidal degeneration—may be another variant.

The diagnosis is made by bone marrow biopsy, which discloses vacuolated macrophages and sea-blue histiocytes, and by measuring the defect in cholesterol esterification in cultured fibroblasts.

Late Infantile–Childhood GM₁ Gangliosidosis

In type 2 or so-called juvenile GM₁ gangliosidosis, the onset is between 12 and 24 months, with survival for 3 to 10 years. The first sign is usually *difficulty in walking*, with frequent falls, followed by awkwardness of arm movements, loss of speech, severe mental regression, gradual development of spastic quadripareisis and pseudobulbar palsy (dysarthria, dysphagia, drooling), and seizures. Retinal changes are variable—usually they are absent, but macular red spots may be seen at the age of 10 to 12 years; vision is usually retained, but squints (comitant) are common. There is a facial dysmorphism resembling that of the Hurler syndrome, and the liver and spleen are enlarged. Important laboratory findings are hypoplasia of the thoracolumbar vertebral bodies, mild hypoplasia of the acetabula, and the presence in the bone marrow of histiocytes with clear vacuoles or wrinkled cytoplasm. As noted on page 807, leukocytes and cultured skin fibroblasts show a *deficiency* or absence of β -galactosidase activity. GM₁ ganglioside accumulates in the cerebral neurons.

The Neuronal Ceroid Lipofuscinoses (Batten Disease)

As a group, the lipofuscinoses have been the most frequent of the neurodegenerative diseases of infancy and childhood diagnosed at

the Lysosomal Enzyme Laboratory of the E. K. Shriver Center. Four types have been identified: Santavuori-Haltia Finnish infantile type, Jansky-Bielschowsky early-childhood type, Vogt-Spielmeyer juvenile type, and Kufs adult type. All except a few adult cases are autosomal recessive. The storage material in neuronal cytoplasm consists of two pigmented lipids, presumably ceroid and lipofuscin, which are cross-linked polymers of polyunsaturated fatty acids and have the property of autofluorescence. Mole has published a useful review of the genetics of these diseases and points out that at least eight gene loci are implicated, for six of which the mutation has been identified. All the infantile forms and one juvenile form of the disease are due to mutations affecting the lysosomal enzyme palmitoyl-protein thioesterase. Other lysosomal enzymes are abnormal in the remaining juvenile and in the adult forms.

In the *Finnish form* of the disease, infants from 3 to 18 months of age, after a normal period of development, undergo psychomotor regression with ataxia, hypotonia, and *widespread myoclonus*. There are retinal changes with extinction of the electroretinogram, slowing of the EEG with spike and slow-wave discharges, and eventually an isoelectric record. Within a few years these patients become blind, develop spastic quadriplegia and microcephaly, and succumb.

In the *Jansky-Bielschowsky type*, the onset of symptoms is between 2 and 4 years, after normal or slightly retarded earlier development, with survival to 4 to 8 years of age. Usually the first neurologic manifestations are seizures (petit mal or grand mal) and *myoclonic jerks* evoked by proprioceptive and other sensory stimuli, including voluntary movement and emotional excitement. Incoordination, tremor, ataxia, and spastic weakness with lively tendon reflexes and Babinski signs, deterioration of mental faculties, and dysarthria proceed to dementia and eventually to mutism. In patients with relatively late onset, a progressive dementia is the car-

dinal manifestation. Visual failure may occur early in some cases because of *retinal degeneration* (of rods and cones) with pigmentary deposits, but in others vision is normal. The electroretinogram becomes isoelectric if vision is affected. Abnormal inclusions (translucent vacuoles) are seen in 10 to 30 percent of circulating lymphocytes, and azurophilic granules in neutrophils. High-voltage EEG spikes are induced by photic stimuli. Only in early-onset cases is there microcephaly.

Pathologic examination shows neuronal loss in the cerebral and cerebellar cortices (granule and Purkinje cells), and curvilinear storage particles and osmophilic granules are visible in the remaining neurons. Inclusions are also observed in cutaneous nerve twigs and endothelial cells of blood vessels, findings which permit diagnosis during life by electron microscopy of skin, conjunctival, or rectal mucosal biopsies. In many patients with lipofuscinoses, *diagnosis* can be confirmed by demonstrating the presence of one of several recently identified gene mutations. There are no definite markers for the group in blood or urine, but in some patients a structural component of mitochondria is excreted in excess (the so-called C-fragment). In the differential diagnosis, one must consider late infantile GM₁ gangliosidosis, idiopathic epilepsy, Alpers disease, and other forms of neuronal ceroid-lipofuscinosis.

The lipofuscinoses of later onset—the Vogt-Spielmeyer (juvenile) type and the Kufs (adult) type—are discussed further on. There is no treatment for the basic disease process, but approaches involving gene therapy are being explored.

Mucopolysaccharidoses (Table 37-7)

This is a group of diseases in which the storage of lipid in neurons is combined with that of polysaccharides in connective tissues. As a consequence there is a conjunction of neurologic and skeletal

Table 37-7
Classification of the mucopolysaccharidoses

NUMBER	EPONYM	CLINICAL MANIFESTATIONS	ENZYME DEFICIENCY	GLYCOSAMINOGLYCAN
MPS I ^a	Hurler	Corneal clouding, severe skeletal changes and MR, ^b organomegaly, heart disease	α -L-Iduronidase	Dermatan sulfate, heparan sulfate
MPS II	Hunter	Dysostosis, normal corneas, MR, joint stiffness, hydrocephalus, short stature, organomegaly	Iduronate sulfatase	Dermatan sulfate, heparan sulfate
MPS III	Sanfilippo	MR, mild or absent somatic changes, hyperactivity, hepatosplenomegaly	Heparan N-sulfatase	Heparan sulfate
MPS IV	Morquio	Distinctive skeletal abnormalities, slight corneal clouding, odontoid hypoplasia, normal intelligence, hepatomegaly	Galactose 6-sulfatase	Keratan sulfate, chondroitin 6-sulfate
MPS V	No longer used			
MPS VI	Maroteaux-Lamy	Dysostosis, corneal clouding, normal intelligence, spinal cord compression, organomegaly	<i>N</i> -acetylgalactosamine, 4-sulfatase (arylsulfatase B)	Dermatan sulfate
MPS VII	Sly	Dysostosis, hepatosplenomegaly, wide range of severity, corneal clouding	β -Glucuronidase	Dermatan sulfate, heparan sulfate, chondroitin 4-sulfate

^a Less severe phenotypes are known as Scheie or Hurler-Scheie syndromes.

^b MR = mental retardation.

SOURCE: Modified by permission from Neufeld and Muenzer.

abnormalities that is virtually unique. The nervous system may also be involved secondarily as a result of skeletal deformities and thickening and hyperplasia of connective tissue at the base of the brain, leading to obliteration of the subarachnoid space and obstructive hydrocephalus or compression of the cervical cord. The prevalence of mucopolysaccharides as a whole is approximately 1 per 8000 births, according to Meikle and colleagues. Depending on the degree of visceral-skeletal and neurologic changes, at least seven distinct clinical subtypes are recognized (see Table 37-7).

The basic abnormality is an enzymatic defect that prevents the degradation of acid mucopolysaccharides (now called *glycosaminoglycans*). They can be measured and are increased in serum, leukocytes, or cultured fibroblasts. The storage is, again, within lysosomes in the brain, spinal cord, heart, viscera, bone, and connective tissue. All forms of the disease except the Hunter syndrome, which is sex-linked, are inherited in an autosomal recessive pattern. The studies of Neufeld and Muenzer indicate that each type of mucopolysaccharidosis is caused by a defect in a different enzyme.

Hurler Disease This, the classic form, also known as MPS I, begins clinically toward the end of the first year. *Mental retardation* is severe, and *skeletal abnormalities* are prominent (dwarfism; gargoyle facies; large head with synostosis of longitudinal suture; kyphosis; broad hands with short, stubby fingers; flexion contractures at knees and elbows). Conductive deafness and corticospinal signs are usually present. Protuberant abdomen, hernias, *enlarged liver and spleen*, valvular heart disease, chronic rhinitis, recurrent respiratory infections, and *corneal opacities* complete the picture. The biochemical abnormalities consist of the accumulation of *dermatan* and *heparan sulfate* (*glycosaminoglycans*) in the tissues and their *excretion in the urine*, due probably to absence of activity of α -L-iduronidase. Also, there is an increase in the ganglioside content in nerve cells of the brains of these patients. In the milder Scheie (MPS V) variant of Hurler disease, intelligence and life span are normal.

Treatment Enzyme replacement therapy (laraonidase) is now becoming available. The enzymes are produced with recombinant technology and are successful where previous attempts with enzymes delivered by white cell or other infusions had been ineffective. Also being studied is hematopoietic stem cell bone marrow transplantation (cord blood from unrelated donors is used most often; see Staba et al). In order to be effective, treatment must commence before the accumulation of glycosaminoglycans and neurologic decline. The eye and bone deterioration associated with Hurler disease is not improved. In children with the milder Scheie form and those with CNS involvement, bone marrow transplantation is not helpful and enzyme replacement is recommended. Enzyme treatment is also being tried concurrently with bone marrow transplantation in early cases. These approaches have not been effective in the Hunter or the Sanfilippo diseases, discussed below.

Hunter Disease Unlike the Hurler and other types, the Hunter form (MPS II) is transmitted as an *X-linked trait*. The Hurler and Hunter syndromes are clinically alike except that the Hunter form is milder: mental retardation is less severe than in the Hurler type, deafness is less common, and *corneal clouding is usually absent*. Probably there are two forms of the syndrome—a more severe one, in which the patients do not survive beyond their midteens, and a less severe form, with relatively normal intelligence and survival to middle age. Excessive amounts of dermatan and heparan sulfate are excreted in the urine. The basic abnormality is a *deficiency of iduronate sulfatase*.

Sanfilippo Disease This form, or MPS III, expresses itself clinically between 2 and 3 years of age, with progressive intellectual deterioration. The patients are of short stature, but in other respects the physical changes are fewer and less severe than in the Hunter and Hurler syndromes. Three and possibly four types of Sanfilippo disease, designated A, B, C, and D, are distinguished on the basis of their enzymatic defects (Neufeld and Muenzer). All subtypes are phenotypically similar, and all of them may excrete excessive amounts of heparan sulfate in the urine.

Morquio Disease This form of the disease, MPS IV, is characterized by marked *dwarfism* and *osteoporosis*. Skeletal deformity and compression of the spinal cord and medulla are constant threats, because of hypoplasia of the odontoid process and atlantoaxial dislocation and thickening of the dura around the cervical cord and inferior surface of the cerebellum. Intelligence is affected only slightly or not at all. *Corneal opacities may be present*. Patients excrete large amounts of keratan sulfate in the urine; two types of enzymatic deficiency have been identified (Neufeld and Muenzer).

Maroteaux-Lamy Disease This syndrome, MPS VI, includes severe skeletal deformities (short stature, anteriorly beaked vertebrae) but *normal intelligence*. Several patients observed by our colleagues have had a cervical pachymeningitis with spinal cord compression and hydrocephalus during adult life. Spinal cord function improved with cervical decompression and the hydrocephalus with ventriculoatrial shunting (Young et al). Hepatosplenomegaly is often present. Large amounts of dermatan sulfate are excreted in the urine, as a result of an *arylsulfatase B deficiency*.

β -Glucuronidase Deficiency (Sly Disease) This (MPS VII) is a rare type of mucopolysaccharidosis, the clinical features of which have yet to be sharply delineated. Short stature, progressive thoracolumbar gibbus, hepatosplenomegaly, and the bony changes of dysostosis multiplex (as in the Hurler type) are the main clinical features. There is excessive excretion of dermatan and heparan sulfate, the result of a deficiency of β -glucuronidase. Attempts to treat the mucopolysaccharidoses by enzyme replacement therapy, bone marrow transplantation, and gene transfer are in progress. None of these are far enough along to determine their efficacy.

Mucolipidoses and Other Diseases of Complex Carbohydrates (Sialidoses; Oligosaccharidoses—Table 37-3)

In recent years several new diseases have been described in which there is an abnormal accumulation of mucopolysaccharides, sphingolipids, and glycolipids in visceral, mesenchymal, and neural tissues, due to an α -N-acetylneuramidase defect. In some types there is an additional deficiency of β -galactosidase. All are autosomal recessive diseases that manifest many of the clinical features of Hurler disease, but—in contrast to the mucopolysaccharidoses—normal amounts of mucopolysaccharides are excreted in the urine. Frequently, GM₁ gangliosidosis, described above, is also classified with the mucolipidoses. The other members of this category are synopsized below and in Table 37-3.

Mucolipidoses At least three and possibly four closely related forms have been described. In mucolipidosis I (*lipomucopolysaccharidosis*), the morphologic features are those of gargoyleism, with

slowly progressive mental retardation. Cherry-red spots in the maculae, corneal opacities, and ataxia have been noted in some patients. Vacuolation of lymphocytes, marrow cells, hepatocytes, and Kupffer cells in the liver and metachromatic changes in the sural nerve have been described.

In *mucolipidosis II ("I-cell" disease)*, the most common of the mucolipidoses, there is usually an early onset of psychomotor retardation, but in some cases this does not appear until the second or third decade. *Abnormal facies and periosteal thickening (dysostosis multiplex*, like that of GM₁ gangliosidosis and Hurler disease) are characteristic. *Gingival hyperplasia* is prominent, and the *liver and spleen are enlarged*; but deafness is not found and corneal opacities are slower to develop. Tonic-clonic seizures are frequent in older patients. In most cases, death from heart failure occurs by the third to eighth year. There is a typical vacuolation of lymphocytes, Kupffer cells, and cells of the renal glomeruli. Bone marrow cells are also vacuolated and contain refractile cytoplasmic granules (hence the designation *inclusion-cell*, or *I-cell, disease*). A deficiency of several lysosomal enzymes required for the catabolism of mucopolysaccharides, glycolipids, and glycoproteins have been found.

In *mucolipidosis III (pseudo-Hurler polydystrophy)*, the biochemical abnormalities are like those of I-cell disease, but there are clinical differences. In the pseudo-Hurler type, symptoms do not appear until 2 years of age or later and are relatively mild. Retardation of growth, fine corneal opacities, and valvular heart disease are the major manifestations.

Yet another variant, so-called mucolipidosis IV, has been described (see Tellez-Nagel et al). Here, clouding of the corneas is noticed soon after birth, and profound developmental retardation is evident by 1 year of age. Skeletal deformities, enlargement of liver and spleen, seizures, or other neurologic abnormalities are notably lacking. Ultrastructural examination of conjunctival and skin fibroblasts has demonstrated lysosomal inclusions of material similar to lipids and mucopolysaccharides that remain to be further characterized.

Mannosidosis This is another rare hereditary disorder with poorly differentiated symptomatology. The onset is in the first 2 years, with *Hurler-like facial and skeletal deformities, mental retardation*, and slight motor disability. Corticospinal signs, loss of hearing, variable degrees of gingival hyperplasia, and spoke-like opacities of the lens (but no diffuse corneal clouding) may be present. The liver and spleen are enlarged in some cases. Radiographs show beaking of the vertebral bodies and poor trabeculation of long bones. Vacuolated lymphocytes and granulated leukocytes are present and aid in diagnosis. The urinary mucopolysaccharides are normal. *Mannosiduria is diagnostic*, caused by a defect in α -mannosidase. Mannose-containing oligosaccharides accumulate in nerve cells, spleen, liver, and leukocytes (see Kistler et al).

Fucosidosis This also is a rare autosomal recessive disorder, with neurologic deterioration beginning usually at 12 to 15 months and progressing to spastic quadriplegia, decerebrate rigidity, severe psychomotor regression, and death within 4 to 6 years. *Hepatosplenomegaly*, splenomegaly, enlarged salivary glands, thickened skin, excessive sweating, normal or typical gargoyle facies, *beaking of the vertebral bodies*, and vacuolated lymphocytes are the main features. A variant of this disease has been described with slower progression and survival into late childhood and adolescence and even into adult life (Ikeda et al). The latter type is characterized by

mental and motor retardation, along with the corneal opacities, coarse facial features, skeletal deformities of gargoyleism, and dermatologic changes of Fabry disease (angiokeratoma corporis diffusum), but no hepatosplenomegaly. The basic abnormality in both types is a lack of lysosomal L-fucosidase, resulting in accumulation of fucose-rich sphingolipids, glycoproteins, and oligosaccharides in cells of the skin, conjunctivae, and rectal mucosa.

Aspartylglycosaminuria This disease is characterized by the early onset of psychomotor regression; delayed, inadequate speech; severe behavioral abnormalities (*bouts of hyperactivity mixed with apathy and hypoactivity or psychotic manifestations*); progressive dementia; clumsy movements; corticospinal signs; corneal clouding (rare); retinal abnormalities and cataracts; coarse facies including low bridge of the nose, epicanthi, thickening of the lips and skin; enlarged liver; and abdominal hernias in some. Radiographs show minimal *beaking of the vertebral bodies*, and the blood lymphocytes are vacuolated.

The pattern of inheritance in this entire group of diseases, as already stated, is probably autosomal recessive. Diagnostic methods applicable to amniotic fluid and cells are being developed so that prenatal diagnosis will be possible, prompted often by the occurrence of the disease in an earlier child. Neurons are vacuolated rather than stuffed with granules, much like the lymphocytes and liver cells. The specific biochemical abnormalities, as far as they are known, are listed in Table 37-3.

Cockayne Syndrome

This disorder is probably inherited as an autosomal recessive trait. The onset is in late infancy, after apparently normal earlier development. The main clinical findings are *stunting of growth*, evident by the second and third years; *photosensitivity of the skin*; microcephaly; *retinitis pigmentosa, cataracts*, blindness, and pendular nystagmus; nerve deafness; *delayed psychomotor* and speech development; spastic weakness and *ataxia of limbs and gait*; occasionally athetosis; amyotrophy with abolished reflexes and reduced nerve conduction velocities; wizened face, sunken eyes, prominent nose, prognathism, anhydrosis, and poor lacrimation (resembling progeria and bird-headed dwarfism). Some cases show calcification of the basal ganglia. The CSF is normal, and there are no diagnostic biochemical findings.

Pathologic examination reveals a small brain, striatal and cerebellar calcifications, leukodystrophy like that of Pelizaeus-Merzbacher disease, and a severe cerebellar cortical atrophy. The peripheral nerve changes are those of a primary segmental demyelination.

It is now apparent that Cockayne syndrome, like ataxia-telangiectasia, is a consequence of mutations in genes that mediate DNA repair. At least three different forms of Cockayne syndrome have been identified, each with a different underlying gene defect.

Rett Syndrome

This syndrome is mentioned here because for many years, on the basis of psychomotor regression after a period of normal development, it was presumed to have a metabolic basis (urea cycle defect). However, neither this metabolic defect nor any other has ever been substantiated. Recently, the responsible gene mutation has been discovered. The syndrome is discussed fully in Chap. 38, with other forms of developmental mental retardation and autism.

Other Diseases of Late Infancy and Early Childhood

Globoid cell leukodystrophy (Krabbe), subacute necrotizing encephalomyopathy (Leigh), and Gaucher disease may also begin in late infancy or early childhood. They have been described in the preceding section of this chapter. Familial striatocerebellar calcification (Fahr disease) and Lesch-Nyhan disease may also become manifest in this age period, but they usually have a later onset and are therefore described with the diseases of later childhood in the section that follows.

Diagnosis of Metabolic Diseases of Late Infancy and Early Childhood

This group of metabolic disorders presents many of the same diagnostic problems as those of early infancy. The flow chart in Figure 37-4, which divides these disorders into dysmorphic, visceromegalic, and purely neurologic groups, is equally serviceable in the differential diagnosis of both age groups. As with the early infantile diseases, certain clusters of neurologic, skeletal, dermal, ophthalmic, and laboratory findings are highly distinctive and often permit the identification of a particular disease. These signs are listed below:

1. Evidence of involvement of peripheral nerves (weakness, hypotonia, areflexia, sensory loss, reduced conduction velocities) in conjunction with lesions of the CNS—metachromatic leukodystrophy, Krabbe leukodystrophy, neuroaxonal dystrophy, and Leigh disease (rare)
 2. Ophthalmic signs
 - a. Corneal clouding—several of the mucopolysaccharidoses (Hurler, Scheie, Morquio, Maroteaux-Lamy), mucolipidoses, tyrosinemia, aspartylglycosaminuria (rare)
 - b. Cherry-red macular spot—GM₂ gangliosidosis, GM₁ gangliosidosis (half the cases), lipomucopolysaccharidosis, occasionally Niemann-Pick disease
 - c. Retinal degeneration with pigmentary deposits—Jansky-Bielschowsky lipid storage disease, GM₁ gangliosidosis, syndrome of sea-blue histiocytes
 - d. Optic atrophy and blindness—metachromatic leukodystrophy, neuroaxonal dystrophy
 - e. Cataracts—Marinesco-Sjögren syndrome, Fabry disease, mannosidosis
 - f. Ocular apraxia—ataxia-telangiectasia, Niemann-Pick disease
 - g. Impairment of vertical eye movements—late infantile Niemann-Pick disease, juvenile dystonic lipidosis, sea-blue histiocyte syndrome, Wilson disease
 - h. Jerky eye movements, limited abduction—late infantile Gaucher disease
 4. Extrapyramidal signs—late-onset Niemann-Pick disease (rigidity, abnormal postures), juvenile dystonic lipidosis (dystonia, choreoathetosis), Rett, ataxia-telangiectasia (ataxis), Sanfilippo mucopolysaccharidosis, type I glutaric aciduria, Wilson disease, Segawa dopa-responsive dystonia
 5. Facial dysmorphism—Hurler, Scheie, Morquio, and Maroteaux-Lamy forms of mucopolysaccharidosis, aspartylglycosaminuria, mucolipidoses, GM₁ gangliosidosis, mannosidosis, fucosidosis (some cases), multisulfatase deficiencies (Austin), some mitochondrial disorders

6. Dwarfism, spine deformities, arthropathies—Hurler, Mory-
quio, and other mucopolysaccharidoses, Cockayne syn-
drome
 7. Enlarged liver and spleen—Niemann-Pick disease, Gaucher
disease, all mucopolysaccharidoses, fucosidosis, mucolip-
idoses, GM₁ gangliosidosis
 8. Alterations of skin—photosensitivity (Cockayne syndrome
and one form of porphyria); papular nevi and angioker-
toma (Fabry disease, fucosidosis); telangiectasia of ears,
conjunctiva, chest (ataxia-telangiectasia); ichthyosis
(Sjögren-Larsen disease, caused by fatty alcohol dehydro-
genase deficiency); plaque-like lesions in Hunter syndrome
 9. Beaked thoracolumbar vertebrae—all mucopolysacchari-
dos, mucolipidoses, mannosidosis, fucosidosis; aspartyl-
glycosaminuria, multiple sulfatase deficiencies
 10. Deafness—mucopolysaccharidoses, mannosidosis, Cock-
ayne syndrome
 11. Hypertrophied gums—mucolipidoses, mannosidosis
 12. Vacuolated lymphocytes—all mucopolysaccharidoses, mu-
colipidoses, mannosidosis, fucosidosis
 13. Granules in neutrophils—all mucopolysaccharidoses, mu-
colipidoses, mannosidosis, fucosidosis, multiple sulfatase
deficiencies

In our experience the most difficult diagnostic problems in this age period are raised by neuroaxonal dystrophy, metachromatic leukodystrophy, the mitochondrial disorder subacute necrotizing encephalomyopathy (Leigh disease), some cases of lipofuscinosis, and the late form of GM₁ gangliosidosis. In none of these diseases is the clinical picture entirely stereotyped. Most helpful in the clinical diagnosis of neuroaxonal dystrophy is the onset, at 1 to 2 years of age, of severe hypotonia with retained reflexes and Babinski signs, early visual involvement without retinal changes, lack of seizures, normal CSF, physiologic evidence of denervation of muscles, fast-frequency EEG, normal CT scan, and *N*-acetyl-galactosaminidase deficiency in cultured fibroblasts. Metachromatic leukodystrophy can be excluded if the CSF protein is normal and if nerve conduction velocities and enzymatic studies of leukocytes and fibroblasts are normal. Similar criteria enable one to rule out GM₁ gangliosidosis. Leigh disease may begin at the same age, with hypotonia and optic atrophy, but abnormalities of ocular movement and respiration appear early; in many cases the lactic acidosis and pyruvate decarboxylase defect will corroborate the diagnosis. Sequencing tests of the mitochondrial genome now allow definitive diagnosis in most cases, as described in a later section. Also in Leigh disease, CT scanning and MRI may disclose hypodense lesions in the basal ganglia and brainstem, in contrast to the normal CT scan in neuroaxonal dystrophy. In metachromatic leukodystrophy, the cerebral white matter shows a diffusely decreased attenuation and the MR images are striking (Fig. 37-6). Lipofuscinosis cannot always be diagnosed accurately; curvilinear bodies in nerve twigs and in the endothelial cells in skin biopsies and the recently discovered gene mutations are the most informative laboratory tests.

INHERITED METABOLIC ENCEPHALOPATHIES OF LATE CHILDHOOD AND ADOLESCENCE

Unavoidably, one must refer here to certain inherited metabolic diseases already described that permit survival into late childhood.

and adolescence as well as to diseases that begin in adolescence or adult life after a normal childhood. There is a tendency for them to be less severe and less rapidly progressive, an attribute shared by many diseases with a dominant mode of inheritance. Nonetheless, there are diseases, such as Wilson disease, in which the onset of neurologic symptoms occurs after the 10th year and in rare instances after the 30th year, and the mode of inheritance is recessive in type. However, in the latter instance, the basic abnormality has existed since early childhood in the form of a ceruloplasmin deficiency with early cirrhosis and splenomegaly; only the neurologic disorder is of late onset. This brings us to another principle—that the pathogenesis of the cerebral lesion may involve a factor or factors once removed from the underlying biologic abnormality.

Genetic heterogeneity poses another problem with respect to both the clinical and biochemical findings. It is well established that a single clinical phenotype such as the one seen in Hurler disease can be the expression of a number of different alleles of a given gene mutation. Conversely, a number of different clinical phenotypes may be based on different degrees of the same enzyme deficiency. One must, therefore, not rely solely on clinical appearances for diagnosis but always combine them with biochemical tests and molecular genetic studies for confirmation. No one of these lines of data, including genomics, is sufficient for classification of disease.

The diseases in this category are probably of greater interest to neurologists than the preceding ones, for they more consistently cause familiar neurologic abnormalities such as epilepsy, polymyoclonus, dementia, cerebellar ataxia, choreoathetosis, dystonia, tremor, spastic-ataxic paraparesis, blindness, deafness, and stroke. These manifestations appear much the same in late childhood and adolescence as they do in adult life, and the neurologist whose experience has been mainly with adult patients feels quite comfortable with them.

Diseases in this age period have a diversity of manifestations, yet each disease tends to have a certain characteristic pattern of neurologic expression, as though the pathogenetic mechanism were acting more selectively on particular systems of neurons. Such affinities between the disease process and certain anatomic structures raise the question of *pathoclisis*, i.e., specific vulnerability of particular neuronal systems to certain morbid agents. Stated another way, for each disease there is a common and relatively stereotyped clinical syndrome and a small number of variants; conversely, certain other symptoms and syndromes are rarely observed with a given disease. At the same time, however, it is clear that more than one disease may cause the same syndrome.

In deference to these principles, the diseases in this section are grouped according to their most common mode of clinical expression, as follows:

1. The progressive cerebellar ataxias of childhood and adolescence
2. The familial polymyoclonias and epilepsies
3. Extrapyramidal syndromes of parkinsonian type
4. The syndrome of dystonia and generalized choreoathetosis
5. The syndrome of bilateral hemiplegia, cerebral blindness and deafness, and other manifestations of focal cerebral disorder
6. Strokes in association with inherited metabolic diseases
7. Metabolic polyneuropathies
8. Personality changes and behavioral disturbances as manifestations of inherited metabolic diseases

It is advantageous to be familiar with these groupings, for a knowledge of them, like the age of onset and gray and white matter distinctions in diseases of earlier onset, facilitates clinical diagnosis. Variants seen personally by the authors are mentioned in the descriptions of the diseases themselves. One word of caution—it is a mistake to assume that the diseases in these categories affect one and only one particular part of the nervous system or to assume that they are exclusively neurologic. Once the biochemical abnormality is discovered, it is usually found to implicate cells of certain nonneurologic tissues as well; whether or not the effects of such involvement become symptomatic is often a quantitative matter. Also, one encounters mixed neurologic syndromes in which tremor, myoclonus, cerebellar ataxia, and choreoathetosis are present in various combinations; it is then difficult to decide whether a movement disorder is of one type or another.

The Progressive Cerebellar Ataxias of Late Childhood and Adolescence

In the preceding section it was pointed out that there is a large group of diseases, some with (but most without) a known metabolic basis, in which an acute, episodic, or chronic cerebellar ataxia becomes manifest in early childhood. Here the discussion of the cerebellar ataxias is continued, with reference to those forms that begin in late childhood and adolescence. In these later age periods the number of ataxias of proven metabolic type diminishes markedly. Most of them, of chronic progressive type, are part of the late-onset lipid storage diseases. Of the other cerebellar ataxias of late childhood and adolescence, only the Bassen-Kornzweig acanthocytosis and a genetic fault in vitamin E metabolism fall into the category of a truly metabolic disease—and one could perhaps add late-onset GM₂ gangliosidosis, Refsum disease, and ataxia-telangiectasia. Refsum disease is so clearly a polyneuropathy (cerebellar features only in exceptional cases) that it is presented in Chap. 46. Ataxia-telangiectasia is usually encountered in late childhood, but the ataxia may begin as early as the second year of life; therefore it has been described in the preceding section with the ataxias of early childhood. An account of the effect of vitamin E deficiency on the nervous system is presented on page 997.

There are many other conditions of metabolic type in which cerebellar ataxia figures in the clinical picture. Some of these are associated with polymyoclonus and cherry-red macular spots (mainly sialidosis or neuraminidosis; see below). Cerebellar ataxia is a prominent feature of Unverricht-Lundborg (Baltic) disease and Lafora-body disease (Chap. 16). The Cockayne syndrome and Marinesco-Sjögren disease, already described under “Inherited Metabolic Diseases of Late Infancy and Early Childhood,” persist into later childhood and adolescence or may even have their onset in this later period. In cerebrotendinous xanthomatosis (see further on), spastic weakness and pseudobulbar palsy are combined with cerebellar ataxia. Prader-Willi children have a broad-based gait and are clumsy in addition to being obese, genitally deficient, and diabetic. One family of five males with a syndrome of hyperuricemia, spinocerebellar ataxia, and deafness has been reported by Rosenberg and colleagues, and several other variants of defective purine and pyrimidine metabolism fit into this category; the enzymatic defect of Lesch-Nyhan disease was not present, however. Marsden and coworkers have observed cerebellar ataxia beginning in late childhood, as an expression of adrenoleukodystrophy (see below). The familial syndrome of neuropathy, ataxia, and retinitis pigmentosa (NARP, page 844) caused by a mitochondrial genome muta-

tion that impairs ATP synthase can closely mimic the Marinesco-Sjögren syndrome.

Doubtless, many of the progressive forms of cerebellar ataxia now classified as degenerative and described in Chap. 39 will be proved to have an underlying biochemical or similar subcellular pathogenesis and will logically fall in place here, with the metabolic diseases. At present, when faced with a progressive ataxia of cerebellar type even in a young adult, the reader should consult both this chapter and Chap. 39.

The *acute forms of cerebellar ataxia* that occur in late childhood and adolescence are essentially nonmetabolic, being traceable to postinfectious encephalomyelitis (page 641) or to postanoxic, postmeningitic, or posthyperthermic states and certain drug intoxications. With relatively pure cerebellar ataxias of this age period, postinfectious cerebellitis, cerebellar tumors (medulloblastomas, astrocytomas, hemangioblastomas, and ganglioneuromas of Lhermitte-Duclos) should be considered in the differential diagnosis. MRI establishes the correct diagnosis.

Bassen-Kornzweig Acanthocytosis (Abetalipoproteinemia)

This disease, first described by Bassen and Kornzweig in 1950, excited great interest, for it gave promise of a breakthrough into a hitherto obscure group of "degenerative" disorders. In the 15-year period that followed the original report, less than a dozen cases were recorded, and several of the reports were based on the study of the same case. In our experience, it is a rare disease; we have seen only four cases. The resemblance to Friedreich ataxia is not so close that an experienced clinician would be likely to confuse the two.

The inheritance of this disease is autosomal recessive. The initial symptoms, occurring between 6 and 12 years (range, 2 to 20 years), are weakness of the limbs with areflexia and an ataxia of sensory (tabetic) type, to which a cerebellar component is added later (see also page 1158). Steatorrhea, raising the suspicion of celiac disease (sprue), often precedes the weak, unsteady gait. Later, in more than half the patients, vision may fail because of retinal degeneration (similar to retinitis pigmentosa). Kyphoscoliosis, pes cavus, and Babinski signs are other elements in the clinical picture. The neurologic disorder is relatively slowly progressive—by the second to third decade, the patient is usually bedridden.

The diagnostic laboratory findings are spiky or thorny red blood cells (acanthocytes), low sedimentation rate, and a marked reduction in the serum of low-density lipoproteins (cholesterol, phospholipid, and β -lipoprotein levels are all subnormal). Pathologic study has revealed the presence of foamy, vacuolated epithelial cells in the intestinal mucosa (causing absorption block); diminished numbers of myelinated nerve fibers in sural nerve biopsies, depletion of Purkinje and granule cells in all parts of the cerebellum; loss of fibers in the posterior columns and spinocerebellar tracts; loss of anterior horn and retinal ganglion cells and of muscle fibers and fibrosis of the myocardium. It has been proposed that the basic defect is an inability of the body to synthesize the proteins of cell membranes because of the impaired absorption of fat through the mucosa of the small intestine. Vitamin E deficiency may be a pathogenic factor, since the administration of a low-fat diet and high doses of vitamins A and E may prevent progression of the neurologic disorder, according to Illingworth and colleagues.

Often mentioned in the context of acanthocytosis is another rare condition, the McLeod syndrome, in which are combined heterogeneous combinations of progressive muscular atrophy, seizures, involuntary movements, and elevated serum CK. The acan-

thocytosis in this disease is the result of an abnormality of the red cell surface Kell antigen (Kx, coding for the protein called XK).

Familial Hypobetalipoproteinemia This is a well-defined disease, resembling abetalipoproteinemia, in which there is hypobetalipoproteinemia, acanthocytosis of red blood corpuscles, retinitis pigmentosa, and a pallidal atrophy (so-called HARP syndrome). Inheritance is autosomal dominant, and heterozygotes may exhibit some part of the syndrome. Many cases are caused by mutations in the gene encoding beta-lipoprotein B. Fat droplets may be seen in the jejunal mucosa, indicating malabsorption. Cases have been reported from Europe, Asia, and the United States. Treatment consists of restriction of dietary fat and supplements of vitamin E.

An adult form of acanthocytosis associated with hereditary chorea and dystonia has also been recognized, but evidence of lipid malabsorption is lacking. This disease is described in Chap. 39.

Hereditary Paroxysmal Cerebellar Ataxia This not uncommon syndrome of periodic ataxia, akin to the familial paroxysmal choreoathetosis and periodic dystonia described in Chap. 4, is inherited as an autosomal dominant trait. The gene for hereditary paroxysmal ataxia codes for a subunit of the calcium channel. It has its onset in childhood or early adult life and takes the form of disabling episodic attacks of ataxia, nystagmus, and dysarthria, each attack lasting a few minutes or a few hours. Between attacks the patients are asymptomatic or show only a mild nystagmus or minimal clumsiness. The remarkable feature is the prevention of attacks by the administration of acetazolamide, 250 mg thrice daily, as noted originally by Griggs et al. These characteristics apply to what is now termed *familial episodic ataxia* type 2. The rarer type 1 is related to a mutation in the voltage-gated potassium channel and is associated with myokymia and epilepsy.

The Familial Polymyoclonias

As stated in Chap. 6, the term *myoclonus* is applied to many conditions that are not at all alike but share a single clinical feature—a multitude of exceedingly brief, random, arrhythmic twitches of parts of muscles, entire muscles, or groups of muscles. Myoclonic jerks differ from chorea by virtue of their brevity (15 to 50 ms). Notably, both phenomena are considered to be symptomatic of "gray matter" diseases ("polioencephalopathies").

Myoclonus or polymyoclonus may, in certain conditions, stand alone as a relatively pure syndrome. In other cases, it is mixed with epilepsy or athetosis and dystonia, discussed further on. Most often, myoclonus is associated with cerebellar ataxia; it is therefore being considered here, with the progressive cerebellar ataxias. The many acquired forms of polymyoclonus, such as subacute sclerosing panencephalitis, have been mentioned in Chap. 6. In this chapter we are concerned only with those of known or presumed metabolic origin.

Myoclonic Encephalopathy of Infants (Infantile Opsoclonus-Myoclonus Syndrome) Under this title Kinsbourne originally described a form of widespread, continuous myoclonus (except during deep sleep) affecting male and female infants whose development had been normal until the onset of the disease at the age of 9 to 20 months. The myoclonus evolves over a week or less, affects all the muscles of the body, and interferes seriously with all the natural muscular activities of the child. The eyes are notably affected by rapid (up to eight per second), irregular conjugate

movements ("dancing eyes" of an opsoclonic type). The child is irritable and speech may cease. All laboratory tests are normal.

Treatment Adrenocorticotropic hormone and dexamethasone, the latter in doses of 1.5 to 4.0 mg/day, suppress the myoclonus and permit developmental progress. Some patients have recovered from the myoclonus but have been left mentally slow and mildly ataxic. Others have required corticosteroid therapy for 5 to 10 years, with relapse whenever it was discontinued. Ordinary anti-convulsants seem to have no effect. The pathology has not been determined.

A similar syndrome has been observed in conjunction with neuroblastoma in children and as a transient illness of unknown cause (probably viral or postinfectious) in young adults (Baringer et al; see page 641). It is mentioned here because a similar condition is also known in adults, as a paraneoplastic disease with ovarian, breast, gastric, and bronchogenic carcinomas and with other occult tumors.

In a broader survey of the pediatric opsoclonus-myoclonus syndrome, Pranzatelli and associates reported their experience with 27 cases, some with neural crest tumors, others with viral infections or hypoxic injury (intention myoclonus). In nearly all of their patients there was cerebellar ataxia and mental disorder, and 10 percent had seizures. The CSF was normal. The investigators have emphasized the pathogenetic heterogeneity and defined a rare serotonergic type (low levels of 5-hydroxytryptophan and homovanillic acid in the CSF) that responds to 5-hydroxyindole acetic acid.

Familial Progressive Myoclonus Five major categories of familial polymyoclonus of late childhood and adolescence have been delineated: (1) Lafora- or amyloid-body type, (2) juvenile cerebro-retinal degeneration, (3) cherry-red spot—myoclonus (sialidosis or neuraminidosis), (4) mitochondrial encephalopathy, and (5) a more benign degenerative disease (dyssynergia cerebellaris myoclonica of Hunt). Familial myoclonus may also be a prominent feature of two other diseases—GM₂ gangliosidosis and Gaucher disease—which occasionally have their onset in this age period.

Lafora-Body Polymyoclonus with Epilepsy This disease, which is inherited as an autosomal recessive trait, was first identified by Lafora in 1911 on the basis of the large basophilic cytoplasmic bodies that were found in the dentate, brainstem, and thalamic neurons. These inclusions have been shown by Yokoi and colleagues to be composed of a glucose polymer (polyglycosan) that is chemically but not structurally related to glycogen. Possibly some of the cases of familial myoclonus epilepsy reported by Unverricht and by Lundborg were of this type, but since these authors provided no pathologic data, one cannot be sure.

Beginning in late childhood and adolescence (11 to 18 years) in a previously normal individual, the disease announces itself by a seizure, a burst of myoclonic jerks, or both. In about half the cases there are focal (often occipital) seizures. The illness may at first be mistaken for ordinary epilepsy, but within a few months it becomes evident that something far more serious is occurring. The myoclonus becomes widespread and can be evoked as a startle by noise, an unexpected tactile stimulus (even the tap of a reflex hammer), and also by excitement, or certain sustained motor activities. An evoked train of myoclonic jerks may progress to a generalized seizure with loss of consciousness. As the disease advances, the myoclonus interferes increasingly with the patient's motor activities until voluntary function is seriously impaired. Speech may be marred, much as it is in chorea. Close examination may also reveal

an alteration in muscle tone and a slight degree of cerebellar ataxia. At this time, or even before the onset of myoclonus and seizures, the patient may experience visual hallucinations or exhibit irritability, odd traits of character, uninhibited or impulsive behavior, and, ultimately, progressive failure in all cognitive functions. Deafness has been an early sign in a few cases. Rigidity or hypotonia, impaired tendon reflexes, acrocytosis, and rarely corticospinal tract signs are late findings. Finally the patient becomes cachectic and bedfast and succumbs to intercurrent infection. Most do not survive beyond their 25th birthday. Nonetheless there are isolated reports of Lafora-body disease in which symptoms began as late as 40 years, with death as late as 50 years. These late cases may constitute a separate genetic type.

No abnormalities of the blood, urine, or CSF have been detected. The EEG shows diffuse slow waves and spikes as well as bursts of focal or multifocal discharges. Altered hepatocytes with homogeneous PAS-positive bodies that displace the nuclei have been observed in both the presymptomatic and symptomatic stages of the disease. These inclusions have been seen in skin and liver biopsies, even though liver function tests were normal. Neuropathologic examinations have shown a slight loss of granule and Purkinje cells and loss of neurons in the dentate nuclei, inner segment of globus pallidus, and cerebral cortex in addition to the Lafora bodies. The latter may also be seen in the retina, cerebral cortex, myocardium, and striated muscles. Anticonvulsant drugs, especially methsuximide and valproic acid, help in the control of the seizures but have no effect on the basic process.

Polyglycosan Body Disease (See also page 914) This is another closely related disease, the features of which have been reviewed by Robitaille and coworkers, in which glycosamine bodies are found in the central and peripheral nervous system. The clinical syndrome includes dementia, chorea, and amyotrophy with or without sensory loss in the limbs. Similar bodies are found in the cells of the liver and heart. This is a progressive disease usually beginning in adult life. It has been attributed to the accumulation of polymers of glucose. Diagnosis is confirmed by the finding of the polyglycosan bodies in the axons of peripheral nerves or liver cells. The causative mutation in most cases affects the gene for glycogen branching enzyme.

Juvenile Ceroid Lipofuscinosis (Cerebroretinal Degeneration) As stated earlier, this is one of the most variable forms of the lipidoses. The salient clinical features of the later-onset types are severe myoclonus, seizures, and visual loss. In the juvenile type, the first lesions are seen in the maculae; they appear as yellow-gray areas of degeneration and stand in contrast to the cherry-red spot and the encircling white ring of Tay-Sachs disease. At first, the particles of retinal pigment are fine and dust-like; later they aggregate to resemble more the bone-corporeal shapes of retinitis pigmentosa. The liver and spleen are not enlarged and there are no osseous changes. The usual development of these and other manifestations of the disease was outlined by Sjögren, who studied a large number of the late infantile and juvenile types of cases in Sweden. He divided the illness into five stages:

1. Visual impairment, sometimes preceding retinal changes by months.
2. After approximately 2 years, the onset of generalized seizures and myoclonus, often with irritability, poor control of emotions, and stuttering, jerky speech.
3. Gradual intellectual deterioration (poor memory, reduced mental activity, inattentiveness). By this stage the move-

- ments have usually become slow, stiff, and tremulous, resembling somewhat those of Parkinson disease—to which are added elements of cerebellar ataxia and intention tremor, coming in this respect to resemble Wilson disease.
4. Stage of severe dementia in which the patient needs assistance to walk, no longer speaks, and may scream when disturbed or forced to move. The muscles are wasted, though the tendon reflexes remain lively, and the plantar reflexes are extensor.
 5. Finally the patient lies curled up in bed, blind and speechless, with strong extensor plantar reflexes, occasionally adopting dystonic postures. Life usually ends in 10 to 15 years.

In the early stages the EEG picture of random, high-voltage, triphasic waves is diagnostic; later, as the seizures and myoclonic jerks become less frequent and finally cease, only delta waves remain. The electroretinographic waveforms are lost once the retina is affected. The lateral ventricles are slightly dilated in CT scans and on MRI. The CSF is normal. Diagnosis can be confirmed by the appearance of inclusions of a curvilinear “fingerprint” pattern in electron microscopic study of biopsy material, particularly of the eccrine sweat glands of the skin. A defective membrane protein has been identified that forms the inclusion material in the most common, or classic, juvenile phenotype. The genetics of the lipofuscinoses have been reviewed by Mole.

Late Juvenile and Adult Ceroid Lipofuscinosis (Kufs disease) The *Kufs type of ceroid lipofuscinosis*, which develops later (15 to 25 years of age or older), is often unattended by visual or retinal changes and is even slower in its evolution. It is presented here for ease of exposition, but it becomes relevant mostly in relation to dementing illness in young adulthood (page 829). Personality change or dementia is one constellation, the other being myoclonic seizures with subsequent dementia and even later pyramidal and extrapyramidal signs. As the disease progresses, cerebellar ataxia, spasticity and rigidity or athetosis, or mixtures thereof, are combined with dementia. As a measure of the variability of the clinical presentation, a recent patient of ours had vague visual difficulties at age 51 and evolved a spastic quadripareis with disinhibited behavior over 5 years. Further comments regarding the unusual presentations of this disease can be found further on, under “Adult Forms of Inherited Metabolic Disease.” van Bogaert pointed out to our colleague R. D. Adams that relatives of these patients may have retinal changes without neurologic accompaniments. The genetic defect for the adult form has been partially analyzed (see below).

Of all the lipidoses, these cerebroretinal degenerations had for decades defied unifying biochemical definition. Our understanding of these diseases is difficult because they embody both enzymatic defects and structural protein dysfunctions. In a few of the early childhood types, mutations of one of several lysosomal enzymes have been identified, as summarized by Mole and by Wisniewski and colleagues. As mentioned earlier, Zeman and coworkers have shown that the cytoplasmic inclusions are autofluorescent and give a positive histochemical reaction for both ceroid and lipofuscin, but this material is not different biochemically from the lipid substance that accumulates in aging cells. In addition to the presence of curvilinear bodies in the cytoplasm of neurons and other tissues, some in a fingerprint pattern, there is a reduction in type II synapses

in the distal parts of the axon. All these changes precede nerve cell loss. The genetic defects have been tentatively determined for some of the subtypes of neuronal ceroid lipofuscinosis (see Wisniewski et al). These genes have been designated CLN 1 through 8, and they contain over 100 different mutations.

Childhood or Juvenile GM₂ Gangliosidosis Rarely, instances of the recessive type of GM₂ gangliosidosis have their onset at this age period. Twenty-four such cases (from 20 kindreds) were collected from the medical literature by Meek and coworkers. Ataxia and dysarthria were frequently the presenting symptoms, followed by dementia, dysphagia, spasticity, dystonia, seizures, and myoclonus. Degeneration of anterior horn cells with progressive muscular atrophy may be a feature, although this is more characteristic of the adult-onset variety (see further on). Atypical cherry-red spots are observed in some patients. The biochemical abnormality, i.e., a deficiency of hexosaminidase A, is the same as in Tay-Sachs disease but not as severe or as extensive. Progression of the disease is slow, over a period of many years. One of our patients is alive at 50 years, the disease having begun in adolescence.

Late Gaucher Disease with Polymyoclonus A type of Gaucher disease is occasionally encountered in which seizures, severe diffuse myoclonus, supranuclear gaze disorders (slow saccades, saccadic and pursuit horizontal gaze palsies), and cerebellar ataxia begin in late childhood, adolescence, or adult life. The course is slowly progressive. The intellect is relatively spared. The spleen is enlarged. The pathologic and biochemical abnormalities are the same as those of Gaucher disease of earlier onset (Winkelman et al).

Cherry-Red Spot–Myoclonus Syndrome (Sialidosis Type 1, α -Neuramidase Deficiency) This is a relatively new and genetically distinct class of disease characterized by the storage in nervous tissue of sialidated glycopeptides. It is due to a neuramidase deficiency. In some of the patients the onset has been in late childhood or adolescence and in others even later. In addition to the patients initially reported by Rapin and coworkers, 24 similar cases have appeared in the medical literature, and we have personally observed examples.

In the cases described by Rapin and colleagues and in two of our own, the first findings were visual impairment with cherry-red macular spots, similar to those seen in Tay-Sachs disease and less consistently in GM₁ gangliosidosis, Niemann-Pick disease, and metachromatic leukodystrophy. In one case there was severe episodic pain in the hands, legs, and feet during hot weather, reminiscent of Fabry disease. Polymyoclonus followed within a few years and, together with cerebellar ataxia, disabled the patients. Mental function remained relatively normal. Liver and spleen were not enlarged, but storage material was found in the Kupffer cells, neurons of the myenteric plexus, and cerebral neurons, and presumably in cerebellar and retinal neurons.

The cases of Thomas and colleagues were young adults, all members of one generation, who had developed dysarthria, intention myoclonus, cerebellar ataxia, and cherry-red macular lesions. Like the cases of Rapin and coworkers, the heredity was autosomal recessive. There was urinary excretion of sialilated oligosaccharides and a sialidase deficiency in cultured fibroblasts. The two patients described by Tsuji and associates are noteworthy in that they were aged 50 and 30 years, respectively. In addition to the macular lesions, polymyoclonia, and cerebellar ataxia, there were gargoyle-like facial features, corneal opacities, and vertebral dysplasia. These patients also had a neuramidase (partial β -galactosidase) deficiency.

Dentatorubral Cerebellar Atrophy with Polymyoclonus This progressive degeneration of the cerebellar-dentatal efferent system was originally described by Ramsay Hunt under the title of *dys-synergia cerebellaris myoclonica*. The onset is in late childhood; both sexes are vulnerable, and it probably has more than one cause. In Hunt's case, a progressive ataxia was accompanied by a striking degree of action myoclonus. Seizures are infrequent and the intellect is relatively preserved. The neurons of the dentate nuclei and their ascending and descending brainstem axons gradually disappear. Berkovic and associates have studied 84 cases of polymyoclonus, 13 of which conformed to the Hunt syndrome. Of these, 9 proved to have a mitochondrial encephalomyopathy. However, there are other reports (Tassinari et al) in which muscle biopsies showed no mitochondrial abnormalities. In the series of 30 cases reported by Marsden and coworkers, the onset was usually before the age of 21 years. Cortical electrographic discharges were found to precede each myoclonic twitch (cortical myoclonus). A biochemically supported diagnosis could not be made in nearly half of their cases.

We have observed restricted, extremely chronic forms of rhythmic myoclonus that involved only the facial and bulbar muscles. Although this benign familial polymyoclonia has not been associated with any biochemical abnormality, its association with cellular mitochondrial abnormalities in some cases justifies its inclusion in this chapter rather than with the degenerative diseases. Another mitochondrial disorder, the myoclonic epilepsy ragged red fiber (MERRF) disease, begins in the second decade or later with myoclonus and ataxia and enters into the differential diagnosis of this group of diseases. The mitochondrial diseases as a group are considered in the last part of this chapter.

Epilepsies of Hereditary Metabolic Disease (See Chap. 16)

Convulsive seizures may complicate nearly all hereditary metabolic diseases. The seizures may occur at all ages but more frequently in the neonate, infant, or young child than in the older child or adolescent. The seizures take many forms, as discussed in Chap. 16. Most often they are generalized grand mal or partial types; typical petit mal probably does not occur. Some diseases may cause focal seizures, simple or complex partial, before becoming generalized. The combination of series of polymyoclonic jerks progressing to a generalized motor seizure is always highly suggestive of one of the hereditary metabolic diseases. Another highly significant form of presentation is with sensory evoked seizures. The subject of epilepsy and the hereditary metabolic diseases has recently been reviewed by Sansaricq and colleagues.

EXTRAPYRAMIDAL SYNDROMES WITH HEREDITARY METABOLIC DISEASE

Parkinsonian Syndromes

Reference is made here to the distinctive extrapyramidal motor disorders described in Chap. 4. In the typical parkinsonian syndrome, with features of rigidity, tremor, and bradykinesia, strength remains relatively intact and corticospinal signs are absent, but effectiveness of movement is nonetheless impaired by the patient's disinclination to use the affected parts (hypo- or akinesia), by slowness (bradykinesia), and by rigidity and tremor. Other clinical syn-

dromes in this category include choreoathetosis, dystonia, and spasms of gaze.

When the parkinsonian syndrome or some component thereof has its onset in middle or late adult life, it usually indicates idiopathic Parkinson disease or related multisystem forms of striatonigral degeneration. The development of such an extrapyramidal motor disorder in late childhood and adolescence instead suggests Wilson disease, Hallervorden-Spatz disease, and the Segawa type of L-dopa-responsive dystonia as well as other so-called Parkin mutations (see Chap. 39).

Hepatolenticular Degeneration (Wilson Disease, Westphal-Strümpell Pseudosclerosis) Wilson's classic description of "Progressive lenticular degeneration: A familial nervous disease associated with cirrhosis of the liver" appeared in 1912. A similar neurologic disorder had been described previously by Gowers (1906) under the title of "tetanoid chorea" and by Westphal (1883) and Strümpell (1898), as "pseudosclerosis." None of these authors, however, recognized the association with cirrhosis. The clinical studies of Hall (1921) and the histopathologic studies of Spielmeyer (1920), who re-examined sections from the liver and brain of Westphal's and Strümpell's cases, clearly established that the pseudosclerosis described by these authors was the same disease as the one that had been described by Wilson. Interestingly, none of these authors, including Wilson, noticed the golden-brown (Kayser-Fleischer) corneal ring, the one pathognomonic sign of the disease. The corneal abnormality was first described by Kayser in 1902, and in the following year Fleischer related it to pseudosclerosis. Rumpell had demonstrated the greatly increased copper content of the liver and brain as early as 1913, but this discovery was generally ignored until Mandelbrote (1948) found, quite by chance, that the urinary excretion of copper was greatly increased in patients with Wilson disease and that it was increased even more after the intramuscular administration of the chelating agent British antilewisite (BAL). In 1952, Scheinberg and Gitlin discovered that ceruloplasmin, the serum protein that binds copper, is reduced in this disease (see reviews by Scheinberg and Sternlieb for a full historical account and references). Denny Brown first demonstrated a recession of symptoms after prolonged treatment with BAL.

The prevalence of the disease cannot be stated exactly but is on the order of 1 per 50,000 to 1 per 100,000 of the general population. Siblings of a patient with Wilson disease have a 1 in 4 risk of developing the disease. The disease is transmitted as an autosomal recessive trait, and the abnormal gene resides on chromosome 13, in the region 13q14. One of the curious aspects of the genetics of the disease is the multitude of mutations within this gene that give rise to the disease, almost akin to an allelic variant at a normal site; and, no one mutation accounts for more than 30 percent of cases. The gene, called ATP7B (homologous with the ATP7A gene, which is defective in Menkes disease), codes for a membrane-bound, copper-binding ATPase. Inadequate functioning of this enzyme in some way reduces excretion of copper in the bile. As noted further on, liver transplantation halts progression of the disease, indicating that the primary biochemical effect of the mutation is in the liver rather than the nervous system.

The genetic defect gives rise to two fundamental disturbances of copper metabolism—a reduced rate of incorporation of copper into ceruloplasmin and a reduction in biliary excretion of copper. The deposition of copper in tissues is the cause of virtually all the manifestations of the disease—cirrhosis, hemolytic anemia, renal

tubular changes, Kayser-Fleischer rings, and, in all likelihood, the cerebral damage—as discussed below.

Clinical Features The onset of neurologic symptoms is usually in the second and less often in the third decade, rarely beyond that time. Half of patients are symptomatic by age 15, but exceptional cases, including two under our care, had their first clinical manifestations as late as their mid-fifties. In all instances the initial event is a deposition of copper in the liver, leading to an acute or chronic hepatopathy and eventually to multilobular cirrhosis and splenomegaly (Scheinberg and Sternlieb). In childhood, the liver disorder often takes the form of attacks of jaundice, unexplained hepatosplenomegaly, or hypersplenism with thrombocytopenia and bleeding. Rarely is there clear evidence of cirrhosis alone. The hepatic abnormalities may be asymptomatic (except for elevated serum transaminases), in which case the initial clinical presentation is neurologic. In some instances, a hemolytic anemia or, less often, renal tubular acidosis may first draw attention to the disease.

The first neurologic manifestations are most often extrapyramidal with a proclivity to affect the oropharyngeal musculature. The typical presentations are tremor of a limb or of the head and generalized slowness of movement (i.e., a parkinsonian syndrome); or slowness of movement of the tongue, lips, pharynx, larynx, and jaws, resulting in dysarthria, dysphagia, and hoarseness; or there may be slowness of finger movement and occasionally choreic movements or dystonic postures of the limbs. Often the mouth is held slightly open in the early stage of the disease. Exceptionally, an abnormality of behavior (argumentativeness, impulsiveness, excessive emotionality, depression, delusions) or a gradual impairment of intellectual faculties precedes other neurologic signs by a year or more (see Starosta-Rubinstein et al.).

As the disease progresses, the “classic syndrome” evolves: dysphagia and drooling, rigidity and slowness of movements of the limbs; flexed limb postures; fixity of facial muscles with mouth constantly agape, giving an appearance of grinning or a “vacuous smile”; dysarthria or virtual anarthria (bulbar extrapyramidal syndrome); and a tremor in repose that increases when the limbs are outstretched to a coarse, “wing-beating” movement. Slowed saccadic eye movements and limitation of upgaze are also characteristic. A notable feature is the tendency for the motor disorders to be concentrated in the bulbar musculature and to spread caudally. Thus, the syndrome differs from classic parkinsonism. Usually elements of cerebellar ataxia and intention tremor of variable degree are added at some stage of the disease. Approximately 6 percent of patients develop seizures (Dening et al.). Gradually the disability increases because of increasing rigidity and tremor. The patient becomes mute, immobile, extremely rigid, dystonic, and slowed mentally, the latter usually being a late and variable effect.

With progression of the neurologic disease, the *Kayser-Fleischer rings* become more evident (Fig. 37-7). They take the form of a crescentic rusty-brown discoloration of the deepest layer of the cornea (Descemet’s membrane). In the purely hepatic stage of the disease, the rings may not be evident (in 25 percent of cases), but they are invariably present once the neurologic signs become manifest. A slit-lamp examination may be necessary for their early detection, particularly in brown-eyed patients, but in the majority of patients with neurologic signs the rings can be visualized with the naked eye or with the aid of an indirect ophthalmoscope focused on the limbus.

The diagnosis is virtually certain when there is a similar syndrome in a sibling or when an extrapyramidal motor disorder of this type is conjoined with liver disease and the corneal rings. Var-

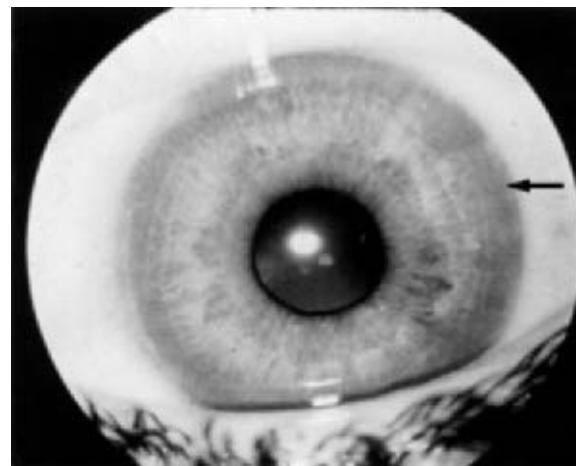

Figure 37-7. Kayser-Fleischer corneal ring (arrow) in Wilson disease. (Reproduced by permission from Lyon et al.)

iants of the above syndrome that the authors have seen are an early choreoathetosis (like Sydenham chorea); prominent dystonic postures; a cerebellar ataxia with minimal rigidity; a syndrome of coarse action or action and intention tremor resembling that of dentatorubral degeneration; an immobile mute state with profound rigidity; and a dementia, character change, or psychosis with relatively few extrapyramidal signs. Action myoclonus as a prominent early manifestation has also been described. The parkinsonian features do not respond to L-dopa treatment.

Laboratory Findings In both the typical and variant forms of the disease, the finding of a low serum ceruloplasmin level (less than 20 mg/dL in 80 to 90 percent of patients), low serum copper (3 to 10 mM/L; normal 11 to 24 mM/L), and increased urinary copper excretion (more than 100 mg Cu/24 h) corroborate the diagnosis. Because 90 percent of copper is carried by ceruloplasmin and the latter is generally reduced in Wilson disease, serum copper values alone may be misleadingly normal. Early in the course of the illness, the most reliable diagnostic findings are a high copper content in a biopsy of liver tissue (more than 200 mcg Cu/g dry weight) and a failure to incorporate labeled ^{64}Cu into ceruloplasmin. The latter test, however, fails to dependably differentiate asymptomatic carriers from affected individuals. Measurement of increased curopresis after the administration of penicillamine has not been shown to be more sensitive than an unenhanced 24-h urine collection for copper. Persistent aminoaciduria, reflecting a renal tubular abnormality, is present in most but not all patients. Liver function tests are usually abnormal; some patients are jaundiced and other signs of liver failure may appear late in the illness. In these patients, the serum ammonia may be elevated and the symptomatology may worsen with increases in dietary protein. The cirrhosis is not always evident in a liver biopsy (some regenerative nodules are large, and the biopsy may be taken from one of them). On the other hand, the diagnosis in children may be revealed when a liver biopsy is taken for the evaluation of cirrhosis. As mentioned earlier, the large number of mutations that give rise to the disease makes it impractical to use genetic analysis for diagnosis, but once the gene abnormality has been established in a given family, linkage studies may be used to identify other affected sibs.

It has been established that copper deposition in the liver is the initial disturbance; over time it leads to cirrhosis, so that, as already mentioned, the hepatic stage of the disease precedes neu-

rologic involvement. Cranial CT scans are abnormal even in the hepatic stage and are invariably so when the neurologic disorder supervenes. The lateral ventricles and often the third ventricle are slightly enlarged, the cerebral and cerebellar sulci are widened, the brainstem appears shrunken, and the posterior parts of the lenticular nuclei, red nuclei, and dentate nuclei become hypodense (Ropper et al). With treatment, these radiologic changes become less marked (Williams and Walshe). MRI is an even more sensitive means of visualizing the structural changes, particularly those in the subcortical white matter, midbrain, pons, and cerebellum (Starosta-Rubinstein et al). In the MRI survey by Saatci and colleagues, the putamen was involved most frequently (though not invariably), showing a symmetrical T2 signal change in a laminar pattern; there was also an increase in T1 signal throughout the basal ganglia, particularly in the pallidum. Signal changes are almost universally found in the claustrum and also in the midbrain (pars compacta of the substantia nigra), dentate nucleus of the cerebellum, pons, and thalamus. We have been impressed with a glassy diffuse and confluent signal abnormality on T2-weighted and FLAIR images in the hemispherical white matter in some cases—findings that were mistaken for multiple sclerosis.

Neuropathologic Changes These vary with the rate of progress of the disease. Exceptionally, in the rapidly advancing and fatal form, there is frank cavitation in the lenticular (putaminal and pallidal) nuclei, as observed in Wilson's original cases. In the more chronic form there is only shrinkage and a light-brown discoloration of these structures. Nerve cell loss and some degree of degeneration of myelinated fibers in lenticular nuclei, substantia nigra, and dentate nuclei are usually apparent. Subcortical myelin degeneration is found in some cases. More striking, however, is a marked hyperplasia of protoplasmic astrocytes (Alzheimer type II cells) in the cerebral cortex, basal ganglia, brainstem nuclei, and cerebellum, almost certainly a reaction to liver failure and hyperammonemia.

Treatment Ideally treatment should be started before the appearance of neurologic signs; if this can be effected, neurologic deterioration can be prevented to a large extent. Treatment consists of (1) reduction of dietary copper to less than 1 mg/day, which can usually be accomplished by avoidance of copper-rich foods (liver, mushrooms, cocoa, chocolate, nuts, and shellfish), and (2) administration of the copper chelating agent D-penicillamine (1 to 3 g/day) by mouth, in divided doses. Pyridoxine 25 mg/day should be added in order to prevent anemia. The use of D-penicillamine is associated with a number of problems. Sensitivity reactions to the drug (rash, arthralgia, fever, leukopenia) develop in 20 percent of patients and require a temporary reduction of dosage or a course of prednisone to bring them under control. Reinstatement of drug therapy should then be undertaken, using low dosages (250 mg daily) and, later, small, widely spaced increases. If the patient is still sensitive to D-penicillamine or if severe reactions (lupus-like or nephrotic syndromes) occur, the drug should be discontinued and another chelating agent, triethylene tetramine (trientene) or ammonium tetrathiomolybdate may be substituted. Zinc, which blocks the intestinal absorption of copper, is also a suitable treatment, but ineffective alone. It is given as zinc acetate, 100 to 150 mg daily in three to four divided doses at least 1 h before meals (Hoogenraad et al). The appropriate drug must then be continued for the patient's lifetime. Some women report improvement in neurologic symptoms during pregnancy, although there is no apparent change in copper metabolism during this time. In most patients, neurologic signs improve in response to decoppering agents. The Kayser-

Fleischer rings disappear and liver function tests may return to normal, although the abnormalities of copper metabolism remain unchanged. In moderately severe and advanced cases, clinical improvement may not begin for several months despite full doses of D-penicillamine, and it is important to resist discontinuing the drug during this latent period. One of our patients had a complete remission of severe neurologic symptoms with penicillamine treatment and has remained symptom-free for 30 years.

It is also well known that the institution of treatment with penicillamine may induce an abrupt worsening of neurologic signs, and we have witnessed several such instances, including one that culminated fatally from a cardiac arrhythmia. Furthermore, in many of these patients, the lost function is never retrieved. Presumably this deterioration may be due to the rapid mobilization of copper from the liver and its redistribution to the brain. The slow introduction of penicillamine may avoid this complication. The additional use of zinc or one of the newer agents mentioned above should be instituted as soon as neurologic deterioration becomes evident. In at least one reported case, new lesions of Wilson disease (shown by MRI) developed while the patient was receiving full doses of D-penicillamine and excellent decoppering of the liver had occurred (Brewer et al). In the few patients who develop epilepsy, the seizures may become apparent soon after therapy is begun.

Many wilsonian patients with advanced liver disease have been subjected to liver transplantation, which is curative for the underlying metabolic defect. The degree of neurologic improvement varies; in some it has been remarkable and sustained, confirming that the hepatic defect is primary and that the brain is involved secondarily. According to Schilsky and coworkers, the main indication for transplantation is severe and progressive liver damage, but the operation has been used successfully in some patients with intractable neurologic deterioration and only mild signs of liver disease.

An important aspect of treatment is the screening of potentially affected relatives for abnormalities of serum copper and ceruloplasmin; if any relative is found to have the disease, penicillamine should be given indefinitely to prevent the emergence of neurologic symptoms. A full explanation of the dangers of ceasing the medication must be given, and compliance may have to be monitored.

Hereditary Deficiency of Ceruloplasmin This is a rare illness, quite similar to Wilson disease, occurring in patients with a recessively inherited deficiency of ceruloplasmin; it is not simply a heterozygous form of Wilson disease (the mutation involves a different gene). Cirrhosis and Kayser-Fleischer rings are not features of the disease, but diabetes is common and extrapyramidal signs may or may not arise. Rather than copper, iron is deposited in the brain and liver (see discussion by Logan). Those few cases that have been well studied, mainly Japanese, show mainly an ataxic disorder (Miyajima et al).

Also noted here is a rare and poorly characterized progressive myopathy that closely simulates subacute combined degeneration of B_{12} deficiency; it recently has been associated with low serum copper levels (page 1078).

Hallervorden-Spatz Disease This disease is also known as *pigmentary degeneration of the globus pallidus, substantia nigra, and red nucleus*. It is inherited as an autosomal recessive trait and is due, in all classic cases, to a defect in the gene encoding pantothenate kinase 2 (PANK2) usually in the form of a missense mutation. The onset of symptoms is in late childhood or early adoles-

cence, and it progresses slowly over a period of 10 or more years. The early signs are highly variable but are predominantly motor, both corticospinal (spasticity, hyperreflexia, Babinski signs) and extrapyramidal (rigidity, dystonia, and choreoathetosis). General deterioration of intellect is conjoined. In individual cases, ataxia and myoclonus have appeared at some phase of the illness. The spasticity and rigidity are most prominent in the legs, but in some instances they begin in the bulbar muscles, interfering with speech and swallowing, as happens in Wilson disease. We have observed patients who, over a period of years, exhibited only dystonia of the tongue, blepharospasm, or arching of the back. The relationship of this restricted form to the complete syndrome remains unsettled. Eventually, the patient becomes almost completely inarticulate and unable to walk or use his or her arms. Optic atrophy has been mentioned in a few reports, but we have not observed it. Hayflick and colleagues have found that only one-third of patients with atypical forms of the disease have mutations of the PANK2 gene, and these are of a different type than in the classic disease. Moreover, variant cases tended not to show the characteristic changes on MRI described below.

Reduced levels of PANK2 corroborate the diagnosis, but this test is available only in research laboratories with an interest in the disease. The characteristic deposits of iron in the basal ganglia have not been associated with a demonstrable abnormality of serum iron or of iron metabolism. It has, however, been reported that there is a high uptake of radioactive iron in the region of the basal ganglia following intravenous injection of labeled ferrous citrate (Vakili et al, Szanto and Gallyas). CT scanning reveals hypodense zones in the lenticular nuclei, resembling those of hepatolenticular degeneration, sulfite oxidase deficiency, glutaric aciduria, and Leigh disease, although high-density lesions have been described in one autopsy-proven case of this disease (Tennison et al).

The MRI findings are striking (Fig. 37-8). In T2-weighted images, the pallidum appears intensely black, with a small white area in its medial part ("eye of the tiger" sign; see also Savoirdo et al).

The neuropathology proves to be the most distinctive attribute of the disease. There is an intense brown pigmentation of the globus pallidus, substantia nigra (especially the anteromedial parts), and

red nucleus. Granules and larger amorphous deposits of iron mixed with calcium stud the walls of small blood vessels or lie free in the tissue. A loss of neurons and medullated fibers occurs in the most affected regions. Another unique feature is the presence of swollen axon fragments, which resemble those of neuroaxonal dystrophy; for this reason, some neuropathologists regard Hallervorden-Spatz disease as a juvenile form of neuroaxonal dystrophy. Iron deposits are less conspicuous in the latter disease, leaving this interpretation in doubt. The significance of iron deposition is difficult to judge. To some extent, there is an increase of iron in the basal ganglia in other degenerative diseases. In Parkinson disease and striatonigral degeneration, for example, the deposition of iron is two to three times normal, presumably the result of degeneration of those tissues that are known to be rich in iron.

No treatment is known to be effective. Some of our patients responded temporarily to L-dopa, but the effect was slight. The use of chelating agents to reduce iron storage has not helped.

Differential Diagnosis of Wilson and Hallervorden-Spatz Diseases

Disorders that must be differentiated from Wilson and Hallervorden-Spatz diseases are tardive dyskinesia, restricted forms of dystonia, adult and juvenile Parkinson disease and the related Segawa type of L-dopa-responsive dystonia, early-onset rigid form of Huntington chorea, status dysmyelinatus, Fahr disease (see below), Lafora-body disease, Leigh subacute necrotizing encephalomyopathy, multiple sclerosis, dentatorubropallidolysian degeneration, ceroid lipofuscinosis, polyglucosan disease, and other rare, presumably biochemical disorders of unknown type. Several probable cases evoking these different diagnoses have come to our attention; in each there were some components of the extrapyramidal picture of Wilson disease but without evidence of liver involvement or copper abnormality. Difficult to categorize are diseases such as the one reported by Willvonseder and colleagues and by Tagawa and coworkers—in which a mild dementia, spastic dysarthria, paresis of vertical eye movements, gait disturbance, and splenomegaly came on during early adult life. Here, abnormalities of copper metabolism were found (slightly decreased serum ceruloplasmin, copper turnover values in the range of those in heterozygous carriers of Wilson disease), but there was no increase in urinary copper excretion. It is not known if they carry the Wilson gene. The authors have seen two such patients. One in her fifties had the subacute onset of parkinsonism with severe dysarthria, Wilsonian facies, mild ataxia, and exaggerated facial and limb reflexes. There were no Kayser-Fleischer rings. There were symmetrical signal changes in the MRI in the pallidum and dentate nucleus and diffusely through the white matter. She stabilized without treatment.

In families known to have Huntington chorea, children and some adults may be afflicted with a predominantly rigid-parkinsonian form (Westphal variant). About 5 percent of all cases of Huntington chorea are of this "juvenile type." Rather than a movement disorder, this condition is marked by a slow decay in intellect, slurred speech, rigidity of the limbs, short-stepped gait, and flexion hypertonia of the limbs and trunk. Nevertheless, choreoathetosis does eventually appear in most cases. Ocular movements are full except for upward gaze. The disease is inexorably progressive, and eventually the patient becomes mute and rigidly immobile, with mouth agape, limbs flexed, and hands fisted in fixed, dystonic postures. Progressive supranuclear palsy may for a considerable period of time lack the characteristic limitation of vertical gaze, or it may be minimal. The main features are then axial rigidity, extension

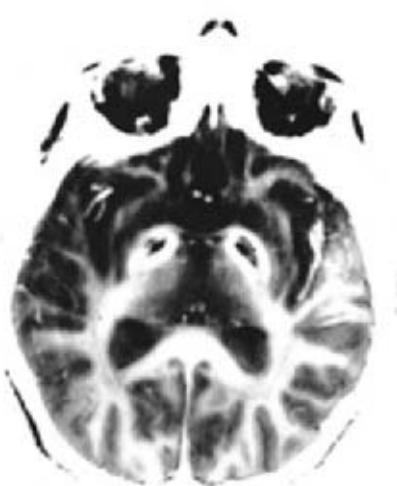

Figure 37-8. Hallervorden-Spatz disease. T2-weighted MRI showing areas of decreased signal intensity of the pallidum bilaterally (corresponding to iron deposition) and a central high signal area due to necrosis ("eye of the tiger" sign).

dystonia of the neck, and some rigidity and dystonia of the limbs. This differentiation has presented problems in diagnosis in a few of our patients whose illness began in their late forties or fifties. See Chap. 39 for discussion of the neuropathology and treatment of these two diseases.

Juvenile paralysis agitans was described by Ramsay Hunt in 1917. Judging by the descriptions, the resemblance to adult Parkinson disease is close. The course was slowly progressive. Postmortem examination showed a shrinkage of the lenticular nuclei and a loss of large cells in the pallidum, but in an anatomic specimen from van Bogaert's laboratory (the age of onset was 7 years), cell loss was noted in the substantia nigra and pallidum. This type of case is being increasingly recognized and is probably related to the early-onset type of parkinsonism-dystonia that is responsive to L-dopa or to one of the emerging group of mutations of the Parkin gene, as discussed in Chap. 39.

In isolated late-life cases of Lafora-body disease (discussed earlier in this chapter), there may be rigidity, akinesia, and tremor; but usually myoclonus, seizures, and dementia dominate the picture. Rarely, the mitochondrial disorder of Leigh disease (described later in the chapter) gives rise to a slowly evolving extrapyramidal rigidity in late childhood or adolescence, with bilateral cavitation of the putamen in CT scans.

The differential diagnosis of the aforementioned diseases continues to present certain difficulties. The recognition of Hallervorden-Spatz disease was for many years a clinical problem bereft of a satisfactory laboratory test, but this has been partially simplified by MRI. The similarities between the diseases included under the rubric of the Parkinson syndrome are in general smaller than the differences. Wilson disease, for example, shares certain signs with Parkinson disease, yet each possesses distinctive features of each. The special qualities of the facial expression in Wilson disease—as well as the dysarthria, severe ataxic tremor, rigidity, and dystonia—are not likely to be confused with Parkinson disease. Furthermore, in several of the diseases in this category, there may be myoclonus and extrapyramidal signs such as choreoathetosis, dystonia, and so on, which are essential parts of the next category of syndromes. Therefore one must not insist that each disease conform strictly to a unique clinical syndrome.

Syndromes of Dystonia and Generalized Chorea and Athetosis

As indicated in Chap. 4, the differences between dystonia and choreoathetosis are not fundamental. If one examines many patients with these involuntary movements, every gradation between the two is seen, and not infrequently, the quicker, unpatterned involuntary movements of mild ballismus are added. Even tremor and myoclonus may complicate the composite movement disorder. With reference to muscular tone in patients with athetosis and dystonia, there are unpredictable associations of hypertonia and hypotonia.

A number of inherited metabolic diseases, all of them rare, express themselves by this syndrome of chorea, athetosis, and dystonia.

The Lesch-Nyhan Syndrome and Hyperuricemia This rare metabolic disease is inherited as an X-linked recessive trait. Although it carries the names of Lesch and Nyhan (1964), the occurrence of uricemia in association with spasticity and choreoathetosis in early childhood had been described earlier by Catel and Schmidt.

Essentially it is a hereditary choreoathetosis with self-mutilation and hyperuricemia. The affected children appear normal at birth and usually develop on schedule up to 3 to 6 months of age. Maturational delay then sets in, initially with hypotonia that later gives way to hypertonia. Also, the patient's behavior becomes abnormal, with aggressiveness and compulsive actions. The uncontrollable self-mutilation, mainly of the lips, occurs early (during the second and third year), and spasticity, choreoathetosis, and tremor come later. Most of the children learn to walk. Speech is delayed, and once attained, it is dysarthric and remains so throughout life. Mental retardation is moderately severe. In patients more than 10 years of age, gouty tophi appear on the ears, and there is increasing risk from gouty nephropathy. The serum levels of uric acid are in the range of 7 to 10 mg/dL.

A deficiency of the enzyme hypoxanthine-guanine-phosphoribosyl transferase (HPRT) has been found in all typical cases of this disease. The HPRT gene lies on the X chromosome (Xq 26-q 27), and accurate diagnosis of affected males and carriers can be made by DNA analysis. As a result of this deficiency, hypoxanthine is either excreted or catabolized to xanthine and uric acid. The details of the biochemical abnormality responsible for CNS dysfunction are unclear.

In the differential diagnosis, one must consider nonspecific mental retardation or autism with hand biting and other self-mutilations, athetosis from birth trauma, and encephalopathies with chronic renal disease. Hyperuricemia has also been reported in a family with spinocerebellar ataxia and deafness and in another with autism and mental retardation, neither of them with the enzymatic defect of Lesch-Nyhan disease. As mentioned earlier, there are several other disorders of purine and pyrimidine metabolism, some of them with hyperuricemia, that present with a neurologic syndrome like that of Lesch-Nyhan.

Treatment This is with the xanthine oxidase inhibitor allopurinol, which blocks the last steps of uric acid synthesis, reduces the uric acid in Lesch-Nyhan disease, and prevents the uricosuric nephropathy, but it seems to have no effect on CNS symptoms. Guanosine 5-monophosphate and inosine 5-monophosphate, both of which are deficient in Lesch-Nyhan disease, have been replaced without benefit to the patient. Transitory success has also been achieved by the administration of 5-hydroxytryptophan in combination with L-dopa. Fluphenazine (Prolixin) is reported to have suppressed the self-mutilation after haloperidol (Haldol) had failed to do so. Behavior modification programs may be of some value.

Calcification of Vessels in Basal Ganglia and Cerebellum (Hypoparathyroidism and Fahr Syndrome) Ferruginization and calcification of vessels in the basal ganglia occur to a slight degree in many elderly persons (and in other mammals) who are otherwise normal. The widespread use of CT scans and MRI has brought the condition to light with increasing frequency (Fig. 37-9). Usually it may be dismissed as an aging phenomenon of no clinical significance. When it occurs early in life and is of such degree as to be visible in plain films of the skull, it must always be regarded as abnormal. An adult case of this type was described by Fahr, so that his name is sometimes attached to this disorder, but it was known long before his publication appeared, and his account added little to our knowledge of the condition.

Many authors have called attention to a form of calcification of the basal ganglia and cerebellum in which choreoathetosis and rigidity are prominent. The clinical state may also take the form of a parkinsonian syndrome or bilateral athetosis. In two of our pa-

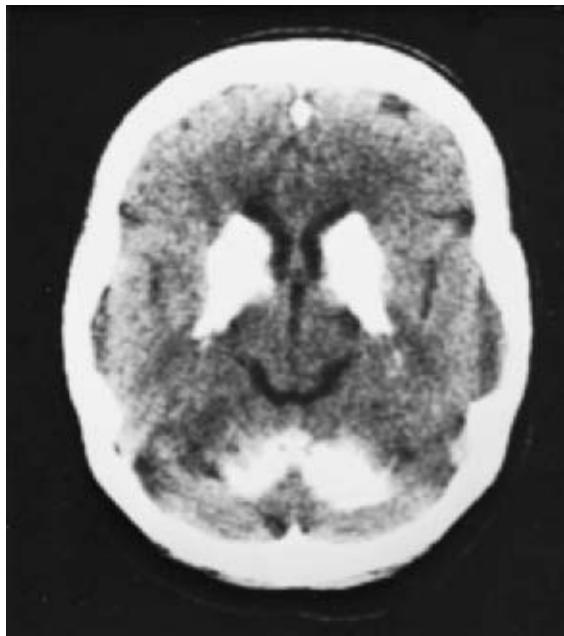

Figure 37-9. Idiopathic basal ganglionic and cerebellar calcification discovered 5 years after the onset of a slowly progressive rigid Parkinson syndrome in a 54-year-old woman.

tients there was a unilateral choreoathetosis, which was replaced gradually by a parkinsonian syndrome, and in another of our sporadic cases, the initial abnormality was a unilateral dystonia, responsive to L-dopa. Some patients have been mentally retarded, others intellectually intact. We have observed a familial form of basal ganglionic–cerebellar calcification inherited as an autosomal recessive trait. Its onset was in adolescence and early adult life, and it presented clinically as a complex syndrome of choreoathetosis, tremor, ataxia, and dementia. The serum calcium levels in the aforementioned types of cases are usually normal, and there is no explanation of the calcification. This was also true of our cases. In a family described by Martinelli and colleagues, there was autosomal dominant inheritance and abnormal vitamin D metabolism.

In hypoparathyroidism (idiopathic or acquired) and pseudohypoparathyroidism (a rare familial disease characterized by the symptoms and signs of hypoparathyroidism in association with distinctive skeletal and developmental abnormalities), the diminution in ionized serum calcium induces not only tetany and seizures but sometimes choreoathetosis as well. This last symptom is presumably due to calcification of the basal ganglia, which occurs in about one-half of the patients. Also, in some instances there are signs of a cerebellar lesion.

Sly and colleagues have described the familial occurrence (21 cases in 12 families) of calcification in the caudate and lenticular nuclei, thalamus, and frontal lobe white matter in association with osteopetrosis (“marble bones”) and renal tubular acidosis. Clinically there were multiple cranial nerve palsies—including optic atrophy as well as psychomotor delay and learning disabilities—but no extrapyramidal signs. The cranial nerve palsies, which are due to bony encroachment in neural foramina, were much less severe than in the lethal form of osteopetrosis. The pattern of inheritance of this disease is autosomal recessive, and the basic abnormality was found to be a deficiency in carbonic anhydrase II in red blood corpuscles and probably in kidney and brain.

Other Metabolic Disorders Associated with Choroathetosis and Dystonia Exceptionally, ceroid-lipofuscinosis of the Kufs type, GM₁ gangliosidosis, late-onset metachromatic leukodystrophy, Niemann-Pick disease (type C), Hallervorden-Spatz disease, and Wilson disease may present with a syndrome of which dystonia or athetosis is an important component. Usually, there are other elements in the clinical picture as well, so that the correct diagnosis is seldom in doubt for long. Dal Canto and colleagues have described a variant of neuronal ceroid-lipofuscinosis in which a boy and girl of unrelated non-Jewish parents developed severe choroathetosis and dystonia at 6 to 7 years of age. Intellectual deterioration, gait abnormality, and seizures were added clinical features. Cerebral biopsy showed intraneuronal inclusions consisting of curvilinear bodies. These observations support the notion of nosologic heterogeneity among the nonglycolipid neuronal storage disorders.

Glutaric acidemia (type I) is another rare metabolic disorder, in which progressive choroathetosis and dystonia are combined with an intermittent acidemia. In some cases, ataxia of movement and a variable degree of mental retardation are also present. Glutaric acid is present in the urine, as are its metabolites 3-OH glutarate and glutamate. The basic defect is in glutaryl CoA dehydrogenase, which has been found in leukocytes, hepatocytes, and fibroblasts. Neuropathologically, there is loss of neurons in the caudate, putamen, and pallidum, with gliosis. A spongy change is said to affect the white matter.

Infants with glutaric acidemia are often subject to sudden episodes of acidosis, coma, and flaccidity. There are signal changes on MRI, corresponding to the acute necrosis of nerve cells in the basal ganglia. These crises can be prevented and the infants can develop normally if the diagnosis is made before the development of neurologic signs, for example, in the sibling of an older affected child, and treatment is undertaken with a diet low in protein, particularly in tryptophan and lysine (Cho et al).

It should be pointed out that acquired extrapyramidal disorders are much more common than inherited ones. A prototype of athetosis is known to follow hypoxic encephalopathy of birth, leading to *état marbré*; of the basal ganglia. This is the basis of the double athetosis syndrome that usually becomes manifest only after the first year of life and persists thereafter (page 878). The Rh and ABO blood incompatibilities that induce erythroblastosis fetalis and *kernicterus* are another cause of a bilateral athetosis at about the same period of life, but this syndrome is distinguished by intense and prolonged neonatal jaundice and the added features of deafness and paralysis of upward gaze (page 878). The same is true of the Crigler-Najjar form of hereditary hyperbilirubinemia, in which kernicterus (with ataxia or athetosis) may rarely appear as late as childhood or adolescence, the defect being one of glucuronicide-bilirubin conjugation. Later in life, the antiphospholipid antibody syndrome may induce chorea as a presenting feature (see page 735).

Finally, a number of other rare diseases, which can only be classified as heredofamilial degenerations, must also figure in the differential diagnosis of choroathetotic or dystonic syndromes and are covered in Chap. 39. Torsion dystonia is the best-known example. Another is the familial dystonia with certain features of Parkinson disease which is highly responsive to L-dopa (Segawa disease). The distinctive chorea-acanthocytosis syndrome is described on page 913. A nonprogressive familial choroathetosis with onset in early childhood has been reported by Pincus and Chutorian; here, cerebellar signs were usually conjoined but the

intellect was spared. This syndrome is probably inherited as an autosomal recessive trait. A paroxysmal and sometimes kinesogenic form of *familial choreoathetosis* was recognized by Mount and Reback in 1940 and subsequently elaborated upon by Lance (page 68). One wonders in retrospect if some of these patients were dopamine-responsive. We have observed attacks of this kind in children with "cerebral palsy" as a manifestation of phenytoin (or carbamazepine) toxicity; lowering the dose of the drug terminated the attacks. Sethi and coworkers have described an adult with dementia and choreoathetosis, simulating Huntington chorea, in whom episodic nausea, vomiting, and lethargy during childhood were due to propionic aciduria. The movement disorder did not appear until the patient was 28 years old. In others, the chorea begins in infancy and persists despite all attempts at treatment. The authors have grouped this disease with the other inherited choreas (Huntington disease, neuroacanthocytosis, familial calcification of basal ganglia, Hallervorden-Spatz disease, acanthocytic chorea, dentatorubrothalamic atrophy).

Most of the above-mentioned diseases are presently classified as degenerative and are discussed in Chap. 39.

SYNDROMES OF BILATERAL HEMIPLEGIA, CEREBRAL BLINDNESS, AND OTHER MANIFESTATIONS OF DECEREBRATION (THE LEUKODYSTROPHIES)

Categorized here are the features that characterize disorders of the cerebral white matter by which most of the familial leukodystrophies are expressed. Of the several varieties of late-onset leukodystrophy, some are of unquestionable metabolic origin and others are of uncertain status. The terms *metachromatic*, *sudanophilic*, *orthochromic*, etc., refer to the distinctive products of myelin degeneration and staining characteristics (or lack thereof) of the white matter in the individual leukodystrophies. As emphasized earlier, all differ from the cerebral gray matter diseases (poliodystrophies), which have a different mode of presentation—seizures, myoclonus, chorea, choreoathetosis, and tremor being prominent. Instead, recognition of the entire group of leukodystrophies is based on symptoms and signs attributable to the interruption of tracts (corticospinal, corticobulbar, cerebellar peduncular, sensory, medial longitudinal fasciculi) and visual pathways (optic nerve, optic tract, geniculocalcarine) and the infrequency or absence of seizures, myoclonus, and spike-and-wave abnormalities in the EEG. However, this distinction is not infallible, particularly in the later stages of the disease.

The syndrome of progressive spasticity and rigidity with spastic dysarthria and pseudobulbar palsy poses another difficult diagnostic problem. One's first impulse is to assume the presence of a corticospinal disorder, especially if tendon reflexes are brisk, but frequently the plantar reflexes are flexor and the facial reflexes are not enhanced. In addition, unusual postures and a more plastic type of rigidity may occur, consistent with an extrapyramidal condition. Furthermore, the combination of reduced or absent tendon reflexes and Babinski signs, signifying a combination of corticospinal and peripheral nerve lesions, is highly characteristic of metachromatic leukoencephalopathy, adrenomyeloneuropathy, or subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency). Such combinations, with mental backwardness and dementia, characterize the mild and late forms of metachromatic leukodystrophy.

The leukodystrophies that become apparent only in later life pose another problem—the clinical and radiologic differentiation from cerebral forms of multiple sclerosis. In cases of early onset, in which myelin has yet to be normally formed, the metabolic disturbance may result in hypomyelination (e.g., Pelizaeus-Merzbacher disease); by contrast, the process in adolescent or adult-onset cases is one of destruction of myelin already formed. In identifying the metabolic diseases of myelin, one is helped by the relative symmetry and steady progression of the clinical signs; the early onset of cognitive impairment (which is uncharacteristic of multiple sclerosis); and the symmetrical and massive degeneration of the cerebral white matter (in distinction to the asymmetrical and often multiple lesions of demyelinative disease). At various times in life, particularly in young individuals, the rare vascular disorder called CADASIL enters into the differential diagnosis (see Chap. 34); late in life, distinguishing a metabolic disorder of myelin from the subcortical multiple infarctions of Binswanger disease and from the ubiquitous rarefaction of the periventricular regions of the cerebrum may be a problem. Differentiation from cerebral gliomatosis, brain lymphoma, and progressive multifocal leukoencephalopathy, all affecting deep cerebral or white matter structures, offers less difficulty.

Adrenoleukodystrophy (ALD); Sudanophilic Leukodystrophy with Bronzing of Skin and Adrenal Atrophy

This combination of leukodystrophy and Addison disease, originally included under the rubric of Schilder disease, is now set apart as an independent metabolic encephalopathy. It is transmitted as an X-linked recessive trait with an incidence of 1 in 20,000 male births. The fundamental defect is an impairment in peroxisomal oxidation of very-long-chain fatty acids (VLCFAs), leading to their accumulation in the brain and adrenal glands (see the publications of H. Moser and of Igarashi and associates). The deficient membrane protein, encoded by a gene that maps to chromosome X28, is a peroxisomal membrane transporter (ABCD1). The gene is located close to the gene for color vision. In the typical X-linked ALD, there is an inability to metabolize VLCFAs, but it came as a surprise that the disease was not caused by an enzyme deficiency. The modern classification of the disease categorizes it as a disorder of peroxisomes, subcellular organelles containing numerous enzymes. This peroxisomal assignation connects adrenoleukodystrophy with Zellweger and Refsum disease.

The onset is usually between 4 and 8 years, sometimes later; in the most common form of this disorder, only males are affected with the entire syndrome (women carriers may display a special myelopathy discussed further on). The signs of either the adrenal insufficiency or the cerebral lesion may be the first to appear. In the case of Siemerling and Creutzfeldt, the first recorded example of this disorder, bronzing of the skin of the hands appeared at 4 years of age; quadripareisis, with dysarthria and dysphagia (i.e., pseudobulbar palsy), became evident at 7 years; a single seizure occurred at 8 years; and by 9 years, shortly before death, the patient was *decerebrate* and unresponsive. In personally observed cases, the first abnormalities appeared at 9 to 10 years and took the form of episodic vomiting, decline in scholastic performance, and change in personality, with silly, inappropriate giggling and crying. After a time, severe vomiting and even an episode of circulatory collapse occurred, following which the gait became unsteady and arms ataxic, with an action or intention tremor. Only then did the addisonian increase of pigmentation of the oral mucosa and the

skin around nipples and over elbows, knees, and scrotum become evident. *Cortical blindness* followed in some instances. The late stages were marked by bilateral hemiplegia (at first asymmetrical), pseudobulbar paralysis, blindness, deafness, and impairment of all higher cerebral functions.

The severity of the disease varies. We are caring for two adult men in whom the cerebral symptoms have been mild, allowing for high-level cognitive achievement, albeit with peculiarities of personality, and with mild spastic gait, urinary difficulty, testicular insufficiency, and baldness. In each family there was a male sibling who died in childhood, ostensibly of adrenal insufficiency.

Griffin and coworkers have described a spinal-neuropathic form of the disease (adrenomyeloneuropathy, AMN). In their patients, evidence of adrenal insufficiency had been present since early childhood, but only in the third decade of life did a progressive spastic paraparesis and a relatively mild polyneuropathy develop. It should be noted that the spasticity is occasionally asymmetrical, and the gait may have an ataxic component. This neurologic picture, in mild form and without adrenal insufficiency, is also the manner in which the disease may present in *female carriers of the gene abnormality* (see below). Like adrenoleukodystrophy, AMN is typically inherited as an X-linked, male-specific trait. However, we have encountered a large family with adrenomyeloneuropathy in which males and females are both affected in a pattern that suggests dominant inheritance. The VLCFAs are modestly elevated in affected individuals, and there is no evidence of cerebral involvement.

Moser and colleagues, using clinical and biochemical criteria, have identified the following subtypes of ALD:

1. A progressive degeneration of cerebral white matter in young males, often with cortical blindness—the classic type, accounting for half of all cases (Fig. 37-10)
2. An intermediate form in juvenile or young adult males with cerebral and spinal involvement (5 percent of cases)
3. A progressive spinal cord tract degeneration in adult males (25 percent of cases)
4. A chronic mild, nonprogressive spastic paraparesis in *heterozygous female carriers* (10 percent of cases)
5. Familial instances of Addison disease without neurologic involvement in males (10 percent)
6. Possibly, in male infants, a form originating at birth (e.g., Zellweger disease)

Illustrating the variability in presentation among kindreds, Marsden and colleagues and, subsequently, Kobayashi and co-workers described a familial spinocerebellar syndrome, and Ohno and associates have reported a sporadic instance of adrenoleukodystrophy presenting as olivopontocerebellar atrophy. Moser found cerebral forms alone in 30 percent, adrenomyeloneuropathy alone in 20 percent, and combined childhood cerebral and myelopathic forms in the remaining half.

Female Heterozygotes Neurologic manifestations have been said to develop in up to 50 percent of female carriers, but in our experience with siblings of affected patients, the figure has been lower. The onset of a *spastic paraparesis* tends to occur later in life, usually in the third or fourth decade, and progression tends to be slow, but an explosive onset has been reported (see Chap. 44). As already mentioned, multiple sclerosis is the main consideration in differential diagnosis, particularly since 20 percent of heterozygotes have

Figure 37-10. Adrenal leukodystrophy in a 7-year-old male. Confluent areas of increased signal involving the frontal, occipital, and parietal white matter (thick arrow) and of the anterior and posterior portions of the corpus callosum (long-stemmed arrows). Reproduced by permission from Bisese JH: *Cranial MRI*. New York, McGraw-Hill, 1991.)

white matter changes on cerebral MRI. Overt adrenal insufficiency is rare in female carriers, but scalp hair may be scant as a subtle manifestation of adrenal hypofunction.

Pathologically in classic instances, massive degeneration of the myelin occurs, often asymmetrically in various parts of the cerebrum, brainstem, optic nerves, and sometimes spinal cord (Fig. 37-10). Degradation products of myelin (sudanophil-positive) are visible in macrophages in recent lesions—namely, sudanophilic demyelination. There is extensive astrocytic gliosis. Axons are damaged, but to a lesser degree. The cortex of the adrenal glands is atrophic, and the cells and invading histiocytes contain an abnormal lipid material. The testes show marked interstitial fibrosis and atrophy of the seminiferous tubules. Electron microscopically, the macrophages of the brain and adrenals and the Leydig cells of the testes contain characteristic lamellar cytoplasmic inclusions.

Laboratory Diagnosis The specific laboratory marker of the disease is an excess of VLCFAs, in particular three measurements are of value: the absolute level of hexacosanoic acid (C26), the ratio of C26 to tetracosanoic acid (C26:C24), and of C26 to docosanoic acid (C26:C22) in plasma, erythrocytes, leukocytes, or cultured fibroblasts as detailed by A. B. Moser and colleagues. This reflects the basic biochemical fault in this disease, namely defective fatty acid oxidation within the peroxisomes. If skin fibroblasts and plasma testing are both performed, 93 percent of female carriers will show the abnormal VLCFA. MRI of the brain is abnormal in the majority of patients with cerebral symptoms and in a proportion of others.

Other laboratory findings are low serum sodium and chloride levels and elevated potassium levels—reflecting the atrophy of the adrenal glands. The latter results in reduced excretion of corticosteroids, low serum cortisol levels, and lack of rise in 17-hydroxyketosteroids after ACTH stimulation. The CSF protein may be elevated.

Treatment Adrenal replacement therapy prolongs life and occasionally effects a partial neurologic remission. A diet enriched with monounsaturated fatty acids and devoid of long-chain fatty acids has been said to slow the progress of the disease when administered before the age of 6. Bone marrow transplantation, to date performed in over 50 children, has been the only treatment shown to stabilize the disease and reverse some of the MRI changes. The reviews by van Geel and colleagues, and the ones by Moser, the leading worker in the field, summarizing diagnosis and treatment, are recommended.

Juvenile and Adult Metachromatic Leukodystrophy (MLD) This form of leukodystrophy has already been described in relation to the inherited metabolic disorders of late infancy and early childhood in an earlier section. It is mentioned here again to emphasize the point that the disease may have its onset at almost any age. Juvenile forms may begin between 4 and 12 years and adult forms between the midteens and the seventh decade. The mutations giving rise to these various forms are described in the earlier section on MLD. Some of the sporadic cases reported in the adult have probably been examples of cerebral multiple sclerosis, but we have seen, as have others, cases of MLD appearing as late as middle adult life. In almost all cases, the clinical picture, like those Turpin and Baumann, was one of slowly evolving intellectual decline or behavioral abnormality, followed by spastic weakness, hyperreflexia, Babinski signs, and stiff, short-stepped gait, with or without a polyneuropathy. Without manifest neurologic signs, misdiagnosis of psychiatric disease is common. As the disease progresses over a period of 3 to 5 years there may be a loss of vision and speech, then of hearing, and finally a state of virtual decerebration.

In some of these cases it is impossible to distinguish the white matter disease from that of Pelizaeus-Merzbacher and of Cockayne, described in the preceding section.

Orthochromatic Leukodystrophy This refers to a heterogeneous group of disorders, also called nonmetachromatic leukodystrophy, in which no enzyme defect or special staining characteristic of degenerated white matter has been identified. Furthermore, most of them have been sporadic, obscuring the nosology of the process. One type is associated with cerebellar ataxia and dementia; other adult cases have been described in which epilepsy was associated with a frontal lobe type of dementia. A surprising feature, such as in the cases of Letourneau and colleagues, has been normal MRI, even with the more sensitive FLAIR sequences.

Cerebrotendinous Xanthomatosis This rare disease is probably transmitted by an autosomal recessive gene. It usually begins in late childhood, with cataracts and xanthomas of tendon sheaths and lungs. As it progresses, difficulty in learning, impairment of retentive memory, and deficits in attention and visuospatial perception (the earliest neurologic manifestations) give way to dementia, ataxic or ataxic-spastic gait, dysarthria and dysphagia, and polyneuropathy. In the late stages (after 5 to 15 years), the patient becomes bedfast and helpless; death occurs at 20 to 30 years of age. In other cases the clinical course is much more benign. Neuropathologic examination shows masses of crystalline cholesterol in the brainstem and cerebellum and sometimes in the spinal cord, with symmetrical destruction of myelin in the involved areas. The lesions are visible by CT scanning and MRI.

The basic defect is in the synthesis of primary bile acids, leading to an increased hepatic production of cholesterol and chole-

tanol, which accumulate in brain and tendons. The serum cholesterol levels are normal in most cases but may be as high as 450 mg/dL in others. The tendon xanthomas contain cholestanol, of which 4 to 9 percent is cholestanol (dihydrocholesterol) according to the studies of Moser. Cholestanol levels in the serum and red cells are increased. The same elevated levels are found in heterozygotes.

Treatment In response to long-term treatment with chenodeoxycholic acid, 750 mg daily, the corticospinal and cerebellar signs and dementia receded in 10 of 17 patients treated and followed by Berginer and coworkers. This drug corrects the defective synthesis of bile acids and restores the low level of chenodeoxycholic acid. Ideally treatment should begin before the neurologic symptoms appear (Meiner et al).

STROKES IN ASSOCIATION WITH INHERITED METABOLIC DISEASES

In Chap. 34 it was remarked that strokes occur from time to time in children and young adults, often due to inherited disorders of the clotting system typified by protein C deficiency, but also due to a number of other metabolic derangements including the mitochondrial disorder, MELAS. Among the many causes, three metabolic diseases must always be considered in the diagnosis of such cases: *homocystinuria*, *Fabry disease*, and *sulfite oxidase deficiency*. Other less common ones are *Tangier disease* and *familial hypercholesterolemia*. Stroke in young persons is also a central feature of the mitochondrial disorder MELAS, discussed further on in this chapter, and of the genetically determined microvasculopathy CADASIL (page 707).

Homocystinuria This aminoaciduria is inherited as an autosomal recessive trait and simulates Marfan disease. Tall, slender habitus; great length of limbs, sometimes scoliosis and arachnodactyly (long, spidery fingers and toes); thin and rather weak muscles; knock-knees; highly arched feet; and kyphosis are the typical skeletal features. Sparse, blond, brittle hair; malar flush; and livedo reticularis are common dermal manifestations, and a dislocation of one or both lenses (usually downward) may occur, imparting a tremulous appearance to the irides (iridodenesis). The only neurologic abnormality is mental retardation, usually of mild degree, which sets this syndrome apart from Marfan disease, in which intellect is unimpaired.

Blood vessel changes—thickening and fibrosis of the coronary, cerebral, and renal arteries—tend to appear later in the illness. An abnormality of platelets favoring clot formation and thrombosis of cerebral arteries has been observed. Some patients have died of coronary occlusions during adolescence, and a myocardial lesion may be the source of emboli to cerebral arteries.

Homocystine is elevated in the blood, CSF, and urine. This is due to an inherited cystathione synthase deficiency that results in an inadequacy of cystathione formation, a substance essential to many tissues including the brain. This may be the explanation of the mental retardation. Plasma methionine levels are also elevated. The infarcts in the brain are clearly related to thrombotic and embolic arterial occlusions. The administration of a low-methionine diet and large doses (50 to 500 mg) of pyridoxine (a cystathione synthase coenzyme) reduces the excretion of homocystine. If vascular lesions have occurred, anticoagulants probably prevent further occlusions.

Homocystinuria may also be an expression of 5,10-methylenetetrahydrofolate reductase deficiency. Again, the clinical manifestations consist of multiple cerebrovascular lesions, dementia, epilepsy, and polyneuropathy. The last is believed to be due to a coincidental folic acid deficiency, but in some cases it may have been caused by chronic phenytoin administration (Nishimura et al).

Much milder elevations of serum homocystine have recently been recognized as contributing to the risk of coronary disease and stroke in otherwise normal individuals.

Fabry Disease (Anderson-Fabry Disease, Hereditary Dystopic Lipidosis) This disease, also known as *angiokeratoma corporis diffusum*, is inherited as an X-linked recessive trait. It occurs in complete form in males and in incomplete form in female carriers. The primary deficit is in the enzyme α -galactosidase A, the result of which is the accumulation of ceramide trihexoside in endothelial, perithelial, and smooth muscle cells of blood vessels as well as in renal tubular and glomerular cells and other viscera and in nerve cells in many parts of the nervous system (hypothalamic and amygdaloid nuclei, substantia nigra, reticular and other nuclei of the brainstem, anterior and intermediolateral horns of the spinal cord, sympathetic and dorsal root ganglia).

The disease becomes manifest clinically in childhood or adolescence, with intermittent lancinating pains and dysesthesias of the extremities. A notable feature of these pains is their evocation by fever, hot weather, and vigorous exercise. Usually there is no sensory loss, but autonomic disturbances have been recorded in a series of our cases. Many years later there is a diffuse vascular involvement that leads to hypertension, renal damage, cardiomegaly, and myocardial ischemia. Thrombotic infarctions occur in the brain during early adult years. Occasional cases are discovered in adulthood with confluent cerebral white matter changes on MRI and progressive problems such as dysarthria.

The characteristic angiokeratomas tend to be most prominent periumbilically and resemble small angiomas that obliterate slightly with pressure. Desnick and colleagues have reviewed the neurologic, neuropathologic, and biochemical findings in this disease, and Cable, Kolodny, and Adams have written informatively on the autonomic aspects.

Treatment Enzyme replacement, given by infusion, is now available. The two main trials of this treatment, summarized in an editorial by Pastores and Thadhani, were each conducted quite differently. Both showed an improvement in kidney and other organ function but only one demonstrated a reduction in neuropathic pain, and neither studied the risk of stroke. Like enzyme replacement therapy for Gaucher disease, prolonged treatment is expensive; but some evidence from the trials cited above indicates that certain aspects of the disease are reversible.

The painful neuropathic features that have brought several cases to our attention are discussed with the polyneuropathies, on page 1159.

Sulfite Oxidase Deficiency This disorder was discussed briefly with the neonatal metabolic disorders (page 804). The occurrence of stroke as a complication of this disorder was placed on record by our colleagues Shih et al. A child 4.5 years of age, whose development had been retarded since birth (seizures and opisthotonus had been present), became hemiplegic. Another unrelated child, supposedly normal until 2 years of age, entered the hospital with fever, confusion, generalized seizures, right hemiplegia, and aphasia (infantile hemiplegia); subluxation of the lenses (upward) was

discovered later. There was an increased level of sulfite and thiosulfite and an abnormal amino acid, S-sulfocysteine, in the blood. One child appeared to respond to a low sulfur–amino acid diet.

CHANGES IN BEHAVIOR AND INTELLECT AS MANIFESTATIONS OF INHERITED METABOLIC DISEASE

Although rare among the vast numbers of maladjusted, sociopathic, and psychotic adolescents in our society, certain metabolic diseases may be the cause of serious disturbances of mental life and behavior. The diagnosis and management of these metabolic diseases are so unusual that some special remarks are appropriate.

All the metabolic diseases of late childhood and adolescence may share to some degree the property of deranging behavior, thinking, feeling, and emotional reactions. Usually, they present later in adolescence and adult life and evolve more slowly than childhood forms. The most obvious and easily detectable of these derangements are in the cognitive sphere, i.e., reduction in the capacity to learn and remember, to calculate, to solve problems, and to exercise verbal skills. Impulsivity, loss of self-control, and antisocial behavior are the most troubling behavioral abnormalities. Certain forms of these impairments are attributable to integrated systems of modules of cerebral neurons and are recognized as special neurologic deficits, such as disinhibition or muting of behavior and affect, the amnesic state, aphasia, dyscalculia, and visual-perceptual disorientation. Each of these phenomena has its own cerebral anatomy, as pointed out in Chap. 22, and the state known as dementia comprises various degrees and combinations of these abnormalities.

Intellectual functions are little developed in early childhood; it is therefore difficult to judge the normal qualities of the mind for this age group. Slowness in learning and in acquiring language functions become manifest in school, and may then be interpreted loosely as mental retardation. Up until school age, these intellectual functions have not developed sufficiently to allow recognition of their regressive course. Only in late childhood do mental retardation and dementia become clearly distinguishable and measurable by standardized tests. Far less tangible are subtle changes in personality and behavior that must always be judged against the standards of the cultural group of which the patient is a member.

The principle that most neuropsychiatrists follow in selecting from the large mass of maladjusted adolescents those with a metabolic brain disease is that such a condition will sooner or later cause a *regression in cognitive and intellectual functions*. Schizophrenia and manic-depressive psychosis and the sociopathies and character disorders do so little or not at all. This is not to say that personality changes and emotional disturbances do not occur in the metabolic encephalopathies; they certainly do. However, their recognition depends more on the demonstration of failing memory, impaired thinking, inability to learn, and loss of verbal and arithmetic abilities, many of which are measured quantitatively by intelligence tests. The appearance of pyramidal signs, aphasia, apraxia, ataxia, or areflexia always sets them apart.

If one reviews all the diseases described in this chapter and selects those that may demonstrate *regression of cognitive function in association with personality change and alteration of behavior*—diseases that may for a time be unaccompanied by other neurologic abnormalities—the following merit special consideration:

1. Wilson disease
2. Hallervorden-Spatz pigmentary degeneration
3. Lafora-body myoclonic epilepsy
4. Late-onset neuronal ceroid-lipofuscinosis (Kufs form)
5. Juvenile and adult Gaucher disease (type III)
6. Some of the mucopolysaccharidoses
7. Adrenoleukodystrophy
8. Metachromatic leukodystrophy
9. Adult GM₂ gangliosidosis
10. Mucolipidosis I (type I sialidosis)
11. Nonwilsonian copper disorder (hereditary ceruloplasmin deficiency)

In each of these diseases, dementia and personality disorder may gradually develop and persist for many months, even a year or two, before other neurologic signs appear. One must look carefully for the earliest signs of movement disorders and other neurologic abnormalities, which greatly clarify the diagnostic problem. A safe rule is to assume that if there are mental and personality changes in each of the above diseases, other subtle neurologic disorders coexist. The common use of neuroleptic drugs, causing tardive dyskinesia, is the major obstacle to applying this rule. The differential diagnosis includes a number of developmental disorders, mainly autism and Rett syndrome.

ADULT FORMS OF INHERITED METABOLIC DISEASES

The increasing range and precision of biochemical and cytologic tests has brought to light a number of inherited metabolic diseases that sometimes have their onset in adult life. Such disorders, while uncommon, nevertheless are important because they must be considered in the differential diagnosis of degenerative diseases and cerebral atrophies, for which explanations are beginning to be found. Also to be considered in the differential diagnosis is an array of mitochondrial disorders, to be discussed further on in this chapter.

In the last decade or two, the authors have personally observed or have otherwise come to know of examples of the following metabolic diseases, the onset of which was in late adolescence or adult life:

1. Metachromatic leukoencephalopathy
2. Adrenoleukodystrophy
3. Globoid body leukodystrophy (Krabbe disease)
4. Kufs form of neuronal ceroid lipofuscinosis
5. GM₂ gangliosidosis
6. Wilson disease
7. Leigh disease
8. Gaucher disease
9. Niemann-Pick disease
10. Mucopolysaccharide encephalopathy
11. Mucolipidosis type I
12. Polyneuropathies (Andrade disease, Fabry disease, porphyria, Refsum disease)
13. Mitochondrial diseases, particularly progressive external ophthalmoplegia and Leigh disease

In the encephalopathic forms of the metabolic and mitochondrial diseases, the diagnosis is usually made only after symptoms have been present for months or years, the disease having been

mistaken for some other condition, particularly depression or a degenerative dementia. Even a manifest psychosis may have occurred in relation to some of these disorders, but such occurrences are admittedly rare. For example, one of our patients with metachromatic leukodystrophy, a 30-year-old man, began failing in college years and was later unsuccessful in holding a job because of carelessness and mistakes in his work and indifference to criticism, irritability, and stubbornness (clearly traceable to a mild dementia). Only when Babinski signs and loss of tendon reflexes in the legs were detected was the correct diagnosis entertained for the first time. By then he had been ill for nearly 10 years. Bosch and Hart described a patient with the onset of dementia at 62 years of age and drew attention to 27 other similar cases of adult-onset metachromatic leukoencephalopathy (see also the seven cases of Turpin and Baumann). Overt signs of neuropathy are usually lacking in these adult-onset cases, but EMG and sural nerve biopsy will disclose the characteristic abnormalities.

One of our adult patients with Wilson disease had been committed to a psychiatric hospital because of his paranoid tendencies and fighting with his family; the presence of a tremor and mild rigidity of the limbs had been attributed at first to phenothiazine drugs. In some of Griffin's cases of adrenomyeloneuropathy, a spastic weakness of the legs and sensory ataxia progressing over several years were the main clinical manifestations; a spinocerebellar degeneration was suspected. One of our patients with Kufs lipid storage disease began to deteriorate mentally in early adult life and only much later showed an increasing rigidity, with athetotic posturing of limbs and difficulty in walking; he succumbed to his disease after more than a decade of symptoms. Another recent patient with Kufs disease presented at age 51 with vague visual difficulty, which was followed by spasticity of the legs, behavioral disinhibition, and dementia spanning 6 years. Josephs and colleagues describe two patients of five with adult-onset type C Niemann-Pick disease who had a psychosis beginning at ages 61 and 27, respectively.

We have observed cerebellar ataxia, polymyoclonus, and progressive blindness in adolescents and adults with a variant of GM₂ gangliosidosis; cherry-red macular spots provided the clue to diagnosis. Several such cases have been reported in the last decade, particularly among the Japanese (Miyatake et al). Notable also are nine cases of a spinocerebellar ataxia from four Ashkenazic Jewish families with dementia or psychosis of adult onset described by Wilner and colleagues. Also on our services have been two adult patients with progressive spinal muscular atrophy who proved to have this same GM₂ hexosaminidase deficiency; the process was clinically almost indistinguishable from a very slowly progressive lower motor neuron form of motor neuron disease (such as Kugelberg-Welander disease in adolescents), but they had no macular changes and displayed the additional features of ataxia and an intermittent and atypical psychosis.

Dementia, optic atrophy, mild cerebellar ataxia, and corticospinal signs have been features of several personally observed patients with Leigh disease who survived in a relatively helpless state for nearly 20 years. Kalimo and associates have reported a similar family. An asymmetrical corticospinal syndrome with areflexia had advanced so slowly in one of our cases of Krabbe disease that she became disabled only in her sixties.

Another of our patients, an adolescent with severe diffuse myoclonus and seizures and slight intellectual deterioration, was found after several years to have one of the rare variants of Gaucher disease. Another with dementia, rigidity, choreoathetosis, slight cerebellar ataxia, and Babinski signs had a variant of Niemann-

Pick disease. For many years our colleagues had under observation a family with Gaucher disease, several members of which had developed seizures, generalized myoclonus, supranuclear gaze palsies, and cerebellar ataxia in early adult life (Winkelman et al). Rarely, Gaucher disease may be associated with an early and severe parkinsonian syndrome.

We have had the experience of finding laboratory evidence of adrenal insufficiency in young men with white matter lesions of the frontal lobes and other parts of the cerebrum; there was no bronzing of the skin, and earlier a diagnosis of multiple sclerosis had been made. Eldridge and coworkers have described a large kindred with widespread noninflammatory degeneration of the cerebral and cerebellar white matter; individual members were thought to have multiple sclerosis before a pattern of autosomal dominant inheritance became evident (possibly this represents CADASIL, page 707). Such cases are likely to be found in multiple sclerosis clinics. Adrenoleukodystrophy presenting in adult life as a spinocerebellar or olivopontocerebellar syndrome has already been mentioned.

These rare forms of inherited metabolic disease are notable for their chronicity and for the early prominence of a particular neurologic symptom or syndrome. Once the disease is established, however, there is nearly always evidence of involvement of multiple neuronal systems, reflected in a subtle or overt dementia, character disorder, or signs referable to corticospinal, cerebellar, extrapyramidal, visual, and peripheral nerve structures. *This multiplicity of neuronal system involvement is much more a feature of heritable metabolic disease than of degenerative disease, and the finding of such involvement should always provoke a search for an inherited metabolic disorder.*

Viewed from another perspective, certain outstanding clinical symptoms that are more often attributable to common diseases of the adult nervous system, such as multiple sclerosis and atherosclerosis, are sometimes the result of an inborn error of metabolism. These rare instances are categorized by their main features in Table 37-8, adopted from Grey et al.

To reiterate, the aforementioned dictum that tract involvement (corticospinal, cerebellar, peduncular, sensory, optic nerve) indicates a leukodystrophy and that “gray matter” signs (seizures, myoclonus, dementia, retinal lesions) indicate a poliodystrophy is useful mainly in the early stages of a disease. Some of the lysosomal storage diseases affect both galactolipids (galactocerebrosides and sulfatides) and gangliosides; hence both white and gray matter are involved. As mentioned earlier, the paper by Turpin and Baumann is of interest when this group of diseases is viewed from the strictly psychiatric point of view.

In concluding this discussion, which classifies the inherited monogenetic metabolic diseases in accordance with their clinical characteristics, the careful reader will appreciate its artificiality. Nearly every one of the diseases of each category may present some neurologic abnormality other than the ones we have emphasized, so that the potential number of variations is almost limitless. However, the plan presented here—of thinking of these diseases in reference to age periods and syndromes, is of heuristic value and facilitates clinical study of this extremely difficult segment of neurologic medicine.

MITOCHONDRIAL DISORDERS

As with the metabolic disorders of the nervous system, the diseases included under this heading are so diverse and may involve so

Table 37-8
Major symptoms of adult-onset inherited metabolic diseases

Dementia and psychosis

- Kufs disease
- Niemann-Pick disease type C
- Wilson disease
- Adrenoleukodystrophy
- Metachromatic leukodystrophy
- Aceruloplasminemia

Motor neuron disease

- GM₂ gangliosidosis
- Polyglycosan disease

Choreoathetosis

- Wilson disease
- GM₂ gangliosidosis
- Niemann-Pick disease type C

Ataxia

- Aceruloplasminemia
- Abetalipoproteinemia
- GM₂ gangliosidosis
- Hartnup disease
- Sialidosis
- Niemann-Pick disease type C

Leukodystrophy

- Krabbe disease
- Metachromatic leukodystrophy
- Adrenoleukodystrophy
- Orthochromatic leukodystrophy

Strokes

- Fabry disease
- Homocystinuria
- MELAS^a

^a Mitochondrial encephalomyopathy, lactic acidosis, and stroke.

SOURCE: Adapted with permission from Grey et al.

many parts of the nervous system that the clinical entities by which they are identified cannot be easily addressed in any one part of this book. In their overlapping relationships, however, these diseases are unlike the more discrete clinical entities caused by nuclear genetic mutations. Their diversity is evident not only in certain details of their clinical presentations but also in the age at which symptoms first become apparent, and—what is most intriguing—sometimes in the abrupt onset of their neurologic manifestations. Most of this variability is understandable from the principles of mitochondrial genetics outlined in the introductory section of this chapter. Of particular importance is the mosaicism of the mitochondria within cells and from cell to cell and the crucial role the organelles play in the oxidative energy metabolism that supports the function of cells in all organs. Fortunately for the clinician, the most important of these diseases are expressed in several recognizable core syndromes and in a few variants thereof. A number of acronyms formed from the initial letters of the main clinical features have been used to designate the major mitochondrial syndromes: MERRF, MELAS, PEO, NARP, etc., as summarized in Table 37-9. The addition of certain subtle dysmorphic features—including short stature; endocrinopathies, particularly diabetes; and a number of other systemic abnormalities such as lactic acidosis (discussed further on)—aids in diagnosis.

These diseases are the result of mutations in the mitochondrial

Table 37-9

The major categories of mitochondrial disorders

SYNDROME	COMMON MITOCHONDRIAL GENE MUTATION	RAGGED RED FIBERS	LACTIC ACIDOSIS
Ragged red fiber polymyopathy	Point mutation at 3250	+	—
Progressive external ophthalmoplegia (PEO) and Kearns-Sayre variants	Heteroplasmic deletions or point mutation at 3243	—	—
Leigh syndrome, fatal lactic acidosis and NARP	Point mutation at 8993	—	+
Myoclonic-epilepsy and ragged red fibers in muscle (MERRF)	Point mutation at 8344	+ (usually)	+/-
Mitochondrial-encephalomyopathy, lactic acidosis, and stroke (MELAS)	Point mutation at 3243	+	+
Leber optic neuropathy (page 949)	Point mutation at 3460, 4160, or 11778	—	—
Myoneuronal-gastrointestinal encephalopathy	Unknown (maternal inheritance)	+	—

Key: + = present; — = absent; NARP = neuropathy with proximal weakness, ataxia, and retinitis pigmentosa.

genome, a ringed DNA of 16,569 base pairs and 37 genes contained within the organelle, or of mutations in a few nuclear genes that code for a component of the mitochondrion. To date, over 100 point mutations and 200 deletions, insertions, and rearrangements have been identified. It is estimated that two-thirds of the point mutations affect the transfer RNA of the mitochondrion, one-third affect polypeptide units of the respiratory chain, and a small number affect mitochondrial ribosomal RNA. This corresponds approximately to the proportion of genes devoted to each of these functions. Di-Mauro and Schon have written a thorough review of mitochondrial genomics and the relevant diseases, which may be consulted by interested readers.

The first described and best-characterized member of this group of diseases is a symmetrical proximal myopathy that can occur as an isolated phenomenon or in combination with any one of the major mitochondrial syndromes. In 1966, Shy and coworkers described the histochemical and electron-microscopic abnormalities of the muscle mitochondria in a childhood myopathy, which they called *megaconial* (meaning marked enlargement of the mitochondria) or *pleoconial* (referring to an excessive number of mitochondria). Later this change came to be known as “ragged red fibers,” so named because of the subsarcolemmal and intermyofibrillar collections of membranous (mitochondrial) material in the type 1 (red) muscle fibers as visualized by the Gomori trichrome stain in sections of frozen muscle. This morphologic change may be an asymptomatic accompaniment of the mitochondrial disorders or, conversely, a mitochondrial disease of the CNS may exist without histologic or ultrastructural abnormalities in the muscle.

A second unifying feature of these diseases is an elevation of lactate or of the lactate-to-pyruvate ratio in the blood and CSF; this is the result of the respiratory chain abnormalities. These elevations are most prominent after exercise, infection, fever, or alcohol ingestion, and—in some conditions—are capable of inducing recurrent ketoacidotic coma, which may be the presenting manifestation of a mitochondrial disease. Leigh syndrome and MELAS particularly have a tendency to exhibit elevations of lactate; however, the diagnosis of either cannot be excluded in the presence of normal levels, even after provocation by exercise. Using phosphorus MRI scans, one can compare levels of inorganic phosphate to phosphocreatine levels in muscle; in genetic muscle diseases of several types, this ratio increases, but it is highest in those of mitochondrial origin.

Although the mitochondrial diseases are considered here as a

group, individual ones are of necessity mentioned in other chapters because of their outstanding characteristics. Thus, the syndrome that combines epilepsy, deafness, and developmental delay with ragged red muscle fibers (myoclonic epilepsy with ragged red fibers, or MERRF) has been discussed in Chap. 16, on epilepsy. The syndrome of progressive external ophthalmoplegia (PEO) has been included with other abnormalities of eye movements (Chap. 50); lactic acidosis and stroke-like episodes (MELAS) were considered in Chap. 34, with the cerebrovascular diseases; and Leber hereditary optic neuropathy, with other causes of visual loss (Chaps. 13 and 39). The Leigh syndrome, a symmetrical subacute necrotizing encephalomyopathy, usually with lactic acidosis, also has a number of complex presentations and is mentioned in the differential diagnosis of several syndromes. For each of the aforementioned diseases, wide clinical experience will bring to light an individual or a family in whom some odd syndrome has been linked to a mitochondrial disorder. Furthermore, two major syndromes may coexist in one individual and fragmentary subsyndromes are known to occur, with onset from childhood to early adult life. It serves little purpose, therefore, to catalogue all of these associations. Only the best-characterized entities, listed in Table 37-9, are described here. The most common combinations of mitochondrial syndromes have been of Kearns-Sayre syndrome with MELAS or with MERRF, progressive ophthalmoplegia with MERRF, and MERRF with MELAS.

We prefer to avoid the issue of what defines a “mitochondrial disorder”—its genetic defect, the biochemical disorder, or the clinical syndrome. The clinician assigns this term to the combination of a genetic mutation of mitochondrial DNA and certain clinical features that constitute a recognizable syndrome; the biochemical changes are taken as markers of the disordered energy-producing mechanisms of the mitochondrial machinery. Recently, mitochondrial failure has also become a focus of interest in various degenerative neurologic conditions, such as Alzheimer and Parkinson diseases, but none of the currently understood mutations of the mitochondrial genome are implicated in these conditions.

Mitochondrial Myopathies

The mildest form of muscle disorder due to mitochondrial disease is a benign and relatively static proximal weakness that tends to be more severe in the arms. Exercise intolerance alone is reported by more than half of these patients. There are adult-onset cases, but

careful questioning usually reveals lifelong symptoms (weakness, poor endurance, discomfort, exertional dyspnea, and tachycardia), which may be so slight and slowly progressive that the patient leads a relatively normal life for decades. Less frequent patterns of muscle disease include a fascioscapulohumeral or limb-girdle pattern of weakness as well as occasional episodes of exertional myoglobinuria. Some patients develop progressive external ophthalmoplegia (PEO) several years after the limb weakness becomes evident. Several mutations are associated with a pure or predominant myopathic syndrome, the most common one being located at position 3250 of the mitochondrial genome. Rarer variants, such as combined skeletal weakness and cardiomyopathy, are referable to other loci.

At the opposite end of the spectrum is an infantile myopathy in which weakness and lactic acidosis become evident in the first week of life and are fatal by 1 year. Many of these patients and some members of their families have a history of renal dysfunction combined with weakness of early onset. The muscle tissue shows numerous ragged red fibers, and cytochrome oxidase activity is virtually absent. DiMauro and others have described a remarkable partly reversible form, which, early on, requires ventilatory support and gastric feeding but improves clinically as the child ages; the lactic acidosis disappears by age 2 or 3 years. In these severe childhood cases, the deficiencies in cytochrome oxidase suggest a defect in mitochondrial genes, but the site has not been found.

As mentioned above, the histologic feature that unites mitochondrial myopathies is the presence of ragged red fibers. This finding points to the diagnosis of a mitochondrial disorder in any case where weakness is coupled with exercise intolerance and elevated serum lactate, particularly if there is a family history of similar problems. Also, the presence of ragged red fibers differentiates the mitochondrial myopathies from the glycogenoses, but it bears emphasizing that ragged red fibers are rare in infants and young children, even in those with confirmed mitochondrial disease.

Progressive External Ophthalmoplegia (PEO) and Kearns-Sayre Syndrome

(See also page 1220)

The combination of progressive ptosis and symmetrical ophthalmoplegia is a common manifestation of mitochondrial disease. Usually there is no diplopia or strabismus or at most only transient diplopia, despite slightly dysconjugate gaze. Mitochondrial abnormalities are found in the extraocular muscles of these patients. We have been impressed at how long the illness can exist before it brings the patient to a physician. To be differentiated is myasthenia gravis, which is characterized by fatigable weakness and responsiveness to cholinergic medications, neither of which is not a feature of mitochondrial disorders. In our experience, nearly all cases of PEO are due to mitochondrial disorders, but rarely the condition may be simulated by one of several genetically determined muscular dystrophies, including oculopharyngeal dystrophy and a type in which there are no other associated weaknesses but is, however, linked to facioscapulohumeral dystrophy (FSH) (Chap. 50).

Progressive external ophthalmoplegia bears a close relationship to the Kearns-Sayre syndrome of retinitis pigmentosa (onset before age 20), ataxia, heart block, and elevated CSF protein; sensorineural deafness, seizures, or pyramidal signs may be added (page 1220). The CNS syndromes of MELAS or MERRF (see further on) may also be combined occasionally with PEO.

Subacute Necrotizing Encephalomyopathy (Leigh Disease; SNE)

This is a familial or sporadically occurring mitochondrial disorder with a wide range of clinical manifestations. Only some of the cases display a maternal pattern of inheritance. The onset of neurologic difficulty in more than half of these patients is in the first year of life, mostly before the sixth month; but late-onset forms, with great heterogeneity of presentation as late as early adulthood, are also known. Neurologic symptoms often appear subacutely or abruptly, sometimes precipitated by a febrile illness or a surgical operation. It has seemed to us that this rapid onset is more characteristic of Leigh disease than it is of the other mitochondrial disorders.

In infants, loss of head control and other recent motor acquisitions, hypotonia, poor sucking, anorexia and vomiting, irritability and continuous crying, generalized seizures, and myoclonic jerks constitute the usual clinical picture. If the onset is in the second year, there is delay in walking, ataxia, dysarthria, psychomotor regression, tonic spasms, characteristic respiratory disturbances (episodic hyperventilation, especially during infections, and periods of apnea, gasping, and quiet sobbing), external ophthalmoplegia, nystagmus, and disorders of gaze (like those of Wernicke disease), paralysis of deglutition, and abnormal movements of the limbs (particularly dystonia but also jerky and choreiform movements). Mild cases, showing mainly developmental delay, have been mistaken for cerebral palsy. Peripheral nerves are involved in some cases (areflexia, weakness, atrophy, and slowed conduction velocities of peripheral nerves); in a few, autonomic failure is the most prominent feature. In some children the disease is episodic; in others it is intermittently progressive and quite protracted, with exacerbation of neurologic symptoms in association with nonspecific infections. The CSF is usually normal, but the protein content may be increased.

The pathologic changes take the form of bilaterally symmetrical foci of spongy necrosis with myelin degeneration, vascular proliferation, and gliosis in the thalamus, midbrain, pons, medulla, and spinal cord. The basal ganglia are characteristically but not invariably affected. Also, there may be a demyelinating type of peripheral neuropathy. In their distribution and histologic appearance, the CNS lesions resemble those of Wernicke disease (due to a deficiency of thiamine) except that the lesions of Leigh disease are more extensive—sometimes involving the striatum—and they tend to spare the mammillary bodies. The lesions, particularly those of the lenticular nuclei and brainstem, may be seen in CT scans and are strikingly demonstrated by MRI. The histochemical appearance of muscle is normal, although electron microscopy may show an increased number of mitochondria.

The clinical boundaries of Leigh disease have not been defined precisely. A familial disorder of infancy and early childhood—referred to as *bilateral striatal necrosis* and associated with dystonia, visual failure, and other neurologic defects—is probably a variant. The same may be true of an obscure adult-onset syndrome of progressive dementia, due to thalamic lesions, in the form of necrosis, vascular proliferation, and gliosis.

The mitochondrial gene mutation most often associated with the Leigh disease is also discussed in relation to the NARP syndrome, below. The close relationship between the two processes re-emphasizes the point that several mitochondrial mutations appear to give rise to the clinical and pathologic picture of a subacute necrotizing encephalopathy.

Neuropathy, Ataxia, Retinitis Pigmentosa Syndrome (NARP)

As just indicated, Leigh syndrome exemplifies to a remarkable degree the heterogeneity of abnormalities that may be associated with cytochrome oxidase deficiency due to a single mitochondrial gene mutation. A minor transversion error, the substitution of one amino acid in the mitochondrial DNA at position 8993, the same site implicated in Leigh syndrome, also gives rise to a maternally inherited syndrome of sensory neuropathy, ataxia, and retinitis pigmentosa (NARP). Included in some cases are developmental delay, seizures, and proximal muscle weakness. This gene abnormality creates a defective ATPase-6 of complex V of the mitochondrial respiratory chain.

The severity of the NARP syndrome corresponds to the amount of aberrant DNA in the mitochondrial genome; mutations involving over 90 percent of mitochondrial DNA produce the more severe phenotype of the Leigh syndrome (SNE). Santorelli and colleagues found that 12 of 50 patients with Leigh syndrome from 10 families displayed the 8993 point mutation. Within one kindred, the mitochondrial aberration may vary from a mild developmental delay, to NARP, to the full-blown Leigh syndrome, or early death with lactic acidosis. These differences in severity are thought to result from the mosaicism of mitochondrial genetics and specifically to the protective effect of even small amounts of the normal mitochondrial genome. The first manifestations of disease may not appear until adulthood, although it only rarely begins after age 20. The similarities to Refsum disease are discussed on page 1157.

Further confounding the clinical classification of this disease complex is the observation that many patients with the Leigh syndrome have a pyruvate dehydrogenase (usually X-linked) or pyruvate decarboxylase deficiency or a cytochrome oxidase deficiency. These are common to many mitochondrial disorders and inherited usually as an autosomal recessive trait. However, patients with Leigh syndrome and the 8993 mutation tend not to have these enzymatic deficiencies. Bridging these complex cases to the typical ones are instances with cytochrome oxidase deficiency with psychomotor retardation, slowed growth, and lactic acidosis, many without the striatal or brainstem spinal necroses of Leigh syndrome.

Congenital Lactic Acidosis and Recurrent Ketoacidosis

Certain types of organic acidemia occurring in early infancy and of unproved genetic etiology have already been mentioned (page 802). Here reference is made to those few cases that are associated with deletions of mitochondrial DNA. The syndrome consists of *psychomotor regression* and *episodic hyperventilation, hypotonia, and convulsions* with intervening periods of normalcy. Chorea-athetosis or progressive ophthalmoplegia have been added in a few. Probably most cases of this type are due to disorders of the mitochondrial respiratory chain, particularly of the pyruvate-decarboxylase complex. Some children are dysmorphic, with a broad nasal bridge, micrognathia, posteriorly rotated ears, short arms and fingers, and other similar but mild dysmorphic features. De Vivo and colleagues have given a synopsis of this disease, as noted in the references. Death usually occurs before the third year. The important laboratory findings are acidosis with high lactate levels and hyperalaninemia. The few cases that have been examined postmortem are found to have necrosis and cavitation of the globus pallidus and cerebral white matter, as in SNE. The diagnosis can

be made by the finding of ragged red fibers in muscle or by measurement of enzyme activity. The process must be distinguished from the several diseases of infancy that are complicated by lactic acidosis.

Myoclonic Epilepsy with Ragged Red Fiber (MERRF) Myopathy

This is perhaps the most distinctive mitochondrial disease, presenting as it does with progressive myoclonic epilepsy or myoclonic ataxia. As was noted in Chap. 6, these cases must be differentiated from several entities with a more predictable clinical course, such as juvenile myoclonic epilepsy, Unverricht-Lundborg disease, Lafora-body disease, Baltic myoclonus, and neuronal ceroid-lipofuscinosis, discussed earlier in this chapter. Tsairis and colleagues were the first to describe the connection between familial myoclonic epilepsy and mitochondrial changes in muscle, and numerous variants have been identified since their report.

In our limited experience with this disease, myoclonus in a child or young adult is the most typical feature and is elicited by startle or by voluntary movement of the limbs. The nature of the seizures varies but includes drop attacks, focal epilepsy, or tonic-clonic types, some of which are photosensitive. The ataxia tends to worsen progressively, replacing the myoclonus and seizures in some instances and remaining a minor feature in others. The myopathy usually produces inapparent or mild weakness, but the presence of mitochondrial muscle abnormalities is necessary for clinical diagnosis. To this constellation may be added any of the other elements of the mitochondrial diseases that have already been denoted, including deafness (present in our cases), mental decline, optic atrophy, ophthalmoplegia, cervical lipomas, short stature, or neuropathy.

Most cases are familial and display maternal inheritance, but the age of onset may vary and affected individuals have been reported with symptoms beginning as late as the sixth decade. Almost always the patients with later onset have the mildest disease, with only myoclonic epilepsy. Conversely, those with onset in the first decade tend to be more severely affected and die before the third decade. As with the other mitochondrial processes, the quantitative burden of mutant DNA bears some relationship to the time of onset and severity of the disease. Eighty percent of patients with MERRF have a point mutation of the mitochondrial genome at locus 8344, which codes for a transfer RNA, and, conversely, most patients with this mutation will ultimately manifest some or all the clinical features of MERRF, including those with crossover features of the Leigh syndrome.

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS)

Patients with this syndrome have normal early development followed by poor growth, focal or generalized seizures, and recurrent acute episodes that resemble strokes or prolonged transient ischemic attacks. The stroke deficits often improve but in some cases lead to a progressive encephalopathy. Some have hemicranial headaches that cannot be distinguished from migraine, and others suffer repetitive vomiting or episodic lactic acidosis. If there is a characteristic feature it is an unusual clinical pattern of focal seizures, sometimes prolonged, which herald a stroke and produce a unique radiographic pattern of infarction involving the cortex and imme-

diate subcortical white matter. The CT scan may also show numerous low-density regions that have no clinical correlates. Most patients have ragged red fibers, but only rarely is there weakness or exercise intolerance.

Approximately 80 percent of MELAS cases are related to a mitochondrial mutation occurring at the 3243 site of the mitochondrial gene, or, in a few instances, at an alternative locus that also codes for a segment of transfer RNA. Maternal inheritance is common, but sporadic cases are well known. In the survey conducted by Hammans and coworkers, only half of the cases of the 3243 mutation were associated with the MELAS syndrome. The finding of an abnormal mitochondrial genome in the endothelium and smooth muscle of cerebral vessels has been suggested as a basis for the strokes and migraine headaches.

The Diagnosis of Mitochondrial Disorders

The characteristic neurologic signs of a mitochondrial disorder fall into four broad groups: (1) combinations of ataxia, seizures, and myoclonus, typified by the MERRF syndrome; (2) migraine-like headaches, recurrent small strokes, and preceding seizures, typified by the MELAS syndrome; (3) ophthalmoplegia and retinitis pigmentosa with polyneuropathy, optic atrophy (Leber type), or deafness (Kearns-Sayre syndrome); and (4) a myopathy that is slowly progressive or fluctuating in severity. These may be combined with dementia, lactic acidosis, short stature, ptosis, pigmentary retinal degeneration, and cardiac conduction defects (as in the Kearns-Sayre syndrome) as well as with multiple symmetrical lipomas. Peripheral nerve involvement, although common in these disorders, is usually asymptomatic; autonomic failure may be a rare manifestation. A panoply of visceral dysfunctions are at times associated with the neurologic features—including bone marrow changes of sideroblastic anemia, renal tubular defects, endocrinopathies (mainly diabetes mellitus, but also hypothyroidism or deficiency of growth hormone), hepatopathy, cardiomyopathy, and recurrent vomiting with intestinal pseudo-obstruction. Diabetes has been a marker in several of the early-onset MELAS and MERRF cases that we have seen, but less often when the first manifestations appeared in adulthood.

The investigation of a suspected case of mitochondrial disease begins with an exploration of the family history for odd childhood diseases, including neonatal death, unexplained seizure disorders,

and progressive neurologic deficits of the types already described. Unexplained deafness or diabetes in family members might also raise the level of suspicion of a mitochondrial disorder. The diagnosis should be suspected when a disorder with these characteristics occurs in a pattern that indicates inheritance solely from the females in the family. That said, one encounters families with mendelian patterns of inheritance due to nuclear gene defects as described in the introductory section of this chapter. Commercial tests of leukocytes for the more frequent mitochondrial point mutation sites (3243, 8993, and 8344) are useful but reveal abnormalities in only about 15 percent of patients, perhaps somewhat higher in MERRF and MELAS, even in those whose muscles contain an abundant quantity of mutant mitochondrial genome. Resting and postexercise lactate and pyruvate determinations are helpful, but this test of aerobic capacity has limitations. The more recent work of Taivassalo and colleagues, while showing a wide range of values, suggests that measurement of the partial pressure of oxygen in venous blood from the forearm after ischemic exercise (ischemic forearm test) may still be useful in distinguishing patients with mitochondrial disease from normal subjects. In the former there is a paradoxical rise in PO_2 from an average of 27 to 38 mmHg, while normals show a decline in this value.

A muscle biopsy may disclose several basic abnormalities; ragged red fibers can be recognized by use of the modified Gomori stain on frozen material, and the absence of succinate dehydrogenase and cytochrome oxidase by appropriate histochemical staining. In cases of suspected Leigh syndrome or MELAS, the CT or MRI may show some of the characteristic cerebral lesions; in the other mitochondrial disorders, there are often focal nondescript hyperintensities on T2-weighted MRI as well as atrophy, lucencies, or calcification. Sampling of chorionic villi for prenatal diagnosis may reveal mutant mitochondrial DNA, but this information is not entirely dependable.

It should be evident from the foregoing discussion that normal findings in any of these tests, including the muscle biopsy, do not exclude mitochondrial disease. In the final analysis, it is the clinical syndrome, family history, and any corroborating evidence of a mitochondrial disorder or its genetic representation that is diagnostic. Jackson and coworkers suggest that isolated phenomena such as dementia, muscle weakness, epilepsy, nerve deafness, migraine with strokes, small stature, myoclonic epilepsy, or cardiomyopathy should prompt consideration of a mitochondrial disorder when no other explanation is evident.

CHAPTER 38

DEVELOPMENTAL DISEASES OF THE NERVOUS SYSTEM

Subsumed under this broad heading is a diversity of both developmental malformations and diseases acquired during the intrauterine period of life. They number in the hundreds, according to the tabulation of Dyken and Krawiecki, although many are very rare. Taxonomically they make up two broad categories. The first includes many unrelated genetic pathologic processes: some stem from germplasm abnormalities; others are associated with triplication, deletion, and translocations of chromosomes; and probably some are inherited on a polygenic basis. A remarkable accomplishment has been the identification in the past several years of specific gene defects that give rise to malformations of the brain. The second category is composed of the effects of a variety of noxious agents acting at different times on the immature nervous system, i.e., during the embryonal, fetal, and paranatal periods of life.

It would be intellectually satisfying if all the states that originate in the intrauterine period could be separated strictly into genetic (hereditary) or nongenetic forms, but in many instances the biologic information and the pathologic changes in the brain at this early age do not allow such a division. For example, among the many diseases in which the neural tube fails to close (rachischisis), more than one member of a family may be affected; but it cannot be stated whether a genetic factor is operative or an exogenous factor, such as folic acid deficiency, has acted on several members during a succession of pregnancies of one mother. Even what appears to be an outright malformation of the brain may be no more than a reflection of the timing of an exogenous process that has affected the nervous system and other organs early in the embryonal period, derailing later processes of development. *Teratology*, the scientific study of neurosomatic malformations, is replete with such examples.

Several points should be noted regarding the frequency of developmental disorders. Smith (see K. L. Jones) points out that a single malformation, usually of no clinical significance, occurs in 14 percent of newborns. Two malformations appear in 0.8 percent, and in this group, a major defect is five times more frequent than in the normal population. Three or more malformations are found in 0.5 percent of newborns, and in this latter group, more than 90 percent have one or more major abnormalities (defined as structural abnormalities of prenatal origin that seriously interfere with viability or physical well-being). The figures for major congenital malformations, compiled by Kalter and Warkany, are somewhat higher. What is most important for the neurologist is the fact that the nervous system is involved in most of these infants with major malformations. In fact, about 40 percent of deaths during the first postnatal year are in some manner related to prenatal malformations of the central nervous system (CNS).

A perusal of the following pages makes it evident that there is a great variety of structural defects of the nervous system in early life; in fact, every part of the brain, spinal cord, nerves, and musculature may be affected. Furthermore, certain principles are applicable to the entire group of developmental brain disorders. *First*, the abnormality of the nervous system is frequently accompanied by an abnormality of some other structure or organ (eye, nose,

cranium, spine, ear, and heart), which relates them chronologically to a certain period of embryogenesis. Conversely, the presence of these malformations of nonnervous tissues suggests that an associated abnormality of the nervous system is developmental in nature. This principle is not inviolable; in certain maldevelopments of the brain, which must have originated in the embryonal period, all other organs are normal. One can only assume that in this instance the brain was more vulnerable than any other organ to prenatal as well as natal influences. Perhaps this occurs because the nervous system, of all organ systems, requires the longest time for its development and maturation, during which it is susceptible to disease. *Second*, a maldevelopment of whatever cause should be present at birth and remain stable thereafter, i.e., be nonprogressive (in contrast to the majority of metabolic diseases of infancy discussed in the preceding chapter). Again, this principle requires qualification—the abnormality may have affected parts of the brain that are not functional at birth, so that an interval of time must elapse postnatally before the defect can express itself. *Third*, for an abnormality to be characterized as developmental, birth should have been nontraumatic and the pregnancy uncomplicated by infection or other injurious event. Conversely, the occurrence of a traumatic birth is not proof of a causative relationship between the injury (or infection) and the abnormality, because a defective nervous system may itself interfere with the birth or the gestational process. *Fourth*, if the congenital abnormality has occurred in other members of the family of the same or previous generations, it is usually genetic—although, as noted above, this does not exclude the possible adverse effects of exogenous agents. *Fifth*, many of the teratologic conditions that cause birth defects pass unrecognized because they end in spontaneous abortions. For example, defects due to chromosomal abnormalities occur in about 0.6 percent of live births, but such defects are found in more than 5 percent of spontaneous abortions at 5 to 12 weeks gestational age. *Sixth*, low birth weight and gestational age, indicative of premature birth, increase the risk of mental subnormality, seizures, cerebral palsy, and death.

Regarding *etiology*, which is really the crux of the problem of birth defects, some order and classification have emerged. In general, malformations may be subdivided into four groups: (1) one in which a single mutant gene is responsible (2.25 per 1000 live births); (2) one in which birth defects are associated with chromosomal aberrations (duplication, breakage); (3) a group comprising defects attributable solely to exogenous factors (a virus or other infectious agent, irradiation, or toxin); and (4) the largest group of all, 60 percent of cases, in which no cause can be identified.

It has been stated that true malformations are due to fundamental endogenous disturbances of cytogenesis and histogenesis occurring in the first half of gestation and that exogenous factors, which destroy brain tissue but do not cause malformations, operate in the second half. The potential fallacy of this division is obvious. An exogenous lesion occurring during the embryonal period may not only destroy tissue but also derail the neuronal migrations of normal development.

Table 38-1
Classification of congenital neurologic disorders

I. Neurologic disorders associated with craniospinal deformities	II. The phakomatoses (see Table 38-4)
A. Enlarged head (see also Table 38-2)	A. Tuberous sclerosis
1. Hydrocephalus	B. Neurofibromatosis
2. Hydranencephaly	C. Cutaneous angiomas with CNS abnormalities
3. Macrocephaly	III. Restricted developmental abnormalities of the nervous system
B. Craniostenoses	A. Focal cortical dysgenesis
1. Turricephaly	B. Möbius syndrome
2. Scaphocephaly	C. Congenital apraxia of gaze
3. Brachycephaly	D. Other restricted congenital abnormalities (Horner syndrome, unilateral ptosis, anisocoria, etc.)
C. Disturbances of neuronal formation and migration	IV. Congenital abnormalities of motor function (cerebral palsy)
1. Anencephaly	A. Subependymal (matrix) hemorrhage
2. Lissencephaly, holoprosencephaly, and gyral malformations	B. Cerebral spastic diplegia
D. Microcephaly	C. Infantile hemiplegia, double hemiplegia, and quadriplegia
1. Primary (vera)	D. Congenital extrapyramidal disorders (double athetosis; erythroblastosis fetalis and kernicterus)
2. Secondary to cerebral disease	E. Congenital ataxias
E. Combinations of cerebral, cranial, and other anomalies	F. The flaccid paralyses
1. Syndactyl craniocerebral anomalies	V. Prenatal and paranatal infections
2. Other craniofacial anomalies	A. Rubella
3. Oculoencephalic defects	B. Cytomegalic inclusion disease
4. Oculoauriculocerebral anomalies	C. Congenital neurosyphilis
5. Dwarfism	D. HIV infection and AIDS
6. Dermatocephalic anomalies	E. Toxoplasmosis
F. Rachischisis	F. Other viral and bacterial infections
1. Cephalic and spinal meningocele, meningoencephalocele, Dandy-Walker syndrome, meningomyelocele	VI. Epilepsies of infancy and childhood
2. Chiari malformation	VII. Mental retardation
3. Platysmia and cervical-spinal anomalies (Chap. 45)	
G. Chromosomal abnormalities	

A textbook on principles of neurology is not the place in which to present a detailed account of all the hereditary and congenital developmental abnormalities that might affect the nervous system. For such details, the interested reader should refer to several excellent monographs. Three that the authors recommend are Brett's *Pediatric Neurology*, Berg's *Principles of Child Neurology*, and Lyon and Evrard's *Neuropediatrie*. These are supplemented by special atlases of congenital malformations mentioned further on. In this chapter we sketch only the major groups and discuss in detail a few of the more common disease entities. The classification in Table 38-1 adheres to a *grouping in accordance with the main presenting abnormality or abnormalities*. Represented here are the common problems that lead families to seek consultation with the pediatric neurologist: (1) structural defects of the cranium, spine, and limbs, and of eyes, nose, ears, jaws, and skin; (2) disturbed motor function—taking the form of retarded development or abnormal movements; (3) epilepsy; and (4) mental retardation. The following discussion focuses on each of these clinical states.

NEUROLOGIC DISORDERS ASSOCIATED WITH CRANIOSPINAL DEFORMITIES

A majority of the disorders in this group are due to a genetic error, including those with a specific chromosomal abnormality, or to some unknown factor. One has only to walk through an institution

for the mentally retarded to appreciate the remarkable number and diversity of physical disfigurements that attend abnormalities of the nervous system. Smith, in the third edition of his monograph on the patterns of human malformations, listed 345 distinctive syndromes; in the fourth edition (edited by K. L. Jones, 1988), many new ones were added. Indeed, a normal-appearing and severely retarded individual stands out in such a crowd and will frequently be found to have an inherited metabolic defect or birth injury.

The intimate relationship between the growth and development of the cranium and that of the brain deserves comment. In embryonic life the most rapidly growing parts of the neural tube induce special changes in and at the same time are influenced by the overlying mesoderm (a process known as *induction*); hence abnormalities in the formation of skull, orbits, nose, and spine are regularly associated with anomalies of the brain and spinal cord. During early fetal life the cranial bones and vertebral arches enclose and protect the developing brain and spinal cord; throughout the period of rapid brain growth, as pressure is exerted on the inner table of the skull, the latter accommodates to the increasing size of the brain. This adaptation is facilitated by the membranous fontanelles, which remain open until maximal brain growth has been attained; only then do they ossify (close).

In addition, stature is controlled by the nervous system, as shown by the fact that a majority of mentally retarded individuals are also stunted physically to a varying degree. Thus disorders of cranivertebral development assume importance not merely be-

cause of the physical disfigurement but also because they often reflect an abnormality of the underlying brain and spinal cord, i.e., they become diagnostic signs.

Cranial Malformations at Birth and in Early Infancy

Certain alterations in size and shape of the head in the infant, child, or even adult always signify a pathologic process that affected the brain before birth or in early infancy. The size of the cranium reflects the size of the brain; therefore the tape measure is one of the most useful tools in pediatric neurology—no examination in a neurologically affected child is complete without a measurement of the circumference of the head. Graphs of the head circumference in males and females from birth to 18 years of age have been compiled by Nellhaus. A newborn whose head circumference is below the third percentile for age and sex and whose fontanels are closed may be judged to have a developmental abnormality of the brain. A head that is normal in size at term but fails to keep pace with body length (microcephaly) reflects a later failure of growth and maturation of the cerebral hemispheres (microencephaly).

Enlargement of the Head (Macrocephaly) This can be due to factors extrinsic to the brain, such as hydrocephalus and hydranencephalus (as defined below), or excessive brain growth (megalencephaly or macroencephaly) (Table 38-2). The *hydrocephalic head* is distinguished by several features—frontal protuberance, or bossing; a tendency for the eyes to turn down so that the sclerae are visible between the upper eyelids and iris (sunset sign); thinning of the scalp and prominence of scalp veins; separation of the cranial sutures; and a “cracked pot” sound on percussion of the skull. Infantile hydrocephalus usually comes to medical attention because of an expanding cranium that exceeds normal dimensions for age. The usual causes are type II Chiari malformation, hereditary aqueductal stenosis, and prenatal infections, e.g., toxoplasmosis. These disorders are discussed further on.

The *hydranencephalic head* (hydrocephalus and destruction or failure of development of parts of the cerebrum) is often associated with enlargement of the skull. When it is transilluminated with a strong flashlight in a darkened room, the fluid-filled region of the cranium glows like a jack-o’-lantern. Hydranencephaly is not a well-defined entity. It can be caused by cerebral infarction from intrauterine vascular occlusion or by diseases such as toxoplasmosis and cytomegalovirus (CMV) disease, which destroy parts of each cerebral hemisphere. The lack of brain tissue reduces resistance to intraventricular pressure, permitting great enlargement

of both lateral ventricles; it is especially marked if there is an added hydrocephalic state due to interference with cerebrospinal fluid (CSF) circulation. This type of destruction of the cerebral mantle in the embryonal period may lead to the formation of huge defects, with apposition of ventricular and pial surfaces (*porencephaly*) and subsequent failure of development (evagination) of the brain. Yakovlev and Wadsworth referred to the localized failure of evagination as *schizencephaly* and postulated that it was the result of a focal developmental defect in the wall of the cerebral mantle. They based their interpretation on the finding of malformed cortex in the margins of the defect, but this might indicate only that the lesion preceded neuronal migration. Levine and coworkers have attributed it to a destructive, possibly ischemic lesion occurring in the first few weeks of gestation, at a time when neuronal migration was incomplete. We favor the latter explanation and describe it further in relation to the cerebral palsy. In either event, the lack of resistance of the defective cerebral mantle to ventricular pressure expands the brain and cranium.

The *macrocephalic head* (a large head with normal or only slightly enlarged ventricles) may be indicative of an advancing metabolic disease that enlarges the brain, as in *Alexander disease*, *Canavan’s spongy degeneration of infancy*, and *later phases of Tay-Sachs disease*, all of which are described in Chap. 37. *Agenesis of the corpus callosum*, a common congenital defect, may be associated with macrocephaly and varying degrees of mental impairment, optic defects, and seizures. In a series of 56 patients with agenesis of the corpus callosum, Taylor and David reported the presence of epilepsy in 32 and varying degrees of mental retardation in 28; only 9 had no recognizable neurologic defects. Also noted was a high incidence of psychiatric disturbances in these patients. In such cases, computed tomography (CT) and magnetic resonance imaging (MRI) reveal the characteristic “bat-wing” deformity of the ventricles. There is also asynchrony of electrical activity of the two cerebral hemispheres on the electroencephalogram (EEG). In a few of these patients, an autosomal dominant inheritance has been found (Lynn et al). Agenesis of the corpus callosum is also part of the Aicardi syndrome (see further on) and the Andermann syndrome, and it has been noted in some cases of nonketotic hyperglycinemia.

Subdural hematomas may also enlarge the head and cause bulging of the fontanels and separation of the sutures. In the latter condition, the infant is usually irritable and listless, taking nourishment poorly. Infants and children with neurofibromatosis, osteogenesis imperfecta, and achondroplasia also have enlarged heads; in the last condition some degree of hydrocephalus appears to be responsible. Ultrasonography, which can be performed in the prenatal and neonatal periods, is usually diagnostic in all these cranial enlargements. Also MRI and CT scanning will disclose the size of the ventricles and the presence of subdural blood or fluid (hygroma). Apart from patients with these pathologic states, there are individuals whose heads and brains are enlarged but who are normal in all other respects. Many of these individuals come from families with large heads; Schreier and colleagues, who traced this condition through three generations of some families, declared it to be an autosomal dominant trait. This group represented 20 percent of 557 children referred to a clinic because of cranial enlargement (Lorber and Priestley).

Hemimegalencephaly This term refers to a marked enlargement of one cerebral hemisphere as a result of a developmental abnormality. The cortical gray matter and sometimes the basal ganglia are greatly increased in volume and weight. The cerebellum, brain-

Table 38-2

4. Agenesis of corpus callosum
5. Subdural hematoma
6. Constitutional (familial) macrocephaly
7. Hemimegalencephaly

stem, and spinal cord retain their normal dimensions. The cranium may be misshapen or enlarged but is normal in size in some cases. Rarely, the face and body are enlarged on the side of the enlarged hemisphere. The cortex of the giant hemisphere is thick and disorganized. Neurons are in disarray and some are enlarged; in some places the natural lamination of the cortex is effaced. Nothing is known about causation, but apparently embryogenesis has been deranged at the stage of neuroblast formation.

Clinically, most affected individuals have been mentally retarded and some are epileptic. A degree of hemiparesis may be present, but severe hemispherical neurologic deficits are generally not reported. The hemimegalencephaly has been discovered at autopsy in a few individuals who had no mental or neurologic deficits.

Craniostenoses Some of the most startling cranial deformities are caused by premature closure of the cranial sutures (membranous junctions between bones of the skull). Such conditions are estimated to occur in 1 of every 1000 births, with a predominance in males (Lyon and Evrard). The growth of the cranium is inhibited in a direction perpendicular to the involved suture(s), with a compensatory enlargement in other dimensions, as allowed by the patent sutures. For example, when the lambdoid and coronal sutures are both affected, the thrust of the growing brain enlarges the head in a vertical direction (*tower skull*, or *oxycephaly*, also referred to as *turicephaly* and *acrocephaly*). The orbits are shallow, the eyes bulge, and skull films show islands of bone thinning (*Lückenschadel*). When only the sagittal suture is involved, the head is long and narrow (*scaphocephalic*), and the closed suture projects, keel-like, in the midline. With premature closure of the coronal suture, the head is excessively wide and short (*brachycephalic*). The nervous system is usually normal in these restricted craniostenoses. If this condition is recognized before 3 months of age, the surgeon can make artificial sutures that may permit the shape of the head to become more normal (Shillito and Matson). Once brain growth has been completed, little can be done aside from complex reconstructive surgery. When several sutures (usually coronal and sagittal) are closed, so as to diminish the cranial capacity, intracranial pressure may increase, impairing cerebral function and causing headache, vomiting, and papilledema. Obviously an operation is then needed to increase the capacity of the skull.

In acrocephalosyndactyly or Apert syndrome, craniostenoses that are combined with syndactyly (fused, or webbed, fingers or toes), there are often added complications—mental retardation, deafness, convulsions, and loss of sight secondary to papilledema. The so-called clover-shaped skull is the most severe and lethal of the craniostenoses because of the associated developmental anomalies of the brain (see further on).

When, for any reason, an infant lies with the head turned constantly to one side (because of a shortened sternomastoid muscle or hemianopia, for example), the occiput on that side becomes flattened, as does the opposite frontal bone. The other occipital and frontal bones bulge, so that the maximum length of the skull is not in the sagittal but in the diagonal plane. This condition is called *plagiocephaly*, or *wry head*. Craniostenosis of one-half of a coronal suture may also distort the skull in this way.

Disturbances of Neuronal Migration

Neuroembryologic studies have identified several milestones of neuroblast formation, migration, cortical organization, neuron dif-

ferentiation, and connectivity. Certain developmental anomalies have been traced to one or another of these stages of cytogenesis and histogenesis in the first trimester of gestation and to the growth and differentiation that take place in the second and third trimesters. During the first trimester of gestation, postmitotic neurons that will ultimately reside in the cortex arise in the ventricular zone adjacent to the ventricles. They then migrate along the scaffold of radial glia to form the multilayered cortex. It is striking that neurons moving up the scaffold must pass through neurons that are already in position in the cortex, leading to an “inside-out” lamination in which the most recently born and arrived neurons reside on the outermost surface of the forming cortex.

Originally there is an excess of neurons, many of which degenerate during development—a process properly called *apoptosis*. There are recorded instances in which the full complement of neuroblasts and neurons fails to be generated. Or the emergence of two separate cerebral hemispheres may not occur (*holoprosencephaly*), or the bihemispherical brain may remain small (*microcephaly*). In other described specimens, a diminished number of neurons is less obvious than their failure to migrate to the cortical surface; they remain scattered through the mantle zone in sheets and heterotopic aggregates. One type of focal band-shaped subcortical heterotopia is termed “double-cortex”. *Micropolygyria* refers to an excessive number of abnormally small gyri. It is expressed by a syndrome of mental retardation, seizures, delayed speech, and motor abnormalities. Or, the cortex may fail to become sulcated—i.e., it is *lissencephalic* or may be defectively convoluted, forming microgyric and *pachygryic* (broad gyral) patterns. In yet other brains, neuronal migration is normal for the most part, but small groups of neurons in particular regions may lag or present in regional *heterotopias* (focal dysgeneses) (Fig. 38-1). These migrational disorders, particularly these heterotopias, are just now being recognized by MRI and are found to have a possible functional significance in such states as mental retardation, epilepsy, and dyslexia. Finally, the cortex may be normally formed and structured but there is a failure of differentiation of intra- and intercor-

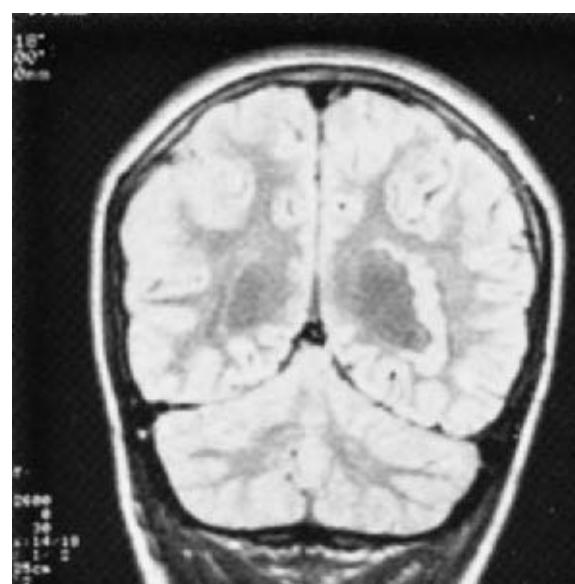

Figure 38-1. MRI in the coronal plane in an infant with seizures. Deep in the white matter, adjacent to the lateral ventricle, is a large heterotopic aggregate of gray matter. Also, there appears to be an increased infolding of the cerebral cortex (polymicrogyria).

tical and interhemispherical connections, the most obvious one being agenesis of the corpus callosum.

The conjunction of cardiac, limb, gut, and bladder abnormalities with neurologic disorder indicates the time at which the insult takes place: cardiac abnormalities occur between the fifth and sixth week; extroversion of the bladder at less than 30 days; duodenal atresia, before 30 days; syndactyly, before 6 weeks; meningocele, before 28 days; anencephaly, before 28 days; cleft lip, before 36 days; syndactyly, cyclopia, and holoprosencephaly, before 23 days.

With these elementary facts of neuroembryology in mind, the bases of the following clinical states are readily conceptualized: anencephaly, lissencephaly, holoprosencephaly, polymicrogyria and pachygryria, microcephaly, and special combinations of cranial and somatic abnormalities. Each is described below.

Also in regard to disorders of brain development, there are special types of tumors thought to be the consequence of abnormal neuronal or glial development; they should be mentioned here. They are variously termed gangliomas, dysembryoblastic neuroepitheliomas, and low-grade astrocytomas. Often they become manifest in the first year of life or even before birth. Their relatively slow growth and benign character suggest that some of them represent hamartomas rather than true neoplasms (see Chap. 31).

Some of the aforementioned cranial abnormalities, of which microcephaly is the most frequent, are secondary to anomalies of cerebral growth. Others—such as abnormalities of the eyes, root of nose, upper lip, ears, and limbs—may represent part of the basic developmental disorder.

Genetics of Cerebral Disorders of Neuronal Migration (Table 38-3) Since each phase of cerebral development is under genetic control, it comes as no surprise that aberrant development might also be genetic. The singular advance in this field has been the identification in recent years of large numbers of genetic defects that underlie the disorders of neuronal migration. These mutations, and what are known of their effects on the developing nervous system, have been reviewed extensively by Mochida and Walsh,

by Kato and Dobyn, and by Ross and Walsh; a summary of the genes is given in Table 38-3. The reader will notice that several quite different genes may give rise to the same type of maldevelopment, but in many cases the role of the affected gene corresponds to a stage and function in brain development that makes the malformation understandable. The specific genetic errors are discussed in each of the sections below. It should at the same time be noted that metabolic disturbances may give rise to malformations of cerebral development. For example, in their review of the inborn errors of metabolism that are linked to cerebral dysgeneses, Nissenkorn and colleagues point out that such disorders as Zellweger syndrome and disorders of fatty oxidation that lead to aberrant neuronal migration and to PKU, hyperglycinemia, and pyruvate dehydrogenase deficiency cause dysgenesis of the corpus callosum.

Anencephaly This is one of the most frequent and also most appalling congenital malformations of the brain. Its incidence is 0.1 to 0.7 per 1000 births, and females predominate in ratios ranging between 3 and 7 to 1. The concordance rate is low, being the same in identical and fraternal twins, but the incidence of the malformation is several times the expected rate if one child in the sibship has already been afflicted. Anencephaly is also more frequent in certain geographic areas, e.g., Ireland, for which various explanations of population genetics or environmental exposure have been postulated. Lacking in cases of anencephaly are large portions of scalp, cranial bones, and brain, including both cerebral cortex and white matter. All that is seen is a hemorrhagic nubbin of nerve, glial, and connective tissue. Brainstem, cerebellum, and spinal cord are present, but often they too are malformed, as are the heart and other organs (15 to 40 percent of cases). In anencephalics who survive for a few days (65 percent die in utero and almost 100 percent before the end of the first postnatal week), startle reactions may be observed, as well as movements of limbs, spontaneous respirations, pupillary light reactions, ocular movements, and corneal reflexes. In a few, avoidance reactions, crying,

Table 38-3

Mutations associated with disorders of neuronal migration and cortical maldevelopment

DISEASE	GENE	GENE FUNCTION
Lissencephaly		
Lissencephaly with cerebellar hypoplasia	RELN (reelin)	Extracellular matrix protein
Lissencephaly (Miller-Dieker) or isolated lissencephaly	LIS1	Microtubule regulator
X-linked lissencephaly with hypogonadism (Partington syndrome)	ARX (aristaless)	Transcription factor
Muscle-eye-brain disease	POMGNT1	Glycosyltransferase
Walker-Warburg	POMT1	Glycosyltransferase
Holoprosencephaly	SHH (sonic hedgehog)	Transcription factor
Double cortex		
Double cortex or X-linked lissencephaly	DCX (doublecortin)	Microtubule-associated protein
Heterotopias		
Periventricular nodular heterotopia	FLNA (filamin A)	Actin-binding protein
Tuberous sclerosis	TSC1 (hamartin)	Tumor suppressor
Tuberous sclerosis	TSC2 (tuberin)	Tumor suppressor
Fukuyama muscular dystrophy	FCMD (fukutin)	Possible glycosyltransferase
Schizencephaly		
Schizencephaly	EMX2	Transcription factor
Microcephaly		
Microcephaly	MCPH1 (microcephalin)	? DNA repair
Microcephaly	MCPH5 ASPM	Mitotic/meiotic spindle

and feeding reflexes can be elicited, indicating that only the rudimentary brain structures are required for these functions.

This condition can be anticipated if the mother's serum levels of α -fetoprotein and acetylcholine esterase are elevated—even more reliably, they are elevated in the amniotic fluid. Positive tests should lead to ultrasound imaging of the fetus. Hydramnios is common. Apparently, the causes of anencephaly are multiple and include chromosomal abnormalities, maternal hyperthermia, and deficiencies of folate, zinc, and copper (see Medical Task Force on Anencephaly in the References). Of these, there is fairly secure evidence that supplemental intake of folic acid during the first trimester of pregnancy (i.e., from the time of conception) greatly reduces the incidence of anencephaly (and of myelomeningocele).

There are additional comments on anencephaly further on in this chapter in the section on rachischisis (lack of fusion of the neural tube).

Lissencephaly (Agyria), Holoprosencephaly, and Gyral Malformations Included under this heading are several forms of neuronal migratory defects. In the lissencephalies, cortical convolutions may be absent altogether and there is morphologic evidence of several types of neuroblast deficiency resulting from either generalized or restricted forms of neuronal migration. Such cases are of particular interest to neonatologists because of their associated physical abnormalities. The degree of impairment of neurologic function seldom allows longevity, so that relatively few examples are to be found in institutions for the mentally retarded. Seizures, poor temperature regulation, failure to accept nourishment, and apneic attacks combine to shorten life. The failures of neuronal migration are of varying degrees of severity. There may be a failure of neurons to form or to migrate along glial guidelines in order to reach the more superficial layers of the cortex (Bielschowsky type); or the cortex, meninges, and eyes may fail to differentiate normally except for the dentate gyrus and hippocampus (Walker-Warburg type); or there may be other relatively minor focal derangements of cortical migrations and laminations with heterotopias of neurons in the white matter.

In the complete lissencephalies, the lateral and third ventricles enlarge due to a lack of the normal quantities of surrounding cerebral tissue (i.e., the aforementioned hydranencephaly). The cerebellar cortex is also abnormal. In some lissencephalic brains, there is slight sulcation presenting as abnormally broad or narrow convolutions, with thick, poorly laminated cortex; these are called *pachygryrias* or *microgyrias*, respectively, but the fundamental migratory abnormality is basically the same. The cerebellum is also abnormal with hypoplasia or aplasia involving the vermis and/or neocerebellum.

In the severe migratory defects, the cranium is small at birth. In one type, which is inherited as an autosomal recessive trait, there are subtle craniofacial features (short nose, small mandible, ear abnormalities) as well as congenital heart disease. In another group, there is an associated familial congenital muscular dystrophy, placing the case between the Fukuyama and Walker-Warburg syndromes (see page 1224). Most severe migratory disorders are sporadic, and the infants seldom survive for long.

Alobar and lobar *holoprosencephalies* are other examples of neuronal migratory defects with craniofacial abnormalities in which development has gone awry in the fifth and sixth weeks of gestation (see Volpe). In these subtypes, the two cerebral hemispheres, either totally or only in part, form as a single telencephalic mass. In nearly every case the cerebral defect is expressed by a

single eye (cyclopia) and absence of nose, imparting an astonishing appearance, which is diagnostic.

In a few of the foregoing malformations, a congenital infection with CMV or rubella has been implicated (Hayward et al.).

The Dandy-Walker syndrome represents a more restricted form of migration and neural tube defect. Here, there is vermian hypoplasia with or without hydrocephalus and, in some cases, an added agenesis of the corpus callosum with cerebral cortical dysgenesis (Landrieu). This defect, which is identified by the cystic enlargement of the fourth ventricle, is discussed further on, with the dysraphic neural tube defects.

That some instances of lissencephaly have a genetic basis has already been mentioned (see Table 38-3). Two genes that modify microtubular function have been identified as causes of lissencephaly: LIS1 and "doublecortin" or DCX. Large chromosomal deletions that span LIS1 cause Miller-Dieker syndrome, in which lissencephaly is associated with distinctive facial abnormalities; small defects in the same gene cause only lissencephaly. Lissencephaly with cerebellar hypoplasia is caused by mutations in the human "reelin" gene (RELN), the analogue of the defective gene in reelin mice (which show a reeling gait and abnormal cortical neuronal lamination). Defects in the transcription factor ARX are associated with X-linked lissencephaly, agenesis of the corpus callosum, and hypogonadism. Periventricular nodular heterotopia is caused by another gene defect, filamin A gene on the X chromosome.

Microcephaly In the above-mentioned cerebral dysplasias, the cranium and brain are small, but there is also a primary form of hereditary microcephaly, called *microcephaly vera*, in which the head is astonishingly reduced in size (circumference less than 45 cm in adult life—i.e., 5 standard deviations below the mean). In contrast, the face is of normal size, the forehead is narrow and recedes sharply, and the occiput is flat. Stature is usually moderately reduced. Such individuals can be recognized at birth by their anthropoid appearance and later by their lumbering gait, extremely low intelligence, and lack of communicative speech. Vision, hearing, and cutaneous sensation are spared. In one of our colleagues' cases, by laborious effort using operant conditioning, it was possible to teach the patient the shapes of simple figures. (His sister's brain, examined by R. D. Adams, was malformed and weighed only 280 g.) In such cases the tendon reflexes in the legs are brisk, and the plantar reflexes may be extensor. Skull films show that the cranial sutures are present, as are convolutional markings on the inner table.

The brain often weighs less than 300 g (normal adult range, 1100 to 1500 g) and shows only a few primary and secondary sulci. The cerebral cortex is thick and unlaminated and grossly deficient in neurons. In a few reported cases, there has been an associated cerebellar hypoplasia or an infantile muscular atrophy. Lesser degrees of microencephaly have been associated with progressive motor neuron disease and degeneration of the substantia nigra (Halperin et al.).

Evrard and associates have described another rare, special type of microcephaly, which they call "radial microbrain." Birth is at term, but the infant dies in the first month of postnatal life. The sulcal pattern is normal, and neuronal arrangements in the cerebral cortex are normal as well. The defect appears to be in the small number of neurons that are generated, not in their migration.

Disorders of the Pial Surface This category of maldevelopment is characterized by inappropriate migration of neurons to the pial

surface, leading to a nodularity of the surface described as a *cobblestone* appearance. In the three disorders with this pathologic finding, the clinical picture is one of mental retardation conjoined with congenital muscular dystrophy. Three identified gene defects are thought to alter the glycosylation of critical proteins in the brain and in skeletal muscle. These genes include the gene fukutin in Fukuyama muscular dystrophy (page 1224), the POMGNT1 gene in muscle-eye-brain disease, and the POMT1 gene in Walker-Warburg syndrome (page 1224) as summarized in Table 38-3.

Combined Cerebral, Cranial, and Somatic Abnormalities

As has been remarked, many diseases that interfere with cerebral development also deform the cranial and facial bones, eyes, nose, and ears. Such somatic stigmata therefore assume significance as indicators of altered cerebral structure and function. Moreover, they constitute irrefutable evidence that the associated neural abnormality is in the nature of a maldevelopment, either hereditary or the result of a disease acquired during the intrauterine period.

There are so many cerebrosomatic anomalies that one can hardly retain visual images of them, much less recall all the physicians' names by which they are known. Of necessity one turns to atlases, one of the best of which has been compiled by Holmes and colleagues and is based on clinical material drawn in large part from the Fernald School and Eunice K. Shriver Center in Massachusetts. The reader may also turn to the books by Gorlin and colleagues and by Jones for specific information. Ford's *Diseases of the Nervous System in Infancy, Childhood, and Adolescence* is still a valuable reference, as is Jablonski's *Dictionary of Syndromes and Eponymic Diseases*.

There is some advantage in grouping these anomalies according to whether the extremities, face, eyes, ears, and skin are associated with a cerebral defect. The sheer number and variety of these anomalies permit only an enumeration of the more common ones and their most obvious physical characteristics. To identify a particular anomaly, one must turn to the specialized monographs and atlases mentioned above. Unfortunately, apart from certain genetic linkages, no useful leads as to their origin have been forthcoming.

The Syndactylic-Craniocerebral Anomalies (Acrocephalosyndactyly) Commonly, fusion of two fingers or two toes or the presence of a tab of skin representing an extra digit may be seen at birth in an otherwise normal individual. However, as pointed out above, when syndactyly is of more severe degree and is accompanied by premature closure of cranial sutures, the nervous system usually proves to be abnormal as well. The general term *acrocephalosyndactyly* is used to describe the several combinations of craniostenotic and facial deformities and fusion of digits. Several of these disorders are a consequence of mutations in genes encoding one of two fibroblast growth factors or proteins related to them. The following descriptions include only the major features; most have, in addition, distinctive malformations of the orbits, ears, and palate.

1. **Acrocephalosyndactyly types I and II (typical and atypical Apert syndrome).** Turri-brachycephalic skull, syndactyly of hands and feet ("mitten hands," "sock feet"), moderate to severe mental retardation.
2. **Acrocephalosyndactyly III (Saethre-Chotzen syndrome).** Various types of craniostenosis, proximally fused and shortened

digits, moderate degree of mental retardation. Transmission as an autosomal dominant trait.

3. **Acrocephalosyndactyly IV (Pfeiffer syndrome).** Turri-brachycephaly; broad, enlarged thumbs and great toes; partially flexed elbows (radiohumeral or radioulnar synostoses); mild and variable mental retardation; autosomal dominant inheritance.
4. **Acrocephalopolysyndactyly V (Carpenter syndrome).** Premature fusion of all cranial sutures with acrocephaly, flat bridge of nose, medial canthi displaced laterally, excess digits and syndactyly, subnormal intelligence.
5. **Acrocephalosyndactyly with absent digits.** High, bitemporally flattened head; absent toes and syndactylic fingers; moderate mental retardation.
6. **Acrocephaly with cleft lip and palate, radial aplasia, and absent digits.** Microbrachycephaly due to craniostenosis, cleft lip and palate, absent radial bones, severe mental retardation.
7. **Dyschondroplasia, facial anomalies, and polysyndactyly.** Keel-shaped skull and ridge through center of forehead (metopic suture), short arms and legs, postaxial polydactyly and short digits, moderate mental retardation.

In all the foregoing types of syndactyly and cranial abnormality, which may be regarded as variants of a common syndrome, the diagnosis can be made at a glance because of the deformed head, protuberant eyes, and abnormal hands and feet. The degree of mental retardation proves to be variable, usually moderate to severe, but occasionally intelligence is normal or nearly so. The brain has been examined in only a few instances and not in a fashion to display fully the type and extent of this developmental abnormality.

Other Craniocephalic-Skeletal Anomalies Members of this group have distinctive anomalies of the cranium, face, and other parts, but craniostenosis is not a consistent feature.

1. **Craniofacial dysostosis (Crouzon syndrome).** Variable degrees of craniostenosis; broad forehead with prominence in the region of the anterior fontanel region; shallow orbits with proptosis; midline facial hypoplasia and short upper lip; malformed auditory canals and ears; high, narrow palate; moderate mental retardation. As noted above, a genetic defect in one of the fibroblast growth factor receptors is responsible for about one-third of cases that are not associated with other deformities (Moloney et al). Autosomal dominant inheritance is seen in most cases.
2. **Median cleft facial syndrome (frontonasal dysplasia; hypertelorism of Greig).** Widely spaced eyes, broad nasal root, cleft nose and premaxilla, V-shaped frontal hairline, heterotopic anterior frontal fontanel (midline cranial defect); mild to severe mental retardation.
3. **Chondrodystrophy calcificans congenita (chondrodysplasia punctata, Conradi-Hünermann syndrome).** Prominent forehead; flat nose; widely separated eyes; short neck and trunk with kyphoscoliosis; dry, scaly, atrophic skin; cicatricial alopecia; irregularly deformed vertebral bodies; mental retardation infrequent. Severe shortening of limbs in some cases.
4. **Orofaciodigital syndrome.** All the patients are female. Pseudoclefs involving the mandible, tongue, maxilla, and palate;

- hypertrophied buccal frenuli; hamartomas of tongue; sparse scalp hair; subnormal intelligence in one-half of cases.
5. *Pyknodysostosis*. Large head and frontal-occipital bossing, underdeveloped facial bones, micrognathia, unerupted and deformed teeth, dense and defective long bones with shortened limbs, short and broad terminal digits of fingers and toes, mental retardation in one-quarter of the cases.
 6. *Craniotubular bone dysplasias and hyperostoses*. Included under this title are several different genetic disorders of bone, characterized by modeling errors of tubular and cranial bones. Frontal and occipital hyperostosis, overgrowth of facial bones, and widening of long bones occur in various combinations. Hypertelorism, broad nasal root, nasal obstruction, seizures, visual failure, deafness, prognathism, and retardation of growth are the major features.

Oculoencephalic (Cranio-Ocular) Defects In this category of anomalies, there is simultaneous failure or imperfect development of eye and brain. One member of this group, the oculocerebrorenal syndrome of Lowe, has already been mentioned on page 812, and, of course, a number of the mucopolysaccharidoses are characterized by corneal opacities, skeletal changes, and psychomotor regression. Also, congenital syphilis, rubella, toxoplasmosis, and CMV inclusion disease may affect retina and brain; hypoxia at birth requiring treatment with oxygen may injure the brain and lead to *retrolental fibrodyplasia*. The true developmental defects in this group are as follows:

1. *Anophthalmia with mental retardation*. Sex-linked recessive. Absent eyes; orbits and maxillae remain underdeveloped, but adnexal tissues of eyes (lids) are intact; subnormal intelligence. Some cases of anophthalmia have been ascribed to genes encoding transcription factors that play a role in the development of the neuraxis (SOX₂, RAX, RAX6).
2. *Norrie disease*. Also sex-linked recessive; some sight may be present at birth; later, eyes become shrunken and recessed (phthisis bulbi); some have short digits, outbursts of anger, hallucinations, and possibly regression of psychomotor function. A novel gene, norrin, on the X chromosome has been implicated.
3. *Oculocerebral syndrome with hypopigmentation*. Autosomal recessive with absence of pigment of hair and skin; small, cloudy, vascularized corneas and small globes (microphthalmia); marked mental retardation; athetotic movements of limbs.
4. *Microphthalmia with corneal opacities, eccentric pupils, spasticity, and severe mental retardation*.
5. *Aicardi syndrome with ocular abnormality*. Chorioretinopathy, retinal lacunae, staphyloma, coloboma of optic nerve, microphthalmos, mental retardation, infantile spasms and other forms of epilepsy, agenesis of corpus callosum, and cortical heterotopias. The “bat-wing” deformity of the third and lateral ventricles on MR images and asynchronous burst-suppression discharges and sleep spindles are diagnostic. The condition is found only in females.
6. *Lissencephaly of the Walker-Warburg type*. This anomaly has already been mentioned, as has its association with congenital muscular dystrophy. Autosomal recessive inheritance. Ocular lesions are constant but variable (retinal dysplasia, microphthalmia, coloboma, cataracts, corneal opacities). There may be hydrocephalus, and by CT scans or MRI, the

lack of cerebral sulci (lissencephaly) is disclosed. The abnormal eyes and orbits and absence of cerebellar vermis are diagnostic (see Table 38-3).

7. *Congenital tapetoretinal degeneration (Leber amaurosis)*. Visual loss from birth, moderate to severe mental retardation, and microcephaly. Early onset of blindness and absent electrical potentials on the electroretinogram (ERG) distinguish it from later-onset Leber optic atrophy.
8. *Septo-optic dysplasia (de Morsier syndrome)*. Diminished visual acuity, small optic discs, absence of septum pellucidum, and precocious puberty. Varying degrees of pituitary insufficiency may be present, requiring endocrine replacement.

Oculoauriculocephalic Anomalies These are less important from the neurologic standpoint, and mental retardation is present only in some cases.

1. *Mandibulofacial dysostosis (Treacher-Collins syndrome, Franceschetti-Zwahlen-Klein syndrome)*
2. *Oculoauriculovertebral dysplasia (Goldenhar syndrome)*
3. *Oculomandibulodyscephaly with hypotrichosis (Hallermann-Streiff syndrome)*

Dwarfism Midgets are abnormally small but perfectly formed people of normal intelligence; they differ from dwarfs, who are not only very small but whose bodily proportions are markedly abnormal. They may or may not be mentally normal. A majority of mentally retarded patients fall below average for height and weight, but there is a small group whose fully attained height is well below 135 cm (4 1/2 ft) and who stand apart by this quality alone (see K. L. Jones for Smith's classification of dwarfs).

1. *Nanocephalic dwarfism (Seckel bird-headed dwarfism)*. The uncomplimentary term *bird head* has been applied to individuals with a small head, large-appearing eyeballs, beaked nose, and underdeveloped chin. Such a physiognomy is not unique to any disease, but when combined with dwarfism it includes a few more or less specific syndromes. Up to 1976, approximately 25 cases had been reported, some with other skeletal and urogenital abnormalities, such as medial curvature of middle digits; occasional syndactyly of toes; dislocations of elbow, hip, and knee; premature closure of cranial sutures; and clubfoot deformity. These individuals are short at birth and remain so, living until adolescence or adulthood. Retardation is severe. A recessive autosomal type of inheritance is probable. At autopsy the brain is found to have a simplified convolutional pattern; one of our patients had a type of myelin degeneration similar to that of Pelizaeus-Merzbacher disease.
2. *Russell-Silver syndrome*. Possibly an autosomal dominant pattern of inheritance, with short stature of prenatal onset, craniofacial dysostosis, short arms, congenital hemihypertrophy (arm and leg on one side larger and longer), pseudoxydroscephalic head (normal-sized cranium with small facial bones), abnormalities of genital development in one-third of cases, delay in closure of fontanelles and in epiphyseal maturation, elevation of urinary gonadotropins. Some cases appear to be due to a nonmutational modification of genes, which are nonetheless inherited (imprinting).
3. *Smith-Lemli-Opitz syndrome*. Autosomal recessive inheritance with microcephaly, broad nasal tip and anteverted

- nares, wide-set eyes, epicanthal folds, ptosis, small chin, low-set ears, enlarged alveolar maxillary ridge, cutaneous syndactyly, hypospadias in boys, short stature, subnormal neonatal activity, normal amino acids and serum immunoglobulins. Older survivors are bereft of language and paraparetic, with increased reflexes and Babinski signs. The hips are usually dislocated. The karyotype is normal. The brain is small but has not been fully examined. Two of our patients are sibling girls.
4. *Rubinstein-Taybi syndrome*. Microcephaly but no craniostenosis, downward palpebral slant, heavy eyebrows, beaked nose with nasal septum extending below alae nasi, mild retrognathia, "grimacing smile," strabismus, cataracts, obstruction of nasolacrimal canals, broad thumbs and toes, clinodactyly, overlapping digits, excessive hair growth, hypotonia, lax ligaments, stiff gait, seizures, hyperactive tendon reflexes, absence of corpus callosum, mental retardation, and short stature. This dominantly inherited disease is due to disruption of so-called CREB-binding protein, a nuclear protein necessary for gene expression that is modulated by cyclic AMP.
 5. *Pierre Robin syndrome*. Possible autosomal recessive pattern of inheritance with microcephaly but no craniostenosis, small and symmetrically receded chin, glossotaxis (tongue falls back into pharynx), cleft palate, flat bridge of nose, low-set ears, mental deficiency, and congenital heart disease in half the cases. Camptomelia (bent bones), diastrophic dwarfism (short limbs) common.
 6. *DeLange syndrome (Cornelia DeLange syndrome)*. The phenotype shows some degree of variability, but the essential diagnostic features are intrauterine growth retardation and stature falling below the third percentile at all ages, microbrachycephaly, generalized hirsutism and eyebrows that meet across the midline (synophrys), anteverted nostrils, long upper lip, and skeletal abnormalities (flexion of elbows, webbing of second and third toes, clinodactyly of fifth fingers, transverse palmar crease). All are moderately or, more often, severely retarded mentally, which, with craniofacial abnormalities, is diagnostic. It has been said, and it has been our experience, that many of these patients are prone to have a bad disposition, manifest by biting and spitting. There are no chromosomal abnormalities. A polygenic inheritance has been postulated, but most cases are sporadic.
 7. *Smith-Magenis syndrome*. This is due to deletions on chromosome 17, in which there is learning disability, severe behavioral problems (violence and self-injury), hyperactivity, deafness, and ocular abnormalities.

Neurocutaneous Anomalies with Mental Retardation

It is not surprising that skin and nervous system should share in pathologic states that impair development, since both have a common ectodermal derivation. Nevertheless, it is difficult to find a common theme in the diseases that affect both organs. In some instances, it is clear that ectoderm has been malformed from early intrauterine life; in others, a number of nondevelopmental acquired diseases of skin may have been superimposed. For reasons to be elaborated later, neurofibromatosis, tuberous sclerosis, and Sturge-Weber encephalofacial angiomatosis must be set apart in a different category of disease termed *phakomatoses*.

Hemangiomas of the skin are without doubt the most frequent cutaneous abnormalities present at birth, and usually they are entirely innocent. Many recede in the first months of life. On the other hand, an extensive vascular nevus located in the territory of the trigeminal nerve—and sometimes in other parts of the body as well—causes permanent disfigurement and usually portends an associated cerebral lesion.

Other neurocutaneous diseases are summarized below. A more complete review of these diseases will be found in the article by Short and Adams in Fitzpatrick's *Dermatology* and the monograph edited by Gomez, listed in the References. The related category of phakomatoses is discussed on page 865. The importance of recognizing the cutaneous abnormalities relates to the fact that the nervous system is usually abnormal, and often the skin lesion appears before the neurologic symptoms are detectable. Thus the skin lesion becomes a predictor of potential neurologic involvement.

1. *Basal-cell nevus syndrome*. This condition is transmitted as an autosomal dominant trait and is characterized by superficial pits in the palms and soles; multiple solid or cystic tumors over the head, face, and neck appearing in infancy or early childhood; mental retardation in some cases; frontoparietal bossing; hypertelorism; and kyphoscoliosis.
2. *Congenital ichthyosis, hypogonadism, and mental retardation*. This disorder is inherited as a sex-linked recessive trait. Aside from the characteristic triad of anomalies, there are no special features.
3. *Xeroderma pigmentosum*. The genetic pattern of inheritance is autosomal recessive. Skin lesions appear in infancy, taking the form of erythema, blistering, scaling, scarring, and pigmentation on exposure to sunlight; old lesions are telangiectatic and parchment-like, covered with fine scales; skin cancer may develop later; loss of eyelashes, dry bulbar conjunctivae; microcephaly, hypogonadism, and mental retardation (50 percent of cases). Kanda and associates classify this disease with the DeSanctis-Cacchione syndrome of "xerodermic idiocy" and believe the basic mechanism to be a faulty repair of DNA. These authors described two young adults with low intelligence, evidence of spinal cord degeneration, and peripheral neuropathy. The peripheral nerve lesions resembled those of amyloidosis, Riley-Day syndrome, and Fabry disease in that there was a predominant loss of small fibers. Other variants are described.
4. *Sjögren-Larssen syndrome*. Autosomal recessive with congenital ichthyosiform erythroderma, normal or thin scalp hair, sometimes defective dental enamel, pigmentary degeneration of retinae, spastic legs, and mental retardation.
5. *Poikiloderma congenitale (Rothmund-Thompson syndrome)*. Autosomal recessive heredity; appearance of skin changes from the third to sixth months of life; diffuse pink coloration of cheeks spreading to ears and buttocks, later replaced by macular and reticular pattern of skin atrophy mixed with striae, telangiectasia, and pigmentation; sparse hair in half of the cases; cataracts; small genitalia; abnormal hands and feet; short stature; and mental retardation.
6. *Linear sebaceous nevus syndrome*. Genetics uncertain. Here there is a linear nevus of one side of face and trunk, lipodermoids on bulbar conjunctivae, vascularization of corneas, mental retardation, focal seizures, and spike and slow waves in the EEG.

7. *Incontinentia pigmenti (Bloch-Sulzberger syndrome)*. Only females affected; appearance of dermal lesions in first weeks of life; vesicles and bullae followed by hyperkeratoses and streaks of pigmentation, scarring of scalp, and alopecia; abnormalities of dentition; hemiparesis; quadriplegia; seizures; mental retardation; and up to 50 percent eosinophils in blood. The status of this disease is uncertain.
8. *Focal dermal hypoplasia*. Also a disease limited to females. Areas of dermal hypoplasia with protrusions of subcutaneous fat, hypo- and hyperpigmentation, scoliosis, syndactyly in a few, short stature, thin body habitus. Intelligence is occasionally subnormal.

Other rare entities are neurocutaneous melanosis, neuroectodermal melanolytic disease with mental retardation, progeria, Cockayne syndrome, and ataxia-telangiectasia (Chap. 37; see also Gomez 1987).

Dysraphism, or Rachischisis (Encephaloceles and Spina Bifida)

Included under this heading are the large number of disorders of fusion of dorsal midline structures of the primitive neural tube, a process that takes place during the first 3 weeks of postconceptual life. Exogenous factors are presumed to be operative in most cases. The entire cranium may be missing at birth, and the undeveloped brain lies in the base of the skull, a small vascular mass without recognizable nervous structures. This state, *anencephaly*, has been discussed earlier, under "Disturbances of Neuronal Migration," and

it is the most frequent of the rachischises. It has many associations with other conditions in which the vertebral laminae fail to fuse.

An evagination of brain tissue and its coverings through an unfused midline defect in the skull is called an *encephalocele*. Frontal encephaloceles may deform the forehead or remain occult. Associated defects of the frontal cortex, anterior corpus callosum, and optic-hypothalamic structures as well as CSF leakage into frontal or ethmoid sinuses pose a risk of meningitis. Some of these children are relatively normal mentally. Far more severe are the posterior encephaloceles, some of which are enormous and are attended by grave neurologic deficits. However, lesser degrees of the defect are well known and may be small or hidden, such as a *meningoencephalocele* connected with the rest of the brain through a small opening in the skull. Small nasal encephaloceles may cause no neurologic signs, but if they are mistaken for nasal polyps and snipped off, CSF fistulae may result. The larger occipital ones are associated with blindness, ataxia, and mental retardation.

A failure of development of the midline portion of the cerebellum, referred to earlier, forms the basis of the *Dandy-Walker syndrome* (Fig. 38-2). A cyst-like structure, representing the greatly dilated fourth ventricle, expands in the midline, causing the occipital bone to bulge posteriorly and displace the tentorium and torcula upward. In addition, the cerebellar vermis is aplastic, the corpus callosum may be deficient or absent, and there is dilatation of the aqueduct as well as the third and lateral ventricles.

Even more frequent are abnormalities of closure of the vertebral arches. These take the form of a *spina bifida occulta*, *meningocele*, and *meningomyelocele* of the lumbosacral or other regions.

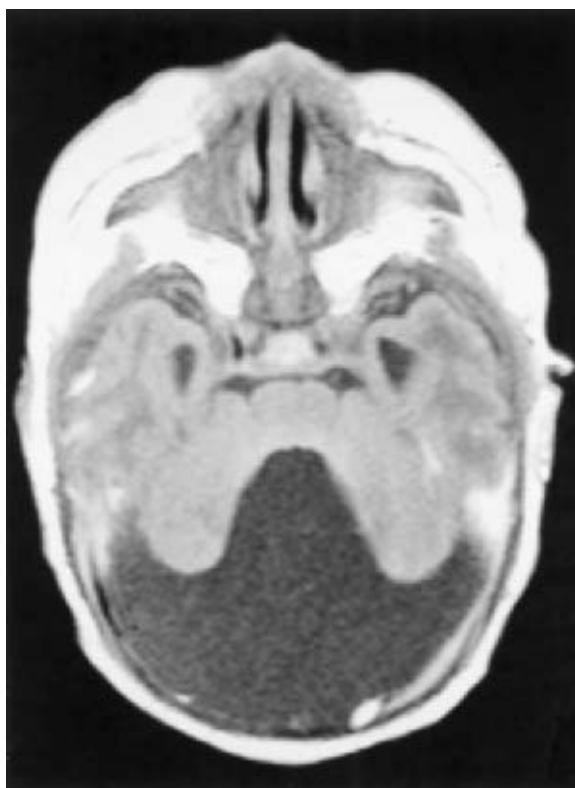

Figure 38-2. Dandy-Walker syndrome. MRI showing agenesis of the midline cerebellum and large midline cyst, representing the greatly dilated fourth ventricle, which occupies almost the entire posterior fossa. A. Axial view. B. Sagittal view.

In *spina bifida occulta*, the cord remains inside the canal and there is no external sac, although a subcutaneous lipoma or a dimple or wisp of hair on the overlying skin may mark the site of the lesion. In *meningocele*, there is a protrusion of only the dura and arachnoid through the defect in the vertebral laminae, forming a cystic swelling usually in the lumbosacral region; the cord remains in the canal, however. In *meningomyelocele*, which is 10 times as frequent as meningocele, the cord (more often the cauda equina) is extruded also and is closely applied to the fundus of the cystic swelling.

The incidence of spinal dysraphism (myeloschisis), like that of anencephaly, varies widely from one locale to another, and the disorder is more likely to occur in a second child if one child has already been affected (the incidence then rises from 1 per 1000 to 40 to 50 per 1000). Exogenous factors (e.g., potato blight in Ireland) have been implicated in the genesis of both myeloschisis and anencephaly. Folic acid, given before the 28th day of pregnancy, can be protective; vitamin A may also have slight protective benefit.

As with anencephaly, the diagnosis can often be inferred from the presence of α -fetoprotein in the amniotic fluid (sampled at 15 to 16 weeks of pregnancy) and the deformity confirmed by ultrasound in utero, as mentioned earlier in this chapter. Blood contamination is a source of error in the fetoprotein test (Milunsky). Acetylcholinesterase immunoassay, done on amniotic fluid, is another reliable means of confirming the presence of neural tube defects. Some parents, on receiving this information, request abortion.

In the case of meningomyelocele, the child is born with a large externalized lumbosacral sac covered by delicate, weeping skin. It may have ruptured in utero or during birth, but more often the covering is intact. There is severe dysfunction of the cauda equina roots or conus medullaris contained in the sac. Stroking of the sac may elicit involuntary movements of the legs. As a rule the legs are motionless; urine dribbles, keeping the patient constantly wet; there is no response to pinprick over the lumbosacral zones; and the tendon reflexes are absent. In contrast, craniocervical structures are normal unless a Chiari malformation is associated (see further on). Differences are noted in the neurologic picture depending on the level of the lesion. If it is entirely sacral, bladder and bowel sphincters are affected but legs escape; if lower lumbar and sacral, the buttocks, legs, and feet are more impaired than hip flexors and quadriceps; if upper lumbar, the feet and legs are sometimes spared and ankle reflexes retained, and there may be Babinski signs. The two dreaded complications of these severe spinal defects are meningitis and progressive hydrocephalus from a Chiari malformation, which is often associated (see below). The subject of neural tube defects has been reviewed by Botto and colleagues.

Treatment Opinions as to proper management vary considerably. Excision and closure of the coverings of the meningomyelocele in the first few days of life is advised if the objective is to prevent a fatal meningitis. After a few weeks or months, as hydrocephalus reveals its presence by rapid increase in head size and enlargement of the ventricles on the CT scan, a ventriculoatrial or ventriculoperitoneal shunt is required. Patients with high spinal lesions and total paraplegia, kyphosis, hydrocephalus, and other major congenital anomalies are usually not accepted for treatment. Less than 30 percent of such patients survive beyond 1 year, and the long-term results of treating these patients have not been encouraging. Lorber and others report that 80 to 90 percent of their surviving patients are mentally retarded to some degree and are paraplegic—thus totally dependent on others for their care. The decision to undertake

rather formidable surgical procedures is being questioned more and more frequently. Exceptionally, the patient with meningomyelocele, and most of those with lumbar meningocele, are mentally normal. Clinical differentiation of this mental state is obviously important.

Other Developmental Spinal Defects and Delayed Effects of Failure of Midline Fusion, Including Tethered Cord The problems of meningomyelocele and its complications are so strictly pediatric and surgical that the neurologist seldom becomes involved—except perhaps in the initial evaluation of the patient—in the treatment of meningeal infection, or in the case of shunt failure with decompensation of hydrocephalus. Of greater interest to the neurologist are a series of closely related abnormalities that produce symptoms for the first time in late childhood, adolescence, or even adult life. These include sinus tracts with recurrent meningeal infections, lumbosacral lipomas with low tethering of the spinal cord (“tethered cord”), and a delayed radicular or spinal cord syndrome; diastematomyelia, cysts, or tumors with spina bifida and a progressive myeloradiculopathy; and a Chiari malformation and syringomyelia that first present in adolescence or adult life. These abnormalities are described below.

Another class of disorders involves an occult lumbosacral dysraphism that is not inherited but is due to faulty development of the cell mass that lies caudal to the posterior neuropore (normally this undergoes closure by the 28th day of embryonic life). Occult spinal dysraphism of this type is also associated with meningoceles, lipomas, and sacrococcygeal teratomas. Another well-recognized anomaly is agenesis of the sacrum and sometimes the lower lumbar vertebrae (*caudal regression syndrome*). Interestingly, in 15 percent of such cases, the mother is diabetic (Lyon and Evrard). Here there is flaccid paralysis of legs, often with arthrogryposis contractures and urinary incontinence. Sensory loss is less prominent, mental function develops normally, and there is no hydrocephalus.

Sinus tracts in the lumbosacral or occipital regions are of importance, for they may be a source of bacterial meningitis at any age. They are often betrayed by a small dimple in the skin or by a tuft of hair along the posterior surface of the body in the midline. (The pilonidal sinus should not be included in this group.) The sinus tract may lead to a terminal myelocystocele and be associated with dermoid cysts or fibrolipomas in the central part of the tract. Cloacal defects (no abdominal wall and no partition between bladder and rectum) may be combined with anterior meningoceles. Evidence of sinus tracts should be sought in every instance of unexplained meningitis, especially when there has been recurrent infection or the cultured organism is of nosocomial dermal origin.

There are, in addition, other *congenital cysts and tumors*, particularly lipoma and dermoid, that arise in the filum terminale and attach (tether) the cord to the sacrum; progressive symptoms and signs are produced as the spine elongates during development, stretching the caudally fixed cord (Fig. 38-3). Some of these children have bladder and leg weakness soon after birth. Others deteriorate neurologically at a later age (generally between 2 and 16 years, sometimes later—see below). According to Chapman and Davis, it is not the myelolipoma but the tethering of the cord that gives rise to symptoms; removal of the tumor is of little benefit unless the cord is untethered (detached from the sacrum) at the same time. This may be difficult, for the lipoma may be fused with the dorsal surface of the spinal cord.

Diastematomyelia is another unusual abnormality of the spinal cord often associated with spina bifida. Here a bony spicule or

Figure 38-3. MRI of an adult with tethered cord and the typical lipoma at its caudal extent (arrow). The conus lies behind the lower lumbar vertebra. No dysraphism is present. The main features were a flaccid bladder, asymmetrical weakness and atrophy of the forelegs, and a degree of spasticity in the legs.

fibrous band protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae and divides the spinal cord in two halves for a variable vertical extent. Or the division of the cord may be complete, each half with its own dural sac and complete set of nerve roots. This longitudinal fissuring and doubling of the cord are spoken of as *diplegomyelia*. With body growth, it leads to a *traction myopathy*, presenting with pain and progressive sensory, motor, and bladder symptoms, sometimes as late as adult life. Removal of the fibrous-bony spicule and untethering of the spinal cord have been beneficial in some cases.

Several clinical syndromes of delayed progressive disease (in adolescents or adults), due mainly to a tethered cord, have been delineated:

1. *Progressive cauda equina syndrome* with lesions in the lumbosacral region. In our experience this has been the most common presentation of the *tethered cord* syndrome, with or without a lipoma or dermoid. Complex disturbances of bladder function that produce urgency and incontinence beginning in the second or third decade may be the only manifestation, or the bladder symptoms may be combined with impotence (in the male) and numbness of the feet and legs or foot drop (Pang and Wilberger). Several of our adult patients have had unusual visceral reflex reactions, such as involun-

tary defecation or priapism with stimulation of the abdomen or perineum.

2. *Progressive spastic weakness* in some of the weak muscles of the legs in a patient known to have had a meningocele or meningomyelocele. Presumably the spinal cord, which is securely attached to the lumbar vertebrae, is stretched during the period of rapid lengthening of the vertebral column.
3. *An acute cauda equina syndrome*, following some unusual activity or accident (e.g., rowing or a fall in a sitting position), in patients who have had an asymptomatic or symptomatic spina bifida or meningocele. The implicated sensory and motor roots are believed to be injured by sudden or repeated stretching.
4. *Syringomyelia* (page 1082). This is a developmental cavity within the cervical cord, extending a variable distance caudally or rostrally, associated with an Arnold-Chiari malformation (see below). Also, there are a variety of neurologic problems associated with spinal abnormalities in the high cervical region [fusion of atlas and occiput or of cervical vertebrae (Klippel-Feil syndrome), congenital dislocation of the odontoid process and atlas, platybasia and basilar impression]. These abnormalities are reviewed in Chap. 44, with other diseases of the spinal cord.

Chiari Malformation

Encompassed by this term are a number of congenital anomalies at the base of the brain, the most consistent of which are (1) extension of a tongue of cerebellar tissue, posterior to the medulla and spinal cord, into the cervical canal and (2) displacement of the medulla into the cervical canal, along with the inferior part of the fourth ventricle. These and associated anomalies were first clearly described by Chiari (1891, 1896). Arnold's name is often attached to the syndrome, but his contribution to our understanding of these malformations was relatively insignificant. Use of the double eponym *Arnold-Chiari malformation* is so entrenched that a dispute over its propriety will not alter its usage. Chiari recognized four types of abnormality. In recent years the term has come to be restricted to Chiari's types I and II—i.e., to the cerebellomedullary malformation without and with a meningomyelocele, respectively. Type III Chiari malformation is no more than a high cervical or occipitocervical meningomyelocele with cerebellar herniation, and type IV consists only of cerebellar hypoplasia. It should be emphasized that a proportion of normal individuals have a small tongue of the posterior cerebellum protruding below the opening of the foramen magnum by a few millimeters; this is usually of no significance and does not justify inclusion as a Chiari malformation.

Several other morphologic features are characteristic of the true anomaly. The medulla and pons are elongated and the aqueduct is narrowed. The displaced tissue (medulla and cerebellum) occludes the foramen magnum; the remainder of the cerebellum, which is small, is also displaced so as to obliterate the cisterna magna. The foramina of Luschka and Magendie open into the cervical canal, and the arachnoidal tissue around the herniated brainstem and cerebellum is fibrotic. All these factors are probably operative in the production of hydrocephalus, which is always associated. Just below the herniated tail of cerebellar tissue there is a kink or spur in the spinal cord, pushed posteriorly by the lower end of the fourth ventricle. In this type of malformation, a meningomyelocele is nearly always found. It should also be empha-

sized that *hydromyelia or syringomyelia of the cervical cord are commonly associated findings.*

Developmental abnormalities of the cerebrum (particularly polymicrogyria) may coexist, and the lower end of the spinal cord (i.e., filum terminale) may extend as low as the sacrum. There are usually cranial bony abnormalities as well. The posterior fossa is small; the foramen magnum is enlarged and grooved posteriorly. Nishikawa et al have suggested that smallness of the posterior fossa, with overcrowding, is the primary abnormality leading to the brain malformation. Often the base of the skull is flattened or infolded by the cervical spine (basilar impression).

Clinical Manifestations In type II Chiari malformation (with meningomyelocele), the problem becomes one of progressive hydrocephalus. Cerebellar signs cannot be discerned in the first few months of life. However, lower cranial nerve abnormalities—laryngeal stridor, fasciculations of the tongue, sternomastoid paralysis (causing head lag when the child is pulled from lying to sitting), facial weakness, deafness, bilateral abducens palsies—may be present in varying combinations. If the patient survives to later childhood or adolescence, one of the syndromes that occurs with the type I malformation may become manifest.

In the more common type I Chiari malformation (without meningocele or other signs of dysraphism), neurologic symptoms may not develop until adolescence or adult life. The symptoms may be those of (1) increased intracranial pressure, mainly headache, (2) progressive cerebellar ataxia, (3) progressive spastic quadripareisis, (4) downbeating nystagmus, or (5) cervical syringomyelia (segmental amyotrophy and sensory loss, with or without pain). Or the patient may show a combination of disorders of the lower cranial nerves, cerebellum, medulla, and spinal cord (sensory and motor tract disorders), usually in conjunction with headache that is mainly occipital. This combination of symptoms is often mistaken for multiple sclerosis or a foramen magnum tumor. The symptoms may have an acute onset after sustained extension of the neck, as, for example, after a long session of dental work, hairdressing in women, or chiropractic manipulation. The physical habitus of such patients may be normal, but about 25 percent have signs of an arrested hydrocephalus or a short “bull neck.” When basilar impression (a congenital abnormality of the occipital bone that invaginates the posterior atlas into the cranial cavity) and a Chiari malformation coexist, it may be impossible to decide which of the two is responsible for the clinical findings.

The tongue of cerebellar tissue and the kinked cervical cord obstruct the upward flow of dye and give a highly characteristic radiologic profile, particularly on sagittal MRI (Fig. 38-4). Inspection of the axial sections of CT scans at the level of the foramen magnum also demonstrates crowding of the upper cervical canal by inferiorly displaced cerebellar tissue, but one must be aware of the variations in the normal position of the cerebellar tonsils at this level. The low-pressure CSF syndrome may also lead to a slight descent of the cerebellar tonsils that is reversible and in our experience not indicative of a Chiari malformation. The CSF is usually normal but may show an elevated pressure and protein level in some cases.

Treatment The treatment of Chiari malformation (and basilar impression) is far from satisfactory. If clinical progression is slight or uncertain, it is probably best to do nothing. If progression is certain and disability is increasing, upper cervical laminectomy and enlargement of the foramen magnum are indicated. Often this pro-

Figure 38-4. Chiari-type malformation and developmental syringomyelia. T1-weighted MRI of the low-lying cerebellar tonsils below the foramen magnum and behind the upper cervical cord (*upper arrow*) and the syrinx cavity in the upper cord (*lower arrow*).

cedure halts the progress of the neurologic illness, arrests the hydrocephalus, or results in some improvement. The outcome, in our experience, has been less satisfactory when decompression was performed mainly for intractable headache. The surgical procedure must be done cautiously. Opening of the dura and extensive manipulation of the malformation or excision of herniated cerebellum may aggravate the symptoms or even cause death. The treatment of an associated syringomyelia and other developmental abnormalities in this region is discussed further on page 1082. We are unable to comment on the use by a limited number of neurosurgeons of posterior fossa decompression for the treatment of chronic fatigue syndrome except to say that it is illogical, even when a Chiari malformation is detected.

CHROMOSOMAL ABNORMALITIES (KARYOTYPIC CHROMOSOMAL DYSGENESES)

A mid-twentieth-century discovery of outstanding significance was the recognition of a group of developmental anomalies of the brain and other organs associated with a demonstrable abnormality of the karyotype of autosomal and sex chromosomes. Jacobs and Lejeune almost simultaneously were the first to note a triplication of the 21st chromosome in the Down syndrome, and there followed the discovery of a number of other trisomies as well as deletions or translocations of other autosomal chromosomes and a lack or excess of one of the sex chromosomes. Such an event must take place

sometime after the formation of the oocyte, during the long period when it lies fallow in the ovary or during the process of conception or germination and first cell divisions. Thus, all the cells in the embryo may carry the changed chromosome or only some of them may, the latter condition being called *mosaicism*.

The precise manner in which triplication or some other imperfection of a chromosome is able to derail the pathways of ontogenesis is a mystery. In some instances, a chromosomal imperfection may result from the lack of a gene or a distortion or fragmentation of a gene, as in the fragile-X syndrome.

Certain chromosomal abnormalities are incompatible with life, and it has been found that the cells of many unexplained abortuses and stillborns show abnormal karyotypes. On the other hand, the organism may survive and exhibit any one of many syndromes, of which the following are the best known and most frequent: (1) Down syndrome (mongolism, trisomy 21); (2) one type of arhinencephaly (trisomy 13, Patau syndrome); (3) trisomy 18 (Edwards syndrome); (4) cri-du-chat syndrome (deletion of short arm of chromosome 5); (5) monosomy 21 (so-called antimongolism); (6) ring chromosomes; (7) Klinefelter syndrome (XXY); (8) Turner syndrome (XO); (9) others (XXXX, XXX, XYY, YY, XXYY); (10) fragile X syndrome, the most common form of inherited mental retardation; (11) Williams syndrome; and (12) Prader-Willi and Angelman syndromes. There are other less frequent types, some of which are also discussed below. The overall frequency of chromosomal abnormalities in live births is 0.6 percent (see the review by Kalter and Warkany). For a comprehensive account of the chromosome-linked disorders the reader is referred to the article by Lemieux and for speculations on the nature of genetic retardations, to that of Nokelainen and Flint.

Down Syndrome Described first in 1866 by Langdon Down, this is the best known of the chromosomal dysgeneses. The frequency is 1 in 600 to 700 births, and this condition accounts for approximately 10 percent of all cases in every large series of cases of severe mental retardation. Familiarity with the condition permits its recognition at birth, but it becomes more obvious with advancing age. The round head, open mouth, stubby hands, slanting palpebral fissures, and short stature impart an unmistakable appearance. The ears are low-set and oval, with small lobules. The palpebral fissures slant slightly upward and outward owing to the presence of medial epicanthal folds that partly cover the inner canthi (hence the old term *mongolism*). The bridge of the nose is poorly developed and the face is flattened (hypoplasia of the maxillae). The tongue is usually enlarged, heavily fissured, and protruded. Gray-white specks of depigmentation are seen in the irides (Brushfield spots). The little fingers are often short (hypoplastic middle phalanx) and incurved (clinodactyly). The fontanelles are patent and slow to close. The hands are broad, with a single transverse (simian) palmar crease and other characteristic dermal markings. Lenticular opacities and congenital heart lesions (septal and other defects) as well as gastrointestinal abnormalities (stenosis of duodenum) are frequent. The patient with Down syndrome is slightly below average size at birth and is characteristically of short stature at later periods of life. The height attained in adult life seldom exceeds that of a 10-year-old child.

Hypotonia of limbs is a prominent finding. At first the Moro response is reduced or absent, and feeding is difficult. Most affected children do not walk until 3 to 4 years of age; their acquisition of speech is delayed, but over 90 percent talk by 5 years. The intelligence quotient (IQ) is variable, and that of a large group follows

a Gaussian curve with the median IQ being 40 to 50 and the range, 20 to 70. A placid, docile, and affectionate personality characterizes most Down patients. A high incidence of atlantoaxial instability puts these individuals at risk of traumatic spinal cord compression in athletic ventures. Also, an increased incidence of myelocytic and lymphocytic leukemia takes its toll. A number of patients have had embolic strokes and brain abscesses secondary to cardiac abnormalities. There is disproportionate occurrence of the rare cerebrovascular disorder known as moyamoya (page 706). Life expectancy is later shortened by the almost universal development of Alzheimer disease by the 40th year of life. This is explained by the presence of the gene for the precursor of the protein amyloid, a central factor in the development of Alzheimer disease, on the triplicated chromosome 21.

One cannot distinguish the Down syndrome with the more common triplication of chromosome 21 from that due to a translocation. There is a strong correlation between some of these types and the age of the mother. The triplication is found in the offspring of older mothers, whereas the less frequent translocation is found equally in the offspring of young and old. In other subtypes of the Down syndrome, referred to as *mosaics*, some cells share in the chromosomal abnormality and others are normal. Mosaics have atypical forms of the syndrome, and some such individuals are actually of normal intelligence. Laboratory tests are not helpful in clarifying the mechanism of the disorder.

The genetic changes that lead to cerebral maldevelopment and dysmorphic physical features are just beginning to be understood. A connection to genes that code for enzymes of folate has been suggested (among other mechanisms). The genetic aspects, as well as features pertaining to the medical care of these patients, are summarized by Rotzen and Patterson. They emphasize the high frequency of enteric sprue (celiac disease) and hypothyroidism and the need for screening for these conditions.

Pathologic Findings Brain weight is approximately 10 percent less than average. The convolutional pattern is rather simple. The frontal lobes are smaller than normal, and the superior temporal gyri are thin. There are claims of delayed myelination of cerebral white matter and also of immature and poorly differentiated cortical neurons. Alzheimer neurofibrillary changes and neuritic plaques are practically always found in Down cases beyond 40 years of age. As Alzheimer disease develops, the usual clinical picture is marked by inattentiveness, reduced speech, impairment of visuospatial orientation, loss of memory and judgment, and seizures.

It is possible to make the diagnosis of Down syndrome by demonstrating the chromosomal abnormalities in cells of the amniotic fluid. About one-third of pregnant mothers also have an abnormal elevation of serum α -fetoprotein in the second trimester of pregnancy. Other independent predictors of fetal Down syndrome are elevated serum chorionic gonadotropin and decreased estriol (Haddow et al). One can uncover a considerable proportion of the Down population by prenatal screening for these serum markers and by performing amniocentesis on women with positive tests to search for the chromosomal abnormality. Early detection is aided by the absence on imaging of a nasal bone between 11 and 14 weeks, at which time it is normally detected (Cicero et al).

Other Chromosomal Dysgeneses

These are listed again here with brief descriptions of their main features.

1. *Trisomy 13 (Patau syndrome)*. Frequency 1 in 2000 live births, more female than male, average maternal age 31 years, microcephaly and sloping forehead, microphthalmos, coloboma of iris, corneal opacities, anosmia, low-set ears, cleft lip and palate, capillary hemangioma, polydactyly, flexed fingers, posterior prominence of heels, dextrocardia, umbilical hernia, impaired hearing, hypertonia, severe mental retardation, death in early childhood.
2. *Trisomy 18*. Frequency 1 in 4000 live births, more in females, average maternal age 34 years, slow growth, occasional seizures, severe mental retardation, hypertonia, ptosis and lid abnormalities, low-set ears, small mouth, mottled skin, clenched fists with index fingers overlapping the third finger, syndactyly, rocker-bottom feet, shortened big toe, ventricular septal defect, umbilical and inguinal hernias, short sternum, small pelvis, small mandible, death in early infancy.
3. *Cri-du-chat syndrome* (deletion in short arm of chromosome 5). Abnormal cry, like a kitten, severe mental retardation, hypertelorism, epicanthal folds, brachycephaly, moon face, antimongoloid slant of palpebral fissures, micrognathia, hypotonia, strabismus.
4. *Ring chromosomes*. Mental retardation with variable physical abnormalities.
5. *Klinefelter syndrome (XXY)*. Only males. Eunuchoid appearance, wide arm span, sparse facial and body hair, high-pitched voice, gynecomastia, small testicles, usually mentally retarded but not severely so; high incidence of psychosis, asthma, and diabetes.
6. *Turner syndrome (XO)*. Only females. Triangular face, small chin, occasionally hypertelorism and epicanthal folds, widely spaced nipples, clinodactyly, cubitus valgus, hypoplastic nails, short stature, webbed neck, delayed sexual development, mild mental retardation.
7. *Colpocephaly*. A rare type of malformation of the brain consisting of marked dilatation of the occipital horns of the lateral ventricles, thickening of the overlying rim of cortical gray matter, and thinning of the white matter. The associated clinical picture comprises mental retardation, spasticity, seizures, and visual abnormalities (due to optic nerve hypoplasia). This disorder is probably of diverse causation, but it is listed here with the chromosomal abnormalities because some cases have been associated with the mosaicism for trisomy 8 (Herskowitz et al). The term *colpocephaly* is often used incorrectly to apply to all forms of ventricular enlargement (including hydrocephalus) associated with abnormal development of the brain.
8. *Fragile X syndrome* (see page 887 for clinical details). This abnormality is among the most common inherited form of mental retardation, estimated to occur in 1 of every 1500 male births and accounting for 10 percent of severe mental retardation in males. Females, with two X chromosomes, are affected about half as frequently, and then only to a slight degree. With the advent of new markers for the detailed structure of chromosomes, Lubs observed an unusual site of frequent breakage ("fragility") on the X chromosome and related it to a syndrome that includes mental retardation, flaring ears, elongated facies, slightly reduced cranial perimeter, normal stature, and enlarged testes. A rare pro-

gressive ataxia has been reported in adults who harbor the chromosomal abnormality.

The chromosomal fragility appears to be due to a heritable, unstable CGG repeating sequence in the X-chromosome. Affected individuals have over 230 repeats and carriers have 60 to 230 repeats. The prolonged sequence inactivates a gene (FMR1) that codes for an RNA-binding protein of as yet an unknown connection to brain function. The genetics of this and other retardations is extensively reviewed by Nokelainen and Flint. Rousseau and colleagues have described a simple and sensitive test, using DNA analysis, for the diagnosis of the syndrome both prenatally and after birth. Because of mosaicism, the length of the triplet repeat does not directly relate to the degree of expression of retardation, and the fragile X alteration occasionally turns up in mentally normal males; in some instances the male children of their daughters have the disease. In some of our cases, the intellectual deficit has been mild in degree; and the main abnormalities have taken the form of troublesome behavior, logorrhea, an autistic type of gaze aversion, and asociality. These and other peculiar features of the syndrome and its unique pattern of inheritance (it is neither recessive nor dominant) have been discussed by Shapiro.

9. *Williams syndrome*. Described by J. C. P. Williams of Australia from the perspective of a supravalvular aortic stenosis and later by Beuren and colleagues, this unique combination of cerebral maldevelopment and cardiovascular abnormalities has been traced in most patients to a microdeletion on chromosome 7 in the region of the gene that codes for the protein elastin. Its frequency is 1 in 20,000 newborns. Further discussion of clinical features of this syndrome will be found on page 888.
10. *Prader-Willi and Angelman syndromes*. The Prader-Willi syndrome has already been mentioned in relation to the hyperphagia of hypothalamic disorders (page 486). It is not uncommon (1 in 20,000 births) and affects both sexes equally. Hypotonia (floppy infant), areflexia, small stature, dysmorphic facies, and hypoplastic genitalia are evident, and arthrogryposis may be present at birth. After the first year, mental retardation becomes obvious and obesity, due to hyperphagia, becomes prominent. Patients are identified by the "H3O" mnemonic, referring to hypomentia, hypotonia, hypogonadism, and obesity. The disorder is associated with a deletion at 15q11-q13 (a so-called microdeletion, as in Williams syndrome), which can be identified by a combination of cytogenetic and DNA analyses. In 70 percent of cases the disease is due to a noninherited deletion from the paternal X chromosome.

The Angelman syndrome, another cause of severe mental retardation, is associated with the identical chromosomal abnormality to that found in the Prader-Willi syndrome, but there is usually a maternally inherited single gene defect. The difference in phenotype derives from a complex genetic phenomenon termed *spatially restricted imprinting*. The phenotype comprises severe mental retardation, microcephaly, refractory seizures, absence of speech, ataxia, inappropriate laughter, prominent jaw, thin upper lip, and prolonged tongue. Outstanding are an unusual marionette-like stance coupled with a persistent tendency to

- laugh and smile (hence the old name “happy puppet syndrome”) (see also Chap. 37).
11. *Rett syndrome*, discussed more fully on page 888, is mentioned here because it is due to a dominant defect on the X chromosome. It affects 1 of every 10,000 to 15,000 girls. After 6 to 18 months of normal development, motor skills and mental abilities seem slowly to regress. Certain hand-wringing and other stereotyped hand movements appear as the disease progresses and are characteristic.

Several generalizations can be made about these chromosomal dysgeneses. First, the autosomal ones are often lethal (*Rett syndrome* is an exception), and they almost always have a devastating effect on cerebral growth and development, whether the infant survives or not. Anomalies of nonneural structures are regularly present—an association so constant that one may safely predict that a normally formed infant will not have a detectable chromosomal defect. However, only in the Down syndrome and trisomy 13 (and possibly trisomy 18) are the physiognomy and bodily configuration highly characteristic. Surprisingly, some of the most grotesque disfigurements, such as anencephaly and multiple severe congenital anomalies, are not related to a morphologic abnormality of chromosomes. By contrast, an insufficiency of sex chromosomes induces only subtle effects on the brain, affecting intellect and personality; to some extent this is true of supernumerary sex chromosomes (XYY, for example).

The nature of the basic abnormality of the brain underlying the mental retardation in many of these chromosomal dysgeneses has not been ascertained. The cerebra are slightly small, but only minor changes are seen in the convolutional pattern and cortical architecture in conventional microscopic preparations. Neurocellular methodologies are not sufficiently advanced to reveal the fundamental cerebral abnormality.

Teratologic Factors

A number of observations have repudiated the former belief that the human embryo is naturally shielded against exogenous causes of maldevelopment. Irradiation during the first trimester, rubella and CMV infections, severe hypothyroidism of the mother during this same period, and the action of aminopterin, alcohol, vitamin A, and thalidomide have all been observed to give rise to serious disorders of development. Also, the offspring of mothers receiving anticonvulsant drugs during the early months of pregnancy have a slightly increased risk of developing birth defects (approximately 5 percent, compared to 3 percent for the general population—see page 296). Among anticonvulsants, the greatest risk is with trimethadione, now rarely used; but phenytoin, carbamazepine, valproate, and phenobarbital have also been implicated. Cleft lip and palate are the most common anomalies attributable to anticonvulsant drugs; other craniofacial defects, spina bifida, minor cardiac defects, and dysraphisms have also been reported at a slightly increased rate (Janz et al). Concerning this, and even more so for other teratogens, there is much controversy. Claims and counter-claims have been made concerning the pathogenicity of numerous substances. Mainly, the data are from animals given amounts far in excess of any possible therapeutic doses in humans. The data from humans are so meager that they are not discussed here. The reader should refer to the article by Kalter and Warkany for further information.

THE PHAKOMATOSES (CONGENITAL NEUROECTODERMOSES)

As stated earlier, there are two broad categories of neurocutaneous diseases. In one, the infant is born with a special type of skin disease or develops it in the first weeks of life; in the other, particular forms of cutaneous abnormality, though often present in minor degree at birth, later evolve as quasineoplastic disorders. The latter, to which van der Hoeve (1920) applied the term *phakomatoses* (from the Greek *phakos*, meaning “mother spot,” “mole,” or “freckle”), include tuberous sclerosis, neurofibromatosis, and cutaneous angiomas with CNS abnormalities. These diseases have many features in common—hereditary transmission, involvement of organs of ectodermal origin (nervous system, eyeball, retina, and skin), slow evolution of lesions in childhood and adolescence, tendency to form hamartomas (benign tumor-like formations due to maldevelopment), and a disposition to fatal malignant transformation. These disorders are discussed below and listed in Table 38-4.

Tuberous Sclerosis (Bourneville Disease)

Tuberous sclerosis is a congenital disease of hereditary type in which a variety of lesions, due to a limited hyperplasia of ectodermal and mesodermal cells, appear in the skin, nervous system, heart, kidney, and other organs. It is characterized clinically by the triad of *adenoma sebaceum*, *epilepsy*, and *mental retardation*. Hypomelanotic skin macules (“ash-leaf” lesions) are another-constant feature; the subepidermal fibrotic “shagreen patch” is diagnostic.

It is stated that Virchow recognized scleromas of the cerebrum in the 1860s and that von Recklinghausen reported a similar lesion combined with multiple myomata of the heart in 1862, but Bourneville’s articles, appearing between 1880 and 1900, presented the first systematic accounts of the disease, and it was he who related the cerebral lesions to those of the skin of the face. Vogt (1890) fully appreciated the significance of the neurocutaneous relationship and formally delineated the triad of facial adenoma sebaceum, epilepsy, and mental retardation. “Epiloia,” a term for the disease introduced by Sherlock in 1911, never gained general acceptance. These and other historical aspects are reviewed in Gomez’s monograph.

Table 38-4
The congenital neuroectodermoses

- | |
|---|
| True phakomatoses |
| 1. Tuberous sclerosis |
| 2. Neurofibromatosis |
| Cutaneous angiomas with abnormalities of the central nervous system |
| 1. (Sturge-Weber syndrome) |
| 2. Dermatomal hemangiomas and spinal vascular malformations |
| 3. Epidermal nevus (linear sebaceous nevus) syndrome |
| 4. Osler-Weber-Rendu disease |
| 5. von Hippel-Lindau disease |
| 6. Ataxia-telangiectasia (Louis-Bar disease) |
| 7. Fabry disease |

Epidemiology This disease has been described in all parts of the world and is equally frequent in all races and both sexes. Heredity is evident in only a minority of cases—50 percent in some series and as little as 14 percent in the series of Bundag and Evans (cited by Brett). The disease is determined by two autosomal dominant genes (see below). The estimated prevalence is 1 in 20,000 to 300,000. The disease involves many organs in addition to the skin and brain, and it may assume a diversity of forms, the least severe of which (i.e., the *forme fruste*) is difficult to diagnose; hence, one cannot be precise about its incidence. Tuberous sclerosis accounts for about 0.66 percent of the mentally retarded in institutions and 0.32 percent of epileptics. It is likely that data drawn from mental hospital populations have exaggerated the overall frequency of mental retardation (Gomez). The medical literature contains a number of reports of patients whose mentality is preserved and who have never had convulsions.

Etiology and Pathogenesis The disease is inherited in an autosomal dominant fashion. The abnormal gene is localized to one of two sites—the long arm of chromosome 9, designated as TSC 1 (hamartin), and the short arm of chromosome 16, TSC 2 (tuberlin). Hamartin and tuberlin interact to suppress cell growth and function as tumor suppressor proteins. In tuberous sclerosis they are inactivated by mutations. This may, in part, explain the proclivity to develop various growths and hamartomas. The cerebral lesions and two of the three associated skin lesions of tuberous sclerosis are of this type. Several hypotheses relating to neuronal migration or to excessive secretion of growth factors have been proposed to link the inactivation of these genes with the pathogenesis of the characteristic lesions. The cellular elements within the nodular cerebral lesions (called tubers; see below) are abnormal in number, size, and orientation. The tumor-like growths in different organs may include cells of more than one type (e.g., fibroblasts, cardiac myoblasts, angioblasts, glioblasts, and neuroblasts), and their number is locally excessive. Something appears to have gone awry with the proliferative process during embryologic development, yet it is usually kept under control, in the sense that only rarely do the growths undergo malignant transformation. Highly specialized cells within the lesions may attain giant size; neurons three to four times normal size may be observed in the cerebral scleroses. These facts emphasize the potentially blastomatous character of the process.

Clinical Manifestations The disease may be evident at the time of birth (the diagnosis has been made by CT scan in neonates), but more often the infant is judged at first to be normal. In approximately 75 percent of cases, attention is drawn to the disease initially by the occurrence of focal or generalized seizures or by retarded psychomotor development. As with any condition that leads to mental retardation, the first suspicion is raised by delay in reaching normal maturational milestones. Whatever the initial symptom, the convulsive disorder and mental retardation become more prominent within 2 to 3 years. The facial cutaneous abnormality, adenoma sebaceum, appears later in childhood, usually between the fourth and tenth years, and is progressive thereafter.

As the years pass, the seizures change pattern. In the first year or two they take the form of massive flexion spasms with hypsarrhythmia (irregular dysrhythmic bursts of high-voltage spikes and slow waves in the EEG). As many as 25 percent of our patients with these types of seizures have been found to have tuberous sclerosis. Later, the seizures change to more typical generalized motor and psychomotor attacks or atypical petit mal. Any one of the sei-

zure types may be brief, especially if the patient is receiving anti-convulsant medication. Seizures are always the most reliable index of the cerebral lesions; focal neurologic abnormalities, which one might expect to occur from the size and location of the lesions, are distinctly uncommon.

Mental function continues to deteriorate slowly. Exceptionally there is a spastic weakness or mild choreoathetosis of the limbs and in a few cases an obstructive hydrocephalus. As in any state of severe mental retardation, a variety of nonspecific motor peculiarities—such as constant crying, muttering, stereotypical rocking and swaying movements, and digital mannerisms—may be observed. In nearly half of the cases, affective and behavioral derangements, often of hyperkinetic and aggressive type, are added to the intellectual deficiency.

The lack of parallelism in the severity of the epilepsy, the mental deficit, and cutaneous abnormalities has been noted by all clinicians who have wide experience with this disease. Some patients are subject to recurrent seizures while retaining relatively normal mental function; in others, trivial skin lesions or a retinal phakoma may suggest the diagnosis in a mentally normal person with few seizures. In such cases, recognition may elude competent neurologists and dermatologists. As a general rule, early onset of seizures is predictive of mental retardation. Gomez and colleagues have suggested that the seizures damage the brain, a point with which we tend to agree in part. However, it seems likely that both the epilepsy and mental retardation are the product of severe involvement of the brain by the lesions of tuberous sclerosis.

Limitation of space allows no more than a catalogue of other visceral abnormalities. In about half the cases, gray or yellow plaques (in reality gliomatous tumors) may be found in the retina in or near the optic disc or at a distance from it. It is from this lesion, called a *phakoma*, that van der Hoeve derived the term that is applied to all neurocutaneous diseases of this class. About half of all benign rhabdomyomas of the heart are associated with tuberous sclerosis; if located in the wall of the atrium, they may cause conduction defects. Other benign tumors of mixed cell type (angiomyolipomas) have been found in the kidneys, liver, lungs, thyroid, testes, and gastrointestinal tract. Cysts of the pleura or lungs, bone cysts in digits, and zones of marbling or densification in bones are some of the less common abnormalities.

In approximately 90 percent of patients with tuberous sclerosis, congenital hypomelanotic macules—“ash-leaf” lesions—formerly mistaken for partial albinism or vitiligo, appear before any of the other skin lesions (Fitzpatrick et al). Gold and Freeman as well as Fitzpatrick and colleagues have emphasized the frequency of these leukodermic lesions and their value in the diagnosis of tuberous sclerosis during infancy, before the appearance of the other characteristic cutaneous lesions. The hypomelanotic areas are arranged in linear fashion over the trunk or limbs and range in size from a few millimeters to several centimeters; their configuration is oval, with one end round and the other pointed, in the shape of an ash leaf. A Wood’s lamp, which transmits only ultraviolet rays, facilitates the demonstration of the ash-leaf lesions because of the absence of melanoblasts, which normally absorb light in the ultraviolet range (360-nm wavelength). These lesions become pink when rubbed and contain sweat glands; they are not usually present on the face or head. There is occasionally a white tuft of hair (poliosis). Electron microscopic examination of the hypomelanotic lesions shows a normal or reduced number of melanocytes, but their dopa reaction is reduced and melanosomes are small.

The well-developed facial lesions (adenomas of Pringle), pathognomonic of tuberous sclerosis, are present in 90 percent of patients over 4 years of age. Typically they are red to pink nodules with a smooth, glistening surface, and they tend to be limited to the nasolabial folds, cheeks, and chin; sometimes they also involve the forehead and scalp. Although called “adenoma sebaceum,” these nodules are actually angiofibromas; the sebaceous glands are only passively involved (Fig. 38-5). The earliest manifestation of facial angiofibromatosis may be a mild erythema over the cheeks and forehead, intensified by crying. The occurrence of large plaques of connective tissue on the forehead is usually expressive of a severe form of the disease.

On the trunk, the diagnostic lesion is the “shagreen patch” (in reality a plaque of subepidermal fibrosis) found most often in the lumbosacral region. It appears as a flat, slightly elevated, flesh-colored area of skin 1 to 10 cm in diameter, with a “pigskin,” “elephant hide,” or “orange peel” appearance (Fig. 38-6). Another common site of fibromatous involvement is the nail bed; subungual fibromas usually appear at puberty and continue to develop with age. Other common skin changes, not in themselves diagnostic, include fibroepithelial tags (soft fibromas), café au lait spots, and port-wine hemangiomas.

Pathology The brain exhibits a number of diagnostic anomalies. Broadening, unnatural whiteness, and firmness of parts of some of the cerebral convolutions are simulated by no other disease. These are the *tubers* after which the disease is named. On the surface of the brain, they range in width from 5 mm to 2 or 3 cm. Their cut surface reveals a lack of demarcation from cortex and white matter and the presence of white flecks of calcium; these, which are readily seen on CT scans and MRI, are called *brain stones* (see below and Fig. 38-7). The walls of the lateral ventricles may be encrusted with white or pink-white masses resembling candle gutterings. When calcified, they appear in radiographs as curvilinear opacities that follow the outline of the ventricle. Rarely, nodules of abnormal tissue are observed in the basal ganglia, thalamus, cerebellum, brainstem, and spinal cord.

Under the microscope the tubers are seen to be composed of interlacing rows of plump, fibrous astrocytes (much like an astrocytoma, though lacking in glial fibrillar protein). In the cerebral cortex and ganglionic structures, derangements of architecture re-

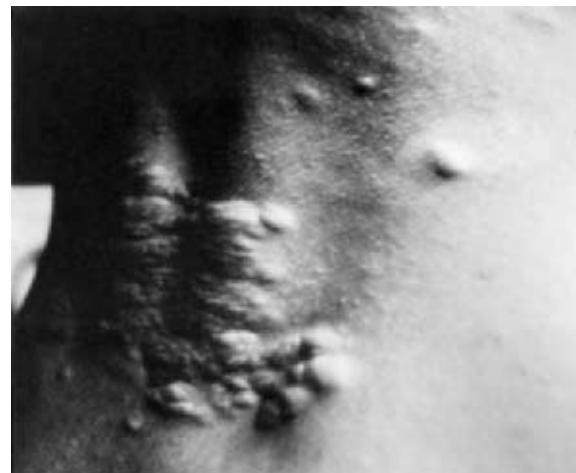

Figure 38-6. Shagreen patch on the skin of the lower back in a young patient with tuberous sclerosis.

sult from the presence of abnormal-looking cells: greatly enlarged “monstrous,” or “balloon” neurons and glial cells—often difficult to distinguish from one another. Also, displaced normal-sized neurons contribute to the chaotic histologic appearance. Gliomatous deposits may obstruct the foramina of Monro or the aqueduct or floor of the fourth ventricle, causing hydrocephalus. Neoplastic transformation of abnormal glial cells, a not infrequent occurrence, usually takes the form of a large-cell astrocytoma, less often of a glioblastoma or meningioma. Recently, certain relationships have been drawn between the balloon cells of this disease and similar cells in focal cortical dysplasias (see Crino for details).

The phakomas of the retina are also composed mainly of neuronal and glial components, but occasionally there is an admixture of fibrous tissue.

Diagnosis When the full combination of seizures and mental and dermal abnormalities is conjoined, the diagnosis is self-evident. It is the early stage of the disease and the *formes frustes* that give trouble, and here the experienced dermatologist can be of great help. Epilepsy—i.e., flexion spasms in infancy—and delay in psychomotor development are by no means diagnostic of tuberous sclerosis, since they occur in many diseases. It is in these cases and also in every sizable population of the epileptic or mentally retarded, especially when the family history is unrevealing, that a search for the dermal equivalents of the disease—the hypomelanotic ash-leaf spots, adenoma sebaceum, collagenous skin patch, phakoma of the retina, or subungual or gingival fibromas—is so rewarding. The finding of any one of these lesions provides confirmation of the partial and atypical case. Adenoma sebaceum may occasionally occur alone and is easily confused with acne vulgaris in the adolescent. The history of epilepsy and/or the demonstration of a dull mentality are helpful, but neither is a requisite for the diagnosis of tuberous sclerosis (see the monograph by Gomez).

The most useful laboratory measures for corroborating the disease are the CT scan and MRI (Fig. 38-7). The calcific lesions tend to be periventricular and are particularly well shown on the CT scan, whereas MRI is more sensitive in detecting hamartomatous subcortical lesions. There is an absence of edema in the surrounding tissue. Roach and colleagues have indicated that an increasing number of cortical lesions demonstrated with MRI appears to correlate with an increased impairment of neurologic function.

Figure 38-5. Adenoma sebaceum of tuberous sclerosis.

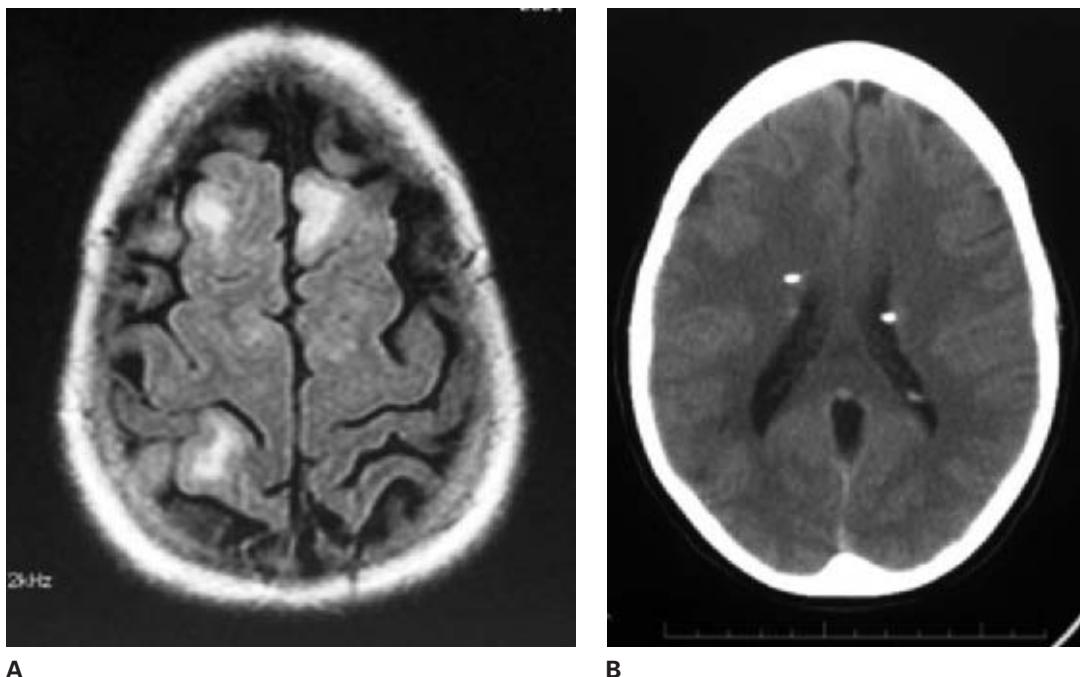

Figure 38-7. Tuberous sclerosis. MRI showing multiple hamartomas (A). Subependymal nodules are demonstrated on CT (B), where their calcific nature has led them to be termed “brain stones.”

Treatment Nothing can be offered in the way of prevention other than genetic counseling. Anticonvulsant therapy of the standard type suppresses the convulsive tendency more or less effectively and should be applied assiduously. Adrenocorticotrophic hormone (ACTH) suppresses the flexor spasms in infancy and tends to normalize the EEG abnormality. It is pointless to attempt the excision of tumors, especially in severely affected individuals (with the exception of renal hamartomas that impair kidney function). However, there are patients who are not mentally impaired and who undergo dermabrasion of the facial lesions for cosmetic reasons, with the knowledge that these slowly regrow. To an increasing degree, neurosurgeons are excising single epileptogenic cortical tubers in otherwise relatively normal children.

Course and Prognosis In general, the disease advances so slowly that years must elapse before one can be sure of progression. Of the severe cases, approximately 30 percent die before the fifth year, and 50 to 75 percent before attaining adult age. Worsening is mainly in the mental sphere. Status epilepticus accounted for many deaths in the past, but improved anticonvulsant therapy has reduced this hazard. Neoplasias take their toll; the authors have had several such patients who died of malignant gliomas arising in striatothalamic regions.

Neurofibromatosis of von Recklinghausen

Neurofibromatosis (NF) is a comparatively common hereditary disease in which the skin, nervous system, bones, endocrine glands, and sometimes other organs are the sites of a variety of congenital abnormalities, often taking the form of benign tumors. The typical clinical picture, usually identifiable at a glance, consists of multiple circumscribed areas of increased skin pigmentation accompanied by dermal and neural tumors of various types.

The condition known as multiple idiopathic neuromas was the

subject of a monograph by R. W. Smith in 1849; even at that time, he referred to examples recorded by other writers. It was von Recklinghausen, however, who in 1882 gave the definitive account of its clinical and pathologic features. The subsequent studies of the disease by Yakovlev and Guthrie, Lichtenstein, Riccardi, and Martuza and Eldridge, and more recently by Crêange et al, and the comprehensive monographs of Crowe and Riccardi and their colleagues are informative references that provide a complete analysis of the clinical, pathologic, and genetic data pertaining to the disease.

Epidemiology Crowe and associates have calculated the prevalence of the disease to be 30 to 40 per 100,000, with the expectancy of one case in every 2500 to 3300 births. Approximately half of their cases had affected relatives, and in all instances the distribution of cases within a family was consistent with an autosomal dominant mode of inheritance. The disease has been observed in all races in different parts of the world, and males and females are about equally affected.

Cause and Pathogenesis The hereditary nature of NF has been appreciated for many years. More recently it has been established that NF comprises two distinct disorders, the genes for which are located on different chromosomes. Both are inherited in an autosomal dominant pattern with a high degree of penetrance, but half the cases are due to new mutations. The classic form of the disease with multiple neurofibromas, described below, is caused by a mutation located near the centromere on chromosome 17 in a gene called neurofibromin (Barker et al). The second type, in which the main feature is bilateral acoustic nerve neuromas, described further on, is caused by a gene termed *merlin* (also called *schwannomin*). These two forms of NF have been loosely referred to as peripheral and central, respectively, but the terms *neurofibromatosis type 1* (*NF1*) and *neurofibromatosis type 2* (*NF2*) are less confusing (Martuza and Eldridge) and are used in the following discussion.

The pathogenesis is less obscure now that the genes implicated in both diseases have been identified. Both involve tumor suppres-

sion. As with tuberous sclerosis, there is a suggestion of a disorder that allows low-grade ectodermal cell proliferation without tumor transformation. Cellular elements derived from the neural crest (i.e., Schwann cells, melanocytes, and endoneurial fibroblasts, the natural components of skin and nerves) proliferate excessively in multiple foci, and the melanocytes function abnormally. The hormones and growth factors involved in this proliferative process and the mechanism by which it occurs are as obscure as in tuberous sclerosis.

Neurofibromatosis Type 1 (Classic or Peripheral NF) In the majority of patients, spots of hyperpigmentation and cutaneous and subcutaneous neurofibromatous tumors are the basis of clinical diagnosis. Pigmentary changes in the skin are nearly always present at birth, but neurofibromas are infrequent at that age. Both lesions increase in number and size during late childhood and adolescence. There may be a spurt of new lesions at puberty or during pregnancy. Exceptionally, a neurofibroma of a cranial nerve or a spinal root (sometimes with compression of the cord), disclosed during neurosurgical intervention, may be the initial manifestation of the disease. In the study of a large series of patients with neurofibromatosis (Crowe et al), approximately one-third were found to have only the cutaneous manifestations noted while being examined for symptoms of some other disease; that is to say, the NF was asymptomatic. Usually these are the patients with the slightest degree of cutaneous abnormality. Of the remaining two-thirds, most consulted a physician because of an embarrassing disfigurement produced by the skin tumors or because some of the neurofibromas were producing neurologic symptoms.

The patches of cutaneous pigmentation, appearing shortly after birth and occurring anywhere on the body, constitute the most obvious clinical expression of the disease. They are approximately oval in shape and vary in size from a millimeter or two to many centimeters and in color from a light to dark brown (the term *café au lait* is applied) and are rarely associated with any other pathologic state (Fig. 38-8). They do not appear to change in number as the patient ages, but they do enlarge during puberty and become more pigmented. In a survey of pigmented spots in the skin, Crowe and associates found that 10 percent of the normal population had one or more spots of this type; however, *anyone with more than six such spots, some exceeding 1.5 cm in diameter in postpubertal individuals (bigger than 0.5 mm in prepubertal ones), nearly always proved to have von Recklinghausen disease*. Of their 223 patients with NF, 95 percent had at least one spot and 78 percent had more than six large ones. Freckle-like or diffuse pigmentation of the axillae and other intertriginous areas (groin, under breast) and small, round, whitish spots are characteristic; when coupled with *café au lait* patches, they are virtually pathognomonic of the disease.

The appearance of multiple cutaneous and subcutaneous tumors in late childhood or early adolescence is the other principal feature of the disease. The cutaneous tumors are situated in the dermis and form discrete soft or firm papules varying in size from a few millimeters to a centimeter or more (molluscum fibrosum; Fig. 38-9). They assume many shapes—flattened, sessile, pedunculated, conical, lobulated, and so on. They are flesh-colored or violaceous and often topped with a comedo. When pressed, the soft tumors tend to invaginate through a small opening in the skin, giving the feeling of a seedless raisin or a scrotum without a testicle. This phenomenon, spoken of as “buttonholing,” is useful in distinguishing the lesions of this disease from other skin tumors,

Figure 38-8. Typical large *café au lait* spot. The presence of six or more hyperpigmented lesions, each over 1.5 cm, is diagnostic of neurofibromatosis type 1.

e.g., multiple lipomas. A patient may have anywhere from a few of these dermal tumors to hundreds.

The subcutaneous neural tumors, which are also multiple, take two forms: (1) firm, discrete nodules attached to a nerve or (2) an overgrowth of subcutaneous tissue, sometimes reaching enormous size. The latter, which are called *plexiform neuromas* (also pachydermatome, elephantiasis neuromatosis, *la tumeur royale*), occur most often in the face, scalp, neck, and chest and may cause hideous disfigurement. When palpated, they feel like a bag of worms or strings; the bone underlying the tumor may thicken. Neurofibromas are easily distinguished from lipomas, which are soft, unattached to the skin or nerve, and not accompanied by any neurologic disorder. [An exception to this last statement is the rare disease of multiple symmetrical lipomatosis with axonal polyneuropathy (Launois-Beausaude disease)]. As a rule, congenital neurofibromas tend to be highly vascular and invasive and are especially prominent in the orbital, periorbital, and cervical regions. They are often

Figure 38-9. Molluscum fibrosum nonneural skin tumors of von Recklinghausen disease.

accompanied by hypertrophy of a segment of the body. When the hyperpigmentation overlies a plexiform neurofibroma and extends to the midline, one should suspect an intraspinal tumor at that level.

Another unique finding is the Lisch nodule. This is a small whitish spot (actually a hamartoma) in the iris that was present in 94 percent of Riccardi's type 1 cases but was not found in patients with type 2 NF or in normal individuals (see Fig. 38-10 and below).

Headache, hydrocephalus, and tumors involving the optic pathways, meningiomas, gliomas, and malignant peripheral nerve tumors are common, even among adults, according to the survey of 158 patients by Créange and colleagues; also, pain was a common symptom in adults and often related to a malignant peripheral nerve sheath tumor.

Other abnormalities associated less consistently with type 1 (peripheral) NF include bone cysts, pathologic fractures (pseudoarthrosis), cranial bone defects with pulsating exophthalmos (sphenoid bone dysgenesis), bone hypertrophy, precocious puberty, pheochromocytoma, scoliosis, syringomyelia, nodules of abnormal glial cells in brain and spinal cord, and macrocephaly, rarely with obstructive hydrocephalus due to overgrowth of glial tissue around the sylvian aqueduct and fourth ventricle. Some degree of intellectual impairment is common; it was found in 40 percent of Riccardi's series of 133 patients. But in our experience the figure is much less and the impairment is usually not profound. Learning difficulty, developmental disorder, and hyperactivity have been more frequent abnormalities, occurring in almost 40 percent of patients. Rosman and Pearce have ascribed mental retardation in NF to congenital malformation of the cerebral cortex (cortical dysgenesis). The incidence of seizures is about 20 times higher than that in the general population.

Exceptionally, NF has been associated with peroneal muscular atrophy, congenital deafness, and partial albinism (Bradley et al).

In childhood, progressive blindness is a particularly troublesome complication. One or both optic nerves are involved in a tumor mass composed mainly of astrocytes. The diagnosis comes to mind at once in a child with any of the cutaneous manifestations of NF. Uncertainty as to its nature arises from the fact that the neuropathologist may be unable to decide between a benign hamartoma and a grade 1 astrocytoma. Progressive enlargement in a succession of MRI scans may be needed to affirm its blastomatous nature.

Neurofibromatosis Type 2 (Acoustic or Central NF) This condition is considerably less frequent than type 1 NF. Here there is

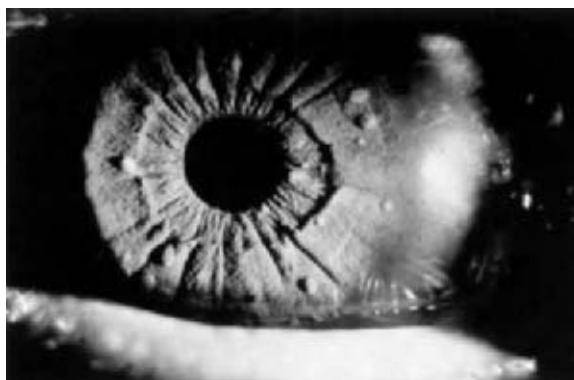

Figure 38-10. Hamartomas of the iris (Lisch nodules), typical of neurofibromatosis type 1.

an absence or paucity of cutaneous lesions. Progressive deafness and the demonstration by enhanced CT or MRI of *bilateral acoustic neuromas* affords accurate diagnosis (see Fig. 31-16). Also, an acoustic neuroma developing before age 30 is suspect as being caused by NF 2. Other cranial or spinal neurofibromas, meningioma (sometimes multiple), and glioma may be added to the syndrome of deafness or may occur prior to its emergence. Juvenile cataracts of the subcortical or capsular variety are seen in some affected patients. Gene analysis for this entity has become available.

Pathology of NF1 and NF2 The cutaneous tumors are characterized by a rather thin epidermis whose basal layer may or may not be pigmented. The collagen and elastin of the dermis is replaced by a loose arrangement of elongated connective tissue cells. The lack of compactness of the normal dermal collagen allows the palpable opening in the skin.

The pigmented (café au lait) lesions contain only the normal numbers of melanocytes; the dark color of the skin is due instead to an excess of melanosomes in the melanocytes. Some of the abnormally large melanosomes measure up to several microns in diameter.

The nerve tumors are composed of a mixture of fibroblasts and Schwann cells (except the optic nerve tumors, which contain a combination of astrocytes and fibroblasts). Predominance of one or the other of these cells in the nerve is the basis of the diagnosis of neurofibroma or schwannoma. Palisading of nuclei and sometimes encircling arrangements of cells (Verocay bodies) are features of both (see Chap. 31). Occasionally, along spinal roots or sympathetic chains, one may find a tumor made up of partially or completely differentiated nerve cells, a typical ganglioneuroma. Clusters of abnormal glial cells may be found in the brain and spinal cord, and, according to Bielschowsky, they imply a link with tuberous sclerosis. Clinically and genetically, however, the two diseases are quite independent.

Malignant degeneration of the tumors is found in 2 to 5 percent of cases; peripherally they become sarcomas, and centrally, astrocytomas or glioblastomas (Fig. 38-11).

Diagnosis If skin tumors and café au lait spots are numerous and Lisch nodules are present in the iris, the identification of the disease as type 1 neurofibromatosis offers no difficulty. A history of the illness in antecedent and collateral family members makes diagnosis even more certain. Doubt arises most frequently in patients with bilateral acoustic neuromas or other cranial or spinal neurofibromas or schwannomas with no skin lesions or only a few random ones. The tendency for these forms of NF to have few skin lesions is well known, but differentiation of type 1 from type 2 may be uncertain unless genetic studies are undertaken. Plexiform neurofibromas with muscle weakness, due to nerve involvement, and abnormalities of underlying bone may be confused with other tumors, especially in young children, who tend to have few café au lait spots and few cutaneous tumors. Hypertrophy of a limb, which may also occur, requires differentiation from other developmental anomalies.

As already mentioned, Crowe and coworkers have expressed the view that 80 percent of patients with von Recklinghausen disease can be diagnosed by the presence of more than six café au lait spots. Of the remaining 20 percent, those over 21 years of age will be found to have multiple cutaneous tumors, axillary freckling, and a few pigmented spots; in those under 21 with no dermal tumors

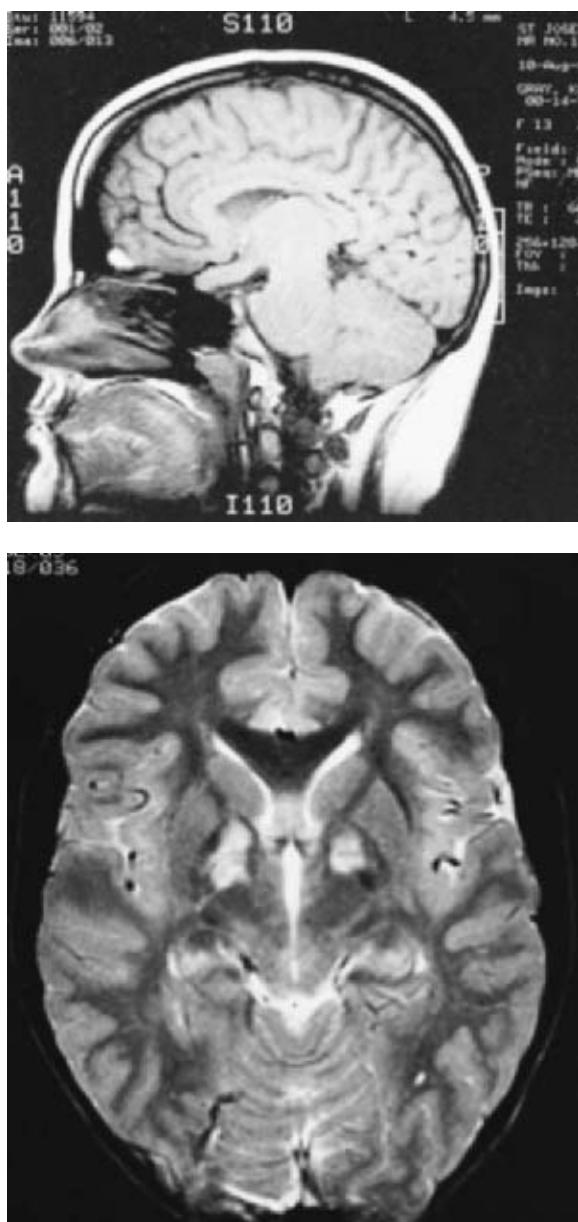

Figure 38-11. Neurofibromatosis type 1. T1-weighted MRI in the sagittal plane demonstrating a glioma involving the optic chiasm and brainstem (above). T2-weighted axial image showing multiple foci of hyperintensity, presumably hamartomas (below).

and only a few café au lait patches, a positive family history and radiographic demonstration of bone cysts will be helpful in some instances. Café au lait spots and cutaneous tumors should always be sought, for they may help the neurologist diagnose an otherwise obscure progressive spinal syndrome, a cerebellopontine angle syndrome, bilateral deafness, progressive blindness, and an occasional case of precocious puberty, hydrocephalus, or mental retardation.

Because of the many conditions that accompany classic NF and because they are potentially dangerous, the initial clinical evaluation should be supplemented by a number of ancillary examinations: measurement of IQ, EEG, slit-lamp examination of irides, radiography of optic foramen and internal auditory meati, visual and auditory evoked responses, and CT scans or MRI of cranium

and sometimes of spine and mediastinum. In the series of Duffner and colleagues, 74 percent of cases had abnormal signals in T2-weighted images of the basal ganglia, thalamus, hypothalamus, brainstem, and cerebellum. The EEG was abnormal in 25 percent. If there is suspicion of a pheochromocytoma, a 24-h urine should be tested for metabolites of epinephrine. Each of these tests not only is an aid to diagnosis but is also essential to the intelligent management of the illness.

Treatment The skin tumors should not be excised unless they are cosmetically objectionable or show an increase in size, suggesting malignant change. The effects of radiotherapy on these lesions are so insignificant that they do not justify the risk of exposure. Plexiform neuromas about the face pose especially difficult problems. Here one must resort to plastic surgery, but the results are not always satisfactory because the growths may implicate cranial nerves superficially (with risk of greater paralysis after surgical excision) or alter the underlying bone, the latter being either eroded from pressure or hypertrophied from increased blood supply. Cranial and spinal neurofibromas are amenable to excision, and the gliomas and meningiomas usually demand surgical measures as well. Here the differentiation of hamartomas from gliomas of structures such as the optic nerves, hypothalamus, or pons may be difficult. Bilateral optic nerve gliomas are usually treated with radiation; unilateral ones are excised. Peripheral nerve tumors that have undergone malignant (sarcomatous) degeneration pose special surgical problems.

Affected individuals should be advised not to have children—a precaution that may not be necessary, because fertility, especially in males, seems to be reduced by the disease. Prognosis varies with the grade of severity, being most favorable in those with only a few lesions. But the disease is always progressive, and the patient should remain under continuous surveillance.

Familial schwannomatosis As commented in Chap. 31 in the discussion of acoustic neuroma, it is now apparent that the propensity to develop multiple schwannomas can also be inherited as a dominant trait, without the vestibular tumors characteristic of NF2. This trait maps to a genetic locus on chromosome 22 that is distinct from the one for NF2.

Other Cutaneous Angiomatoses with Abnormalities of the Central Nervous System

There are at least seven diseases in which a cutaneous or ocular vascular anomaly is associated with an abnormality of the nervous system: (1) meningo- or encephalofacial (encephalotrigeminal) angiomatosis with cerebral calcification (Sturge-Weber syndrome); (2) dermatomal hemangiomas and spinal vascular malformations (sometimes with limb hypertrophy, as also occurs in Klippel-Trenaunay-Weber syndrome and in neurofibromatosis); (3) the epidermal nevus (linear sebaceous nevus) syndrome; (4) familial telangiectasia (Osler-Rendu-Weber disease); (5) hemangioblastoma of cerebellum and retina (von Hippel-Lindau disease); (6) ataxia-telangiectasia (Louis-Bar disease); and (7) angiokeratosis corporis diffusum (Fabry disease). The last three disorders are considered elsewhere: ataxiatelangiectasia and Fabry disease with the inherited metabolic disorders (pages 839 and 1159, respectively) and von Hippel-Lindau disease are discussed below and with hemangioblastoma (page 568).

Meningo- or Encephalofacial Angiomatosis with Cerebral Calcification (Sturge-Weber Syndrome) The vascular nevus is observed at birth to cover a large part of the face and cranium on one side (in the territory of the ophthalmic division of the trigeminal nerve). In one-quarter of the cases the nevus is bilateral. The lesions vary in extent, the most limited being an involvement of only the upper eyelid and forehead and the most extensive being the entire head and even other parts of the body. The nevus is deep red (port-wine nevus), and its margins may be flat or raised; soft or firm papules, evidently composed of vessels, cause surface elevations and irregularities. Orbital tissue, especially the upper eyelid, is almost invariably involved; congenital buphthalmos may enlarge the eye before birth and glaucoma may develop later in that eye, causing blindness. The choroid is implicated in some cases. The increased cutaneous vascularity may result in an overgrowth of connective tissue and underlying bone, giving rise to a deformity like that of the Klippel-Trenaunay-Weber syndrome. Indications of cerebral affection appear as early as the first year of life or later in childhood; the most frequent clinical manifestations are unilateral seizures followed by increasing degrees of spastic hemiparesis with smallness of the arm and leg, hemisensory defect, and homonymous hemianopia, all on the side contralateral to the trigeminal nevus. Skull films (usually normal just after birth) taken after the second year reveal a characteristic "tramline" calcification, which outlines the convolutions of the parieto-occipital cortex. CT scanning and MRI have shown the abnormalities of the involved cortex at an earlier age.

This condition is generally referred to as the Sturge-Weber syndrome, since it was W. Allen Sturge who, in 1879, described a child with sensorimotor seizures contralateral to a facial "port-wine mark," and Parkes Weber (1922, 1929), who gave the first radiographic demonstration of the atrophy and calcification of the cerebral hemisphere homolateral to the skin lesion. This eponym overlooks the important intervening contributions of Kalischer (1897, 1901), who first described the meningeal angioma in conjunction with the facial one; of Volland (1913), who demonstrated the intracortical calcific deposits; and of Dimitri (1923), who described the characteristic double-contoured radiographic shadows. Krabbe (1932, 1934) showed conclusively that the calcification lay not in the blood vessels (as Dimitri and many others had concluded) but in the second and third layers of the cortex (see Wohlwill and Yakovlev for historical review and bibliography).

It must not be thought that all cranial hemangiomas affect the cerebrum; the common facial nevi, especially the flat midline ones and the elevated strawberry nevi, are of no neurologic significance. And a cerebral-meningeal angiomatosis may be present without skin lesions. The involvement of the upper eyelid is of greatest importance; nearly all such cases are associated with cerebral lesions (Barlow). There seems to be a close correlation between the persistence or maldevelopment of the embryonic vascular plexus of the eyelid and forehead and that of the occipitoparietal parts of the brain. When the nevus lies entirely below the upper eyelid or high on the scalp, a cerebral lesion is usually absent, although in a few instances such an angioma has been associated with a vascular malformation of the meninges overlying the brainstem and cerebellum. In angiograms, the abnormal meningeal vessels, which are largely veins, are not well seen; thus they can be distinguished from arteriovenous malformations. These purely meningeal venous nevi are rarely the source of subarachnoid or cerebral hemorrhage, and they do not enlarge to form a mass. The cortical lesion is, however, destructive of cortical tissue, which is replaced by glial tissue that

calcifies. Possibly, diversion of blood to the meninges during seizures causes a progressive ischemia of the cerebral cortex. Barlow has stated that the seizures themselves are responsible for the progressive neurologic deficits and that a special effort should be made to prevent them by carefully regulated medical therapy. Occasionally surgical excision of intractable discharging foci may be necessary, but often this may not be feasible in view of the magnitude of the cerebral lesion. Radiotherapy is unsuccessful in reducing the skin blemish; sensitive individuals usually try to hide it with cosmetics.

Although the encephalotrigeminal syndrome is of congenital origin, its cause and pathogenesis are unknown. Familial coincidence has been observed but is exceptional. No chromosomal abnormality has been demonstrated.

Dermatomal Hemangiomas with Spinal Vascular Malformations A hemangioma of the spinal cord may rarely be accompanied by a vascular nevus in the corresponding dermatome, as was first pointed out by Cobb. Such nevi are most frequent on the arm and trunk. When the cutaneous lesion involves an arm or leg, there may be enlargement of the entire limb or fingers in combination with underdevelopment of certain other parts (Klippel-Trenaunay-Weber syndrome). Some of these angiomatic syndromes combine a spinal or retinodiencephalic arteriovenous malformation (AVM) with a nevus of the trunk or face, respectively. Such cases provide a link to the common AVMs described in Chap. 34.

Epidermal Nevus Syndrome This is a closely related congenital neurocutaneous disorder in which a specific skin lesion (epidermal nevus or linear sebaceous nevus) is associated with a variety of hemicranial and neurologic abnormalities. The skull and brain abnormalities are ipsilateral to the nevus. One-sided thickening of the bones of the skull is characteristic. Mental retardation, seizures, and hemiparesis are the usual neurologic manifestations and have their basis in a wide variety of cerebral lesions—unilateral cerebral atrophy, porencephalic cyst, leptomeningeal hemangioma, arteriovenous malformation, and atresia of cerebral arteries and veins. The somatic and neurologic abnormalities of this syndrome have been comprehensively reviewed by Solomon and Esterley and by Baker and associates.

Hereditary Hemorrhagic Telangiectasia (Osler-Rendu-Weber Disease) This vascular anomaly is transmitted as an autosomal dominant trait. It affects the skin, mucous membranes, gastrointestinal and genitourinary tracts, lungs, and occasionally the nervous system. The basic lesion is probably a defect in the vessel wall, and the main complication, bleeding, is thought to be due to the mechanical fragility of the vessel. Located sparsely in the skin of any part of the body, these vascular lesions first appear during childhood, enlarge during adolescence, and may assume spidery forms, resembling the cutaneous telangiectases of cirrhosis in late adult life. The lesions range from the size of a pinhead to 3 mm or more, are bright red or violaceous, and blanch under pressure.

The significance of the lesions lies in their hemorrhagic tendency. During adult years they may give rise to severe and repeated epistaxis or gastric, intestinal, or urinary tract bleeding and result in an iron-deficiency anemia. Pulmonary fistulas constitute another important feature of the generalized vascular dysplasia; patients with such lesions are particularly subject to brain abscesses and less so to bland embolic strokes.

The angiomas of this disease may form in either the spinal cord or brain, where they can produce apoplectic syndromes; or as in one of our patients, there may be an intermittently progressive focal thalamic syndrome resulting from enlargement of the vascular lesions (or possibly from a succession of small hemorrhages). An unexplained gastrointestinal, genitourinary, intracranial, or intraspinal hemorrhage warrants a search for small cutaneous lesions, which are easily overlooked. Satellite lesions tend to form after obliteration of an angioma.

To date, two mutant genes have been identified as causes of this disease: endoglin and novel kinase.

von Hippel-Lindau Disease (See also page 568) This is a genetic disease of multiple neoplasms, specifically identified by the presence of a hemangioblastoma, sometimes multiple (these are discussed with other cerebral tumors in Chap. 31). The tumor is situated in the cerebellum in most cases but may also arise in the brainstem or spinal cord. In addition to the characteristic cerebellar tumor with its nodule within a cyst, half of these patients have retinal hemangioblastomas and somewhat fewer develop renal cell cancer; an even smaller number have a pheochromocytoma, pancreatic tumors or cysts, or cystadenomas. Polycythemia vera is an interesting feature in a few cases.

The cerebellar hemangioblastoma typically develops in the fourth decade and causes symptoms of ataxia and headache. On imaging studies, the lesions have a striking appearance of a cyst with a nodule contained in its wall, and angiography demonstrates the highly vascular nature of the nodule, which represents the actual neoplasm (Fig. 31-13). The other identifying features of the disease, retinal hemangiomas, are indistinguishable histologically from the craniospinal ones. They are multiple and bilateral, usually appearing earlier than the cerebellar lesions but remaining asymptomatic until they become extensive (retinal detachment is one feature). Their diagnosis is made by funduscopy, by which a large feeding vessel leading to an irregularly shaped ovoid tumor in the retina can usually be appreciated. Imaging studies of the cranium that use dye enhancement will reveal this as well.

Inheritance is autosomal dominant with variable but high penetrance by older age. The causative mutation is in the so-called VHL gene located on chromosome 3. This is a tumor suppressor gene that is inactivated by the mutation and may induce oncogenesis by increasing the expression of vascular mitogenic factors such as vascular endothelial growth factor (VEGF); the precise mechanisms are not known. Renal cell cancer is a serious component of the disease, occurring in up to 60 percent of cases, but the tumors, while multiple, tend initially to be small and of low grade. Nonetheless, renal cancer accounts for one-third of deaths from the disease, the remainder being due largely to complications of the cerebellar neoplasm. An extensive review of the subject is given by Losner and colleagues.

RESTRICTED DEVELOPMENTAL ABNORMALITIES OF THE NERVOUS SYSTEM

In the course of clinical practice, one encounters a remarkable number of restricted disorders of the nervous system, many of which are transmitted from generation to generation as a mendelian, usually dominant trait. Of the more severe ones, only a few of the more striking examples are described here. Milder and more restricted conditions such as stuttering and dyslexia are described in

Chap. 28. The reader may turn to books on genetics or teratology for an account of such oddities as hereditary unilateral ptosis, hereditary Horner syndrome (see page 464), pupillary inequalities, jaw winking, absence of a particular muscle, etc.

Bifacial and Abducens Palsies (Möbius Syndrome) The syndrome of congenital facial diplegia with convergent strabismus is generally referred to as *Möbius syndrome*, although it had been described earlier by von Graefe. Its presence at birth is disclosed by the lack of facial movements and of full eye closure. The most complete review of the subject in the English literature is that of Henderson, and a recent analysis of 37 affected individuals has been given by Harriëtte and colleagues. In Henderson's study of 61 cases of the congenital facial diplegia syndrome, there were 45 instances of an associated abducens palsy, 15 of complete external ophthalmoplegia, 18 of lingual palsy, 17 of clubfeet, 13 of a brachial disorder, 6 of mental defect, and 8 of an absent pectoral muscle. Thus the overlap with other neuromuscular and CNS abnormalities is evident. Harriëtte and coworkers emphasize the frequency of hypoplastic or dysplastic tongue, palatal involvement, and general motor clumsiness. They suggest that the disorder represents a widespread form of brainstem maldevelopment.

Early in life the mouth hangs open, the lower lip is everted, and there is difficulty in sucking. Usually this syndrome can be distinguished from the facial palsy of forceps or birth injury by its bilaterality and the other associated weaknesses. Occasionally more than one family member is affected (usually autosomal dominant inheritance). The cause of this peculiar condition is not known. The few adequate pathologic studies have shown a lack of nerve cells in the motor nuclei of the brainstem, changes that also characterize the Fazio-Londe type of muscular dystrophy (page 947). Rarely, there may be an aplasia of facial muscles. The Möbius syndrome is also referred to on page 1246 in relation to restricted palsies of myopathic and nuclear origin.

Partial paralysis of facial muscles that dates from birth and cannot be attributed to obstetric trauma is not infrequent. In a common type, the lower lip on one side remains immobile when the child smiles or cries; the lip on the unaffected side is drawn downward and outward, resulting in a prominent asymmetry of the lower face. Often it is not appreciated that the side that droops during crying is the normal side (Hoefnagel and Penry).

Congenital Lack of Lateral Gaze (Oculomotor Apraxia of Congenital) (See page 228) Children with this congenital defect are unable to turn their eyes to either side volitionally or on command. Attempting to look to the right, the child turns the head to the right (there is no associated apraxia of head turning, as in acquired apraxia), but the eyes lag and turn to the left. As a result, the patient has to overshoot the mark with the head in order to attain ocular fixation. Once the eyes fixate, the head returns to the primary position. To compensate for the deficiency of eye movements, the patient develops jerky thrusting movements of the head, which characterize all attempts at voluntary gaze. Caloric stimulation of the labyrinth causes tonic movement of the eyes but not nystagmus, as in the normal person. Also, optokinetic nystagmus cannot be induced. Vertical eye movements are normal. A similar ocular condition may occur in conjunction with ataxiatelangiectasia and Gaucher disease. Children with oculomotor apraxia are slow to walk; Ford observed one such child whose sibling had an absence of the vermis of the cerebellum. Aside from

this observation, the anatomic basis of the condition has not been studied.

CONGENITAL ABNORMALITIES OF MOTOR FUNCTION (CEREBRAL PALSY)

In this group of congenital disorders, a major disturbance of motor function, usually nonprogressive, has been present since infancy or early childhood. The popular terms for these conditions have been *infantile cerebral paralysis* (Freud) and *cerebral palsy*. The latter name is not appropriate, nor is it useful from the physician's viewpoint, collocating as it does diseases of widely differing etiologic and anatomic types, wherein the hereditary and acquired and the intrauterine, natal, and postnatal diseases lose their identity. But the name has been adopted as a slogan by fund-raising societies and for all manner of rehabilitation clinics throughout the United States, hence it will not soon disappear from medical terminology. The term, often abbreviated CP, is still being used indiscriminately by many physicians to designate every conceivable cognitive and motor disorder of corticospinal, extrapyramidal, cerebellar, and even neuromuscular type in infants and children.

Etiology of the Congenital Cerebral Motor Disorders

Motor abnormalities that have had their onset early in life are numerous and diverse in their clinical manifestations. Marked prematurity is a determining factor in a large proportion of cases. Each year, about 50,000 infants weighing less than 1500 g are born in the United States. Approximately 85 percent survive. Of these, 5 to 15 percent have a motor disorder of cerebral origin and 25 to 30 percent are found to be mentally impaired at school age (Volpe; see also Hack et al). To ascertain the etiologic and pathogenic factor(s), it is helpful to categorize a given case according to the extent and nature of the motor abnormality. A careful history of possible prenatal, perinatal, or postnatal insults to the developing nervous system must always be sought; certain correlations of these factors with the resulting pattern of neurologic deficit are outlined below. Most patients with these motor abnormalities of infancy and childhood reach adult years. Many but not all have some degree of mental retardation and epilepsy in addition to the motor abnormalities, and there is an unavoidable overlapping in considering the causes and mechanisms of these three clinical states.

The following discussion of these problems is centered on the three major etiologic syndromes—matrix hemorrhages in the immature infant, hypoxic-ischemic encephalopathy (Little disease), and certain developmental motor abnormalities.

Germinat Matrix (Subependymal) Hemorrhage in Premature Infants In low-weight and premature immature infants (20 to 35 weeks gestational age), there sometimes occurs, within a few days after birth, a catastrophic decline in cerebral function, usually preceded by respiratory distress (hyaline membrane disease), with spells of cyanosis and apnea. Also evident are failure of brainstem automatisms (sucking and swallowing), bulging of the fontanelles, and appearance of sanguineous CSF. If the infant becomes completely unresponsive, death usually ensues within a few days. Autopsy discloses a small lake of blood in each cerebral hemisphere (often asymmetrically distributed), occupying the highly cellular (subependymal) germinal matrix zone, near the caudate nucleus at

the level of the foramen of Monro. This region is supplied by the lenticulostriate, choroidal, and Heubner's recurrent arteries and is drained by deep veins, which enter the vein of Galen. In about 25 percent of cases, the blood remains loculated in the matrix zone, while in the others it ruptures into the lateral ventricle or adjacent brain tissue. In a series of 914 consecutive autopsies in newborns, subependymal hemorrhage was found in 284 (31 percent); practically all of these neonates were of low birth weight (Banker and Bruce-Gregorios).

Lesser degrees of this complex of cerebral lesions are now being identified by ultrasonography (Fig. 38-12) and CT scans, and it is apparent that many infants with smaller hemorrhages survive. Some rapidly develop an obstructive hydrocephalus and require a ventricular shunt. In others, the hydrocephalus stabilizes and there is clinical improvement. Several series of surviving cases have now been followed for many years. Those in whom the hemorrhage was more extensive are often left with motor and intellectual handicaps.

Just over half of the patients in the Swedish series of Hagberg and Hagberg, with spastic diplegia, had matrix hemorrhages, leukomalacia (see further on), or both. Congenital hemiplegia or quadriplegia was observed at a lower frequency. In another series of 20 cases of posthemorrhagic hydrocephalus (Chaplin et al), 40 percent had significant motor deficits and over 60 percent had IQ scores of less than 85. In an experience with 12 less severely affected surviving cases (mean birth weight 1.8 kg and gestational age of 32.3 weeks), R. D. Adams noted that only one had a residual spastic diplegia and 9 of the 12 had IQs in the low-normal or normal range.

The cause of matrix hemorrhage is not entirely clear. In all probability it is related to greatly increased pressure in the thin-walled veins of the germinal matrix coupled with a lack of adequate supporting tissue in these zones. During periods of unstable arterial or venous blood pressure that occur with the pulmonary disorders of immature infants, these thin-walled vessels rupture. These infants are also prone to the development of another characteristic lesion of the cerebral white matter (periventricular leukomalacia, probably of venous origin; see below), and the neurologic deficits resulting from these lesions may be added to the residual deficits due to the subependymal hemorrhage (mainly hydrocephalus).

Treatment Control of the respiratory distress of prematurity may reduce the incidence of matrix hemorrhages and periventricular leukomalacia. Claims have been made that the administration of indomethacin ethamsylate, a drug that reduces capillary bleeding, and the intramuscular injection of vitamin E for the first 3 days after birth and possibly the use of betamethasone or other corticosteroids appears to be of value in reducing the incidence of periventricular hemorrhage (Benson et al; Sinha et al; see also Volpe

Figure 38-12. Ultrasound demonstration of subependymal matrix hemorrhage in a premature infant (arrow).

for discussion of control of cerebral hemodynamics and effects of medications in the neonatal period). Acetazolamide and furosemide, which reduce the formation of spinal fluid, have been widely used in the treatment of posthemorrhagic hydrocephalus. However, in a large-scale controlled study, the effects were negligible and shunt placement was required to control worsening hydrocephalus (see International PHVD Drug Trial Group in the References).

Periventricular Leukomalacia These are zones of necrosis of white matter in the deep watershed territories of cortical and central arteries. They lie lateral and posterolateral to the lateral ventricles, in a position to involve the occipital radiations and the sensorimotor fibers in the corona radiata (first described by Bunker and Larroche; see also Shuman and Selednik). The white matter lesions occur in about one-third of cases of subependymal hemorrhage (see above), but they may develop independently in both premature and full-term infants who have suffered hypotension and apnea. In a study of 753 preterm infants, those born at 28 weeks gestation were at highest risk of this complication; the combination of intrauterine infection and premature rupture of membranes carried a 22 percent risk (Zupan et al). Survivors often manifest cerebral hemiplegia or diplegia and variable degrees of mental impairment. The motor disorder is usually more severe than the cognitive and language impairment. Increasingly, small lesions of this nature are being identified in term infants.

The mechanism of this type of periventricular infarction has been debated and the terminology and clinical features, insofar as they overlap with germinal matrix hemorrhage, have been confusing. In recent years, most theories and experimental evidence converge on the notion that these represent venous infarctions. By ultrasonographic examination, the lesions appear as an echodensity in the periventricular white matter. They are also visible by MRI.

Hypoxic-Ischemic Damage and Neonatal Encephalopathy Little's conception of the hypoxic-ischemic form of "birth injury," enunciated in 1862, has been scrutinized over the years. While it is evident that many newborns suffer some degree of perinatal asphyxia, relatively few seem to manifest brain damage. Moreover, many infants with a variety of cerebral motor syndromes appear to have passed the parturitional (perinatal) period without mishap, indicating the greater importance of other prenatal and postnatal causative factors. Nonetheless, *severe neonatal asphyxia* of term or preterm babies can be an important cause of spastic-dystonic-ataxic syndromes, often accompanied by seizures and mental subnormality.

One has the impression that the CNS tolerates hypoxia and reduced blood flow in the immediate postnatal period better than at any other time in life. Indeed, animal experimentation supports this view. Not until the arterial oxygen tension is reduced dramatically to 10 to 15 percent of normal does brain damage occur, and even then the impaired function of other organs contributes to the damage. Nearly always there are irregularities of the heart and hypotension from myocardial damage as well as hepatic and renal failure. Thus it is more correct to think of the encephalopathy in terms of both hypoxia and ischemia, which usually occur in utero and are expressed postnatally by recognizable clinical syndromes.

Fenichel, following the original work of Sarnat and Sarnat in 1976 and of Levene and colleagues, finds it helpful to divide the cerebral syndromes that follow a difficult birth into three groups, according to their severity, each having a greater prognostic value than the Apgar score: (1) In newborns with mild hypoxic-ischemic

encephalopathy, the symptoms are maximal in the first 24 h and take the form of hyperalertness and tremulousness of the limbs and jaw (the "jittery baby") and a low threshold of the Moro reaction. The tone of the limbs is normal except for a mild increase in head lag during traction. The reflexes are brisk and there may be ankle clonus. The anterior fontanel is soft. The EEG is normal. Recovery is usually complete and the risk of handicap is low. (2) Newborns with moderate hypoxic-ischemic encephalopathy are lethargic, obtunded, and hypotonic, with normal movements. After 48 to 72 h, the neonate may improve (having passed through a jittery hyperactive phase) or worsen, becoming less responsive in association with convulsions, cerebral edema, hyponatremia, and hyperammonemia from liver damage. The EEG is abnormal; Fenichel associates epileptiform activity and voltage suppression with an unfavorable outcome. Abnormal visual and auditory evoked potentials are other poor prognostic signs. (3) In neonates with severe hypoxic-ischemic encephalopathy, stupor or coma is present from birth; respirations are irregular, requiring mechanical ventilation. There are usually convulsions within the first 12 h. The limbs are hypotonic and motionless even during attempts to elicit the Moro response. Sucking and swallowing are depressed or absent, but pupillary reactions and eye movements may at first be retained, only to be lost as the coma deepens.

It is in the second and third categories, i.e., the states of moderate to severe encephalopathy, where correction of the respiratory insufficiency and the metabolic abnormalities permits survival, that a number of motor abnormalities (corticospinal, extrapyramidal, and cerebellar) and mental retardation eventually emerge. Included in the category of severe hypoxic-ischemic encephalopathy are also newborns with a variety of developmental anomalies of the brain and other organs. In addition, such infants may have been exposed to certain prenatal risk factors (toxemia of pregnancy, antepartum uterine hemorrhage), or their growth may have been abnormal (small-for-date babies). Some are born at term; others are premature, and the birth process may or may not have been abnormal. One must then consider the possibility, originally pointed out by Sigmund Freud, that the abnormality of the birth process, instead of being causal, was actually the consequence of prenatal pathology. The latter might include preterm intrauterine hypoxia-ischemia.

Other evidence of multifactorial etiology in the "causation" of cerebral palsy has been provided by Nelson and Ellenberg, who found that maternal mental retardation, birth weight below 2000 g, and fetal malformation were among the leading predictors. Breech presentation was another factor, and one-third of these cases also had some noncerebral malformation. Twenty-one percent of the 189 children in their series had also suffered some degree of asphyxia. Additional determinants were maternal seizures, a motor deficit in an older sibling, two or more prior fetal deaths, hyperthyroidism in the mother, pre-eclampsia, or eclampsia. In children with cerebral diplegia born at term, likely contributory factors that were operative in nearly half included toxemia of pregnancy, low birth weight for age, placental infarction, and intrauterine asphyxia.

The factors enumerated above are involved to different degrees in the outcome of pregnancies but are informative because they bring to light the significant proportion of cases of cerebral birth injury in which hypoxia-ischemia, matrix hemorrhages, and leukomalacia were not operative. In this group, we would also include the symmetrical porencephalies and hydranencephalies.

Thus the complexity of assigning a cause for cerebral palsy is evident. In respect to the motor disorders discussed below,

hypoxic-ischemic perinatal injury is still the most commonly specified cause of neonatal encephalopathy but is often unrelated to a permanent defect of cerebral palsy. This statement has been amply confirmed by a large and often cited study from Western Australia that detected neonatal encephalopathy in 3.8 of 1000 term births but was able to identify causative intrapartum factors alone in only 5 percent (Badawi et al). Furthermore, only 10 percent of all the infants with neonatal encephalopathy developed spastic quadriplegia, according to Evans and colleagues. In another recent study, Cowan and colleagues used MRI to determine the proportion of infants with a neonatal encephalopathy who had antenatal brain injury. Excluding those with major congenital malformations or obvious chromosomal abnormalities, 80 percent of cases had no established lesion or brain atrophy. In contrast, those with only seizures and no neonatal encephalopathy in 69 percent of cases had evidence of antenatal damage on MRI; infarctions due to thrombophilic disorders were most common. In conclusion, these studies at least demonstrate the utility of MRI in identifying neonatal forms of encephalopathy. Causing added difficulty is the fact that the clinical signs of perinatal injury may emerge only when the maturational process of the nervous system exposes them at a later period of life.

This field has been complicated by an unprecedented rise in malpractice litigation, spawned in part by the belief that early detection of asphyxia and rapid delivery would have prevented the motor, epileptic, and cognitive problems of birth injury. The fallacy of this assumption is highlighted both by the above comments and by the observation that the incidence of cerebral palsy has not changed in term infants over the past 30 years, despite the institution of fetal monitoring and more frequent cesarean sections.

Clinical Syndromes of Congenital Spastic Motor Disorders
The most frequent motor disorder evolving from the four major categories of neonatal cerebral disease—matrix hemorrhage, periventricular leukomalacia, hypoxic-ischemic encephalopathy, kernicterus (discussed further on)—is spastic diplegia; i.e., a motor disturbance that is severe in the lower limbs and mild in the upper, as discussed below. In addition, hypoxic-ischemic injury occurring in the term or preterm infant may take the form of a hemiplegia, double hemiplegia (quadriplegia), or a mixed pyramidal-extrapyramidal or spastic-ataxic syndrome.

A second form of motor disorder is characterized by the development of severe spastic quadriplegia and mental retardation. The major insult is usually intrapartum asphyxia and attendant fetal distress. Usually such infants will have required resuscitation and will have had low 5-min Apgar scores and seizures, which in this circumstance have important predictive value. The pathologic lesions of the brain in this second group consist of hypoxic-ischemic infarction in distal fields of arterial flow, primarily in the cortex and white matter of parietal and posterior frontal lobes, leaving a ulegyric sclerotic cortex.

A third group, discussed below, is characterized mainly by extrapyramidal abnormalities, combining athetosis, dystonia, and ataxia in various proportions. After reviewing the results of several large series of congenital and neonatal motor disorders, we have concluded that spastic diplegia occurs in 10 to 33 percent of cases, spastic quadriplegia 19 to 43 percent, extrapyramidal forms in 10 to 22 percent, and mixed forms in 9 to 20 percent.

Spastic Diplegia (Little Disease) The pattern of paralysis is more variable than the term *spastic diplegia* implies; actually, several subtypes may be distinguished: the paraplegic, diplegic, quadriple-

gic, pseudobulbar, and generalized. Pure paraplegic and pseudobulbar types are relatively rare. Usually all four extremities are affected, but the legs much more than the arms, which is the real meaning of *diplegia*. Hypotonia—with retained tendon reflexes and hypoactivity—is usually present initially. Only after the first few months will evident weakness and spasticity appear, first in the adductors of the legs. The plantar reflexes, which are often ambiguous in the normal infant, here are clearly extensor, a finding that is pathologic at any later age. Also, stiff, awkward movements of the legs, which are maintained in an extended, adducted posture when the infant is lifted by the axillae, often do not attract attention until several weeks or months have passed. Seizures occur in approximately one-third of the cases, and it is not uncommon to observe a delay in all developmental sequences, especially those that depend on the motor system.

Once walking is attempted, usually at a much later date than usual, the characteristic stance and gait become manifest. The slightly flexed legs are advanced stiffly in short steps, each describing part of an arc of a circle; adduction of the thighs is often so strong that the legs may actually cross (scissors gait); the feet are flexed and turned in with the heels not touching the floor. In the adolescent and adult, the legs tend to be short and small, but the muscles are not markedly atrophic, as in spinal muscular atrophy. Passive manipulation of the limbs reveals spasticity in the extensors and adductors and slight shortening of the calf muscles. The arms may be affected only slightly or not at all, but there may be awkwardness and stiffness of the fingers and, in a few, pronounced weakness and spasticity. In reaching for an object, the hand may overpronate and a grasp may be difficult to release. Speech may be well articulated or noticeably slurred, and in some instances the face is set in a spastic smile. The deep tendon reflexes are exaggerated, those in the legs more than the arms; the plantar reflexes are extensor in the majority of cases. Scoliosis is frequent and may secondarily give rise to root compression and impaired respiratory function. As a rule, there is no disturbance of sphincteric function, though delay in acquiring voluntary control is usual. Athetotic postures and movements of the face, tongue, and hands are present in some patients and may actually conceal the spastic weakness; ataxic and hypotonic forms also exist (see further on).

One subtype of spastic diplegia is associated with a relatively slight diminution in head size and of intelligence. As indicated above, there is no unifying neuropathology; the condition occurs independently of matrix hemorrhages and periventricular leukomalacia as well as with them. The frequency of cerebral spastic diplegia, which is closely related to the degree of prematurity, has declined significantly since the introduction of neonatal intensive care facilities, and there is reason to believe that heredogenetic factors are now of more importance.

Infantile Hemiplegia, Paraplegia, and Quadriplegia Hemiplegia is a common condition of infancy and early childhood. The functional difference between the two sides may be noticed soon after birth, but more often it is not perceived by the mother until after the first 4 to 6 months of life. In a second group, the child is in excellent health for a year or longer before the abrupt onset of hemiplegia (see below). In hemiplegia that dates from earliest infancy—i.e., congenital hemiplegia—the parents first notice that movements of prehension and exploration are carried out with only one arm. A manifest hand preference at an early age should always raise the suspicion of a unilateral motor defect. The affection of the leg is usually recognized later, i.e., during the first attempts to stand and walk. Sitting and walking are usually delayed by a few

months. In the older child, there is evident hyperactivity of tendon reflexes and usually a Babinski sign. The arm is held flexed, adducted, and pronated, and the foot assumes an equinovarus posture. Sensory and visual field defects can be detected in some patients. Mental defect may be associated with infantile hemiplegia but is less common and lesser in degree than with cerebral diplegia and much less common than with bilateral hemiplegia. There may also be speech delay, regardless of the side of the lesion; when this is present, one should look for mental retardation and expect to find a bilaterality of motor abnormality. Convulsions occur in 35 to 50 percent of children with congenital hemiplegia, and these may persist throughout life. They may be generalized but are frequently unilateral and limited to the hemiplegic side (or the contralateral side if the hemiplegia is severe). Often, after a series of seizures, the weakness on the affected side will be increased for several hours or longer (Todd's paralysis). Gastaut and associates have described a hemiconvulsive-hemiplegic syndrome in which the progressive paralysis and cerebral atrophy are attributed to the convulsions. As months and years pass, the osseous and muscular growth of the hemiplegic limbs is retarded, leading to an obvious hemiatrophy.

With respect to the causation of congenital hemiplegia, it is generally agreed that perinatal asphyxia is only one of the possibilities. In the series of 681 children with "cerebral palsy" collected by Hagberg and Hagberg, there were 244 with hemiplegia. Of the latter, 189 were full-term babies and 55 preterm. Prenatal risk factors were identified in only 45 percent, and they were mostly in the infants born prematurely. In nearly half of the cases, there was no clue as to the time in the intrauterine period when the cerebral lesion occurred.

In another group—*acquired infantile hemiplegia*—a normal infant or young child, usually between the ages of 3 and 18 months, develops a massive hemiplegia, with or without aphasia, within hours. The disorder often begins with seizures, and the hemiplegia may not be recognized until the seizures have subsided. In Banker's autopsy series, there was arterial or venous thrombosis in some cases, but instances without vascular occlusions were found. Some of the latter cases, in which arteriography had been normal, may have been embolic, possibly of cardiac origin. In the recent era, imaging has shown a large area of cerebral infarction, not dissimilar to a stroke in the territory of the middle cerebral artery, acquired during infancy but usually with a normal arteriogram (Fig. 38-13). If the stroke occurs at an early age, the recovery of speech may be complete, though reduced scholastic capacity remains. The degree of recovery of motor function varies. Often, as the deficit recedes, the arm becomes involved by athetotic, tremulous, or ataxic movements; there may be an interval of months or years between the hemiplegia and the athetosis.

Encephaloclastic (destructive) lesions underlie most of the cases of infantile hemiplegia and some cases of bilateral hemiplegia (as well as many cases of seizures in the first few days of life). The pathologic change is essentially that of ischemic necrosis. In many cases, the lesions must have been acquired in utero. Precipitant delivery, fetal distress, and prepartum uterine hemorrhage may have been indications of the process. The lesions seemingly reflect those of circulatory insufficiency (ischemia), the result of hypotension or local circulatory failure. What is most notable is that the ischemia tends to affect the tissues lying in arterial cortical border zones; there may also be venous stasis with congestion and hemorrhage occurring particularly in the deep central structures, such as the basal ganglia and periventricular matrix zones. If they are purely hypoxic, the lesions should be bilateral. Myers has repro-

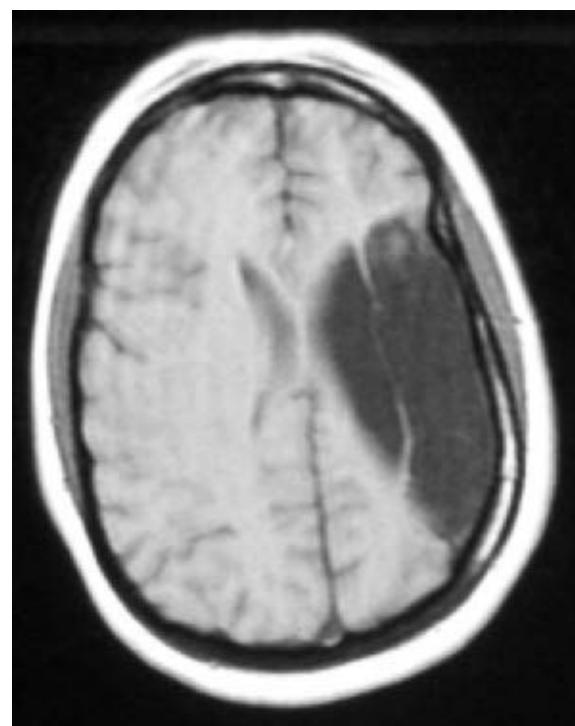

Figure 38-13. MRI of an adult with congenital hemiplegia. There is severe encephalomalacia mainly in the territory of the right middle cerebral artery.

duced such lesions in the neonatal monkey by reducing the maternal circulation for several hours. As the lesions heal, the monkeys develop the same sclerotic changes in the cortex and white matter of the cerebrum (lobar sclerosis) and the "marbling" (*état marbré*) that characterizes the brains of patients with spastic diplegia and double athetosis (see below).

The quadriplegic state differs from bilateral hemiplegias in that the bulbar musculature is often involved in the latter and mental retardation is more severe. The condition is relatively rare and is usually due to a bilateral cerebral lesion. However, one should also be alert to the possibility of a high cervical cord lesion. In the infant, this is usually the result of a fracture dislocation of the cervical spine incurred during a difficult breech delivery. Similarly, in paraplegia, with weakness or paralysis limited to the legs, the lesion may be either a cerebral or a spinal one. Sphincteric disturbances and a loss of somatic sensation below a certain level on the trunk always point to a spinal localization. Congenital cysts, tumors, and diastematomyelia are more frequently causes of paraplegia than of quadriplegia. Another recognized cause of infantile paraplegia is spinal cord infarction from thrombotic complications of umbilical artery catheterization.

Extrapyramidal Syndromes The spastic cerebral diplegias discussed above shade almost imperceptibly into the congenital extrapyramidal syndromes. Patients with the latter syndromes are found in every cerebral palsy clinic, and ultimately they reach adult neurology clinics as well. Corticospinal tract signs may be completely absent, and the student, familiar only with the syndrome of pure spastic diplegia, is always puzzled as to their classification. Some cases of extrapyramidal type are undoubtedly attributable to severe perinatal hypoxia and others to diseases such as erythroblastosis fetalis with kernicterus. In order to state the probable path-

ologic basis and future course of these illnesses, it is desirable to separate the extrapyramidal syndromes of prenatal-natal origin (which usually become manifest during the first year of life) from the acquired or hereditary postnatal syndromes, such as familial athetosis, Wilson disease, dystonia musculorum deformans, and the hereditary cerebellar ataxias, which become manifest later.

Double Athetosis This is probably the most frequent of the congenital extrapyramidal disorders. In our clinical material and in reported series of cases, two types stand out—one that is due to hyperbilirubinemia or Rh incompatibility (*kernicterus*, see below) and the other due to hypoxic-ischemic encephalopathy. With control of neonatal hyperbilirubinemia (by use of anti-Rh immune globulin, exchange transfusions, and phototherapy), *kernicterus* has almost disappeared, whereas the other, more severe hypoxic-ischemic form regularly continues to be seen. Rarely, a congenital, nonhemolytic icterus or a glucose-6-phosphate dehydrogenase deficiency produces the same syndrome.

Like the spastic states, double athetosis may not be recognized at birth but only after several months or a year has elapsed. In some cases the appearance of choreoathetosis is for unexplained reasons delayed for several years; it may seem to progress during adolescence and even early adult life. It must then be differentiated from some of the inherited metabolic and degenerative extrapyramidal diseases. Chorea and athetosis dominate the clinical picture, but bewildering combinations of involuntary movements—including dystonia, ataxic tremor, myoclonus, and even hemiballismus—may be found in a single case. At times, we have been unable to classify the movement disorder because of its complexity. It should be noted that practically all instances of double athetosis are also associated with a defect in voluntary movement.

Choreoathetosis in infants and children varies greatly in severity. In some, the abnormal movements are so mild as to be misinterpreted as restlessness or “the fidgets”; in others, every attempted voluntary act provokes violent involuntary spasms, leaving the patient nearly helpless. The clinical features of choreoathetosis and other involuntary movements is discussed in Chap. 4.

An early hypotonia, followed by retardation of motor development, is the rule in these cases. Erect posture and walking may be delayed until the age of 3 to 5 years and may never be attained in some patients. Tonic neck reflexes or fragments thereof tend to persist well beyond their usual time of disappearance. The plantar reflexes are usually flexor, though they may be difficult to interpret because of the continuous flexion and extension of the toes. Sensory abnormalities are not found. Because of the motor and speech impairment, patients are often erroneously thought to be mentally defective. In some, this conclusion is doubtless correct, but in others intellectual function is adequate, and a few are educable to a high level.

A variety of rehabilitative measures have been tried: physiotherapy, surgery, sensory integrative therapy, progressive patterned movement, and neuromuscular facilitation. We agree with Hur, who has critically reviewed this subject, that properly controlled studies provide no proof of the success of any of these measures. Surely, with growth and development, new postures and motor capacities are acquired. The less severely affected patients can even make successful occupational adjustments. The more severely affected ones rarely achieve a degree of motor control that permits them to live independently. One sees some of these unfortunate persons bobbing and twisting laboriously as they make their way in public places.

Imaging studies are seldom of diagnostic value. Mild cerebral atrophy and loss of volume of the basal ganglia are seen in some cases, and cavitary lesions are present in some of the severe anoxic encephalopathies. The EEG is rarely helpful unless there are seizures.

The most frequent pathologic finding in the brain has been a whitish, marble-like appearance of the putamen, thalamus, and border zones of the cerebral cortex. These whitish strands represent foci of nerve cell loss and gliosis with condensation of bands of transversing myelinated fibers—so-called *status marmoratus* (*état marbré*). This lesion does not develop if the insult occurs after infancy, i.e., after the myelination glia have completed their developmental cycle.

Kernicterus This is now a rare cause of extrapyramidal motor disorder in children and adults. Such cases are the neurologic sequelae of erythroblastosis fetalis secondary to Rh and ABO blood incompatibilities or to a deficiency of the hepatic enzyme glucuronosyltransferase. The symptoms of *kernicterus* appear in the jaundiced neonate on the second or third postnatal day. The infant becomes listless, sucks poorly, develops respiratory difficulties as well as opisthotonus (head retraction), and becomes stuporous as jaundice intensifies. The serum bilirubin is usually greater than 25 mg/dL. In acidotic and hypoxic infants (e.g., those with low birth weight and hyaline membrane disease), the kernicteric lesions develop with much lower levels of serum bilirubin.

The majority of infants with this disease die within the first week or two of life. Many of those who survive are mentally retarded, deaf, hypotonic, totally unable to sit, stand, or walk, and spend their lives in homes for the feeble-minded. There are exceptional patients, however, obviously less damaged, who are mentally normal or at most only slightly limited. These are the ones who develop a variety of persistent neurologic sequelae—choreoathetosis, dystonia, and rigidity of the limbs—a picture not too different from that of cerebral spastic diplegia with involuntary movements. *Kernicterus* should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and paralysis of upward gaze. Later there may be a greenish pigmentation of the dental enamel.

Neonates who die in the acute postnatal stage of *kernicterus* show a unique yellow staining (icterus) of nuclear masses (at one time called the “Kern nuclei”) in the basal ganglia, brainstem, and cerebellum. In those surviving this postnatal insult, the pathologic changes consist of a symmetrically distributed nerve cell loss and gliosis in the subthalamic nucleus of Luys, the globus pallidus, the thalamus, and the oculomotor and cochlear nuclei; these lesions are the result of the hyperbilirubinemia. In more than 30 cases examined by R. D. Adams, the immature cerebral cortex including the hippocampus was spared. In the newborn, unconjugated bilirubin can pass through the poorly developed blood-brain barrier into these nuclei, where it is assumed to be directly toxic. Acidosis and hypoxia exacerbate the effect. Also in the newborn, the development of hyperbilirubinemia is enhanced by a transient deficiency of the enzyme glucuronosyltransferase, essential for the conjugation of bilirubin. *Hereditary hyperbilirubinemia*, due to lack of this enzyme (*Crigler-Najjar syndrome*), may exhibit the same effects on the nervous system at a later period of infancy or childhood as hyperbilirubinemia due to Rh incompatibility.

Immunization, phototherapy, and exchange transfusions designed to prevent high levels of unconjugated serum bilirubin have been shown to protect the nervous system. If the blood bilirubin level can be held to less than 20 mg/dL (10 mg/dL in prematures),

the nervous system may escape postnatal damage. The effective use of these measures has practically eradicated this dreaded disease.

Both kernicterus and ischemic état marbré must be differentiated clinically from hereditary choreoathetosis, the Lesch-Nyhan syndrome, and—later in life—from ataxia-telangiectasia and Friedreich ataxia.

Congenital and Neonatal Ataxias In these patients, difficulty in standing and walking cannot be attributed to spasticity or paralysis. Again, hypotonia and poverty of movement are the initial motor abnormalities; the cerebellar deficit becomes manifest only later, when the patient begins to sit, stand, and walk. There may or may not be a delay in reaching the normal “motor milestones.” Attempts to attain sitting balance will first reveal an unsteadiness that is not soon overcome, even with practice. Reaching for a proffered toy is accomplished by jerky, incoordinated movements. The first steps are unsteady, as would be expected, with many tumbles, but the gait remains clumsy. Instability of the trunk may be accompanied by similar, more or less rhythmic bobbing movements of the head, so-called titubation. Despite the severity of the ataxia, the muscles are of normal size, and voluntary movements, though weak in some patients, are possible in all the limbs. The tendon reflexes are present, and the plantar reflexes are either flexor or extensor. In some cases, the ataxia is later associated with spasticity rather than hypotonia (spastic-ataxic diplegia). Relative improvement may occur in later years. In the older child, a cerebellar gait, ataxia of limb movements, nystagmus, and uneven articulation of words are readily distinguished from myoclonus, chorea, athetosis, dystonia, and tremor. We have seen cases of a cerebellar-like tremor in adults that had been attributed to neonatal injury; the MRI did not show cerebellar atrophy.

In only a few cases have the pathologic changes been studied. Aplasia or hypoplasia of the cerebellum has been observed, but sclerotic lesions of the cerebellum are more common. The CT scan or MRI verifies the cerebellar atrophy. A cerebral and cerebellar lesion may coexist in patients with congenital ataxia, which is the reason for the term *cerebrocerebellar diplegia*.

Several risk factors have been identified in the congenital ataxias. Most importantly, cerebellar ataxia may be the most prominent or sole effect of neonatal ischemia-hypoxia. A genetic factor is operative in some cases (Hagberg and Hagberg). Radiation of the maternal abdomen during the first trimester of pregnancy is said to have resulted in cerebellar hypoplasia. Mercury poisoning in utero is another cause of congenital ataxia. Many cases remain unexplained in our experience.

Pontocerebellar Hypoplasias Aside from the congenital ataxia described above, there are several rare familial forms in which a failure of cerebellar development is associated with mental retardation. Joubert reported a family in which there was dysgenesis of the vermis of the cerebellum; mental retardation; episodic hyperpnea; irregular, jerky eye movements; and unsteady gait. The syndrome appeared in four of six siblings. In other reports, choroidal-retinal colobomas, polydactyly, cryptorchidism, and prognathism have been mentioned. Detailed examination of the cerebra of such individuals has been lacking. In the *Gillespie syndrome*, a combination of aniridia, cerebellar ataxia, and mental retardation are the denominating features. In the *Paine syndrome*, a familial disorder with developmental delay and mental retardation, there is microcephaly, spasticity, optic hypoplasia, and myoclonic ataxia, the last presumably related to the cerebellar hypoplasia. These dysgeneses

and the disequilibrium syndrome reported from Sweden are unified by the cerebellar ataxia; in the past, they fell into the group of ataxic cerebral palsies. Imaging studies demonstrate the cerebellocerebral abnormality. Genetic factors are operative in some, but matters pertaining to etiology remain obscure (see Harding for details). One form of a pure congenital cerebellar hypoplasia has been mapped to a gene locus on chromosome Xq. The ataxia was inherited as an X-linked recessive trait and was nonprogressive beyond early childhood.

Differential Diagnosis of the Congenital Ataxias The congenital ataxias must be distinguished from the progressive hereditary ataxias. The latter are likely to begin at a later age than the congenital ones. Some hereditary ataxias are intermittent or episodic, one of which is responsive to acetazolamide, as pointed out on page 827. Several forms of childhood ataxia are neither congenital nor hereditary; they have an acute onset and may persist during childhood, adolescence, and adult life.

Also to be distinguished from the ataxias of congenital and neonatal origin is an *acute cerebellar ataxia of childhood*, which can usually be traced to a viral infection or a postinfectious encephalitis, particularly after chickenpox. The *opsoclonus-myoclonus (“dancing eyes”) syndrome* of Kinsbourne is another postinfectious disease peculiar to childhood (see pages 239 and 641). The cerebellar ataxia in this disease may be overshadowed by polymyoclonus, which mars every attempted movement. With improvement, under the influence of corticosteroids, a cerebellar disorder of speech and movement becomes evident. A majority of the patients in which the disease became chronic (16 of the 26 cases followed by Marshall et al) were found later to be mentally backward. The cause of the disease has never been established. An occult neuroblastoma or other tumor is uncovered occasionally.

In the differential diagnosis of these acute forms of cerebellar ataxia, one must not overlook intoxication with phenytoin, barbiturates, or similar drugs.

The Flaccid Paryses and the “Floppy Infant” (Table 38-5; See also pages 946 and 1198) The rare cerebral form of generalized flaccidity, first described by Foerster and called *cerebral atonic diplegia*, has already been mentioned. It can usually be distinguished from the paralysis of spinal and peripheral nerve origin and congen-

ital muscular dystrophy by the retention of postural reflexes (flexion of the legs at the knees and hips when the infant is lifted by the axillae), preservation of tendon reflexes, and coincident failure of mental development. The Prader-Willi syndrome, discussed earlier in the chapter, also presents at first as a generalized hypotonia.

The syndrome of *infantile spinal muscular atrophy* (*Werdnig-Hoffmann disease*) is the leading example of flaccid paralysis of lower motor neuron type. Perceptive mothers may be aware of a paucity of fetal movements in utero; in most cases the motor defect becomes evident soon after birth or the infant is born with arthrogryotic deformities. Several other types of familial progressive muscular atrophy have been described in which the onset is in early or late childhood, adolescence, or early adult life. Weakness, atrophy, and reflex loss without sensory change are the main features and are discussed in detail in Chap. 39. A few patients suspected of having infantile or childhood muscular atrophy prove, with the passage of time, to be merely inactive “slack” children, whose motor development has proceeded at a slower rate than normal. Others may remain weak throughout life, with thin musculature. These and several other congenital myopathies—*central core, rod-body, nemaline, mitochondrial, myotubular, and fiber-type disproportion and predominance*—are described in Chap. 52. Unlike Werdnig-Hoffmann disease, the effects of many of them tend to diminish as the natural growth of muscle proceeds. Rarely, polymyositis and acute idiopathic polyneuritis manifest themselves as a syndrome of congenital hypotonia.

Infantile muscular dystrophy and lipid and glycogen storage diseases may also produce a clinical picture of progressive atrophy and weakness of muscles. The diagnosis of *glycogen storage disease* (usually the Pompe form) should be suspected when progressive muscular atrophy is associated with enlargement of the tongue, heart, liver, or spleen. The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen in skeletal muscles, though it is more likely due to degeneration of anterior horn cells that are also distended with glycogen and other substances. Certain forms of *muscular dystrophy* (myotonic dystrophy and several types of congenital dystrophy) may also be evident at birth or soon thereafter. The latter may have led to arthrogryposis and club foot (see page 1244). All of these disorders are described in detail in the chapters on muscle diseases.

Brachial plexus palsies, well-known complications of dystocia, usually result from forcible extraction of the fetus by traction on the shoulder in a breech presentation or from traction and tipping of the head in a shoulder presentation. The effects of such injuries are sometimes lifelong. Their neonatal onset is betrayed later by the small size and inadequate osseous development of the affected limb. Either the upper brachial plexus (fifth and sixth cervical roots) or the lower brachial plexus (seventh and eighth cervical and first thoracic roots) suffer the brunt of the injury. Upper plexus injuries (Erb) are about 20 times more frequent than lower ones (Klumpke). Sometimes the entire plexus is involved (page 1164).

Facial paralysis, due to forceps injury to the facial nerve immediately distal to its exit from the stylomastoid foramen is another common (usually unilateral) peripheral nerve affection in the newborn. Failure of one eye to close and difficulty in sucking make this condition easy to recognize. It must be distinguished from the congenital facial diplegia that is often associated with abducens palsy, i.e., the Möbius syndrome discussed earlier in the chapter. In most cases of facial paralysis due to physical injury, function is recovered after a few weeks; in some, the paralysis is permanent and may account for lifelong facial asymmetry.

Treatment Assistive devices, stretching therapy, and conventional orthopedic measures for joint stabilization and relief of spasticity are all useful. Injection of botulinum toxin for the relief of spasticity has gained wide favor and is now used early in the child’s life to pre-empt deformities. Most published trials have been too small, however, to allow firm conclusions to be drawn about the durability of this treatment. Finally, hyperbaric oxygen treatment of children with cerebral palsy was not effective in a randomized trial conducted by Collet and colleagues, despite periodic claims to the contrary.

In summary, it can be said that all these forms of disabling motor abnormalities rank high as important issues in neuropediatrics. In attempts at prevention, steps have been taken in most hospitals to identify and eliminate risk factors. Indeed, better prenatal care, reduction in premature births, and control of respiratory problems in critical care wards have reduced their incidence and prevalence. Physical and mental therapeutic measures appear to be helpful, but many of the methods have been difficult to evaluate in a nervous system undergoing maturation and development. The neurologist can contribute most by segregating groups of cases of identical pattern and etiology and in differentiating the congenital groups of delayed expressivity from the treatable acquired diseases of this age period. Woefully lacking are critical neuropathologic studies.

INTRAUTERINE AND NEONATAL INFECTIONS

Throughout the intrauterine period the embryo and fetus are subject to particular infections. Since the infective agent must reach the fetus through the placenta, it is evident that the permeability of the latter at different stages of gestation and the immune status of the maternal organism are determinative. We include a discussion of these intrauterine infections here because some of them may lead to malformations or destructive lesions of the brain and, later in life, must be distinguished from developmental abnormalities.

Until the third to fourth month of gestation, the large microbial organisms—such as bacteria, spirochetes, protozoa, and fungi—cannot invade the embryo, even though the mother harbors the infection. Viruses may do so, however—specifically rubella, cytomegalovirus (CMV), human immunodeficiency virus (HIV), and possibly others. The rubella virus enters embryonal tissues during the first trimester, *Treponema pallidum* in the fourth to fifth postconceptional months, and *Toxoplasma* after that period. Bacterial meningitis (except for that due to *Listeria monocytogenes*, described below) is essentially a paranatal infection contracted during or immediately after parturition. Neonatal herpes simplex encephalitis, due to the type 2 (genital) virus, is also usually acquired by passage through an infected birth canal. Some cases of HIV infection may be acquired during delivery, but most are due to transplacental transmission.

The main neonatal infections—toxoplasmosis, rubella, CMV, and herpes—are commonly designated by the acronym TORCH. With the persistence of *Listeria*, the rise of AIDS infections, and a marked reduction in rubella infections, the mnemonic LATC, which includes *Listeria* and AIDS, might be more appropriate. Infants with any of these infections share certain common features, such as low birth weight, prematurity, congenital heart disease, purpura, jaundice, anemia, microcephaly or hydrocephaly, cerebral calcifications, chorioretinitis, cataracts, microphthalmia, and pneumonitis; as a corollary, if any combination of these features is man-

ifest, one should suspect one of these infectious agents and take measures to identify it. However, all these clinical manifestations are not likely to be present in any one infant, and in the cases of rubella and CMV, only a small percentage of infected infants will show major systemic signs or symptoms. Nevertheless, on clinical grounds alone, certain infections can be identified and others excluded. For example, cerebral calcifications are present mainly in toxoplasmosis and CMV encephalopathy, being rare in rubella and absent in HSV encephalitis; the calcifications are widely disseminated in toxoplasmosis and have a periventricular distribution in CMV infection. Cardiac lesions are present only with rubella, and deafness occurs only with CMV and rubella. Thus, there are clinical signposts to guide the clinician in selecting the appropriate diagnostic tests. And importantly, in considering neonatal infections, one must also search for other, less common infectious types (see Chaps. 32 and 33).

Added difficulty in the diagnosis of embryonal and fetal infections arises when the mother has been entirely asymptomatic. Isolation of the organism from fetal and neonatal tissues is possible, but usually they are inaccessible, and it may be impossible to demonstrate antibodies or other immune responses because of the early stage of the infection or limitations of the infant's immune response.

Rubella

Gregg, in 1941, first reported the association of maternal rubella and congenital cataracts in the neonate. His observations were quickly verified, and soon it became widely known that cataracts, deafness, congenital heart disease, and mental retardation constituted a kind of tetrad diagnostic of this disease. That a virus could affect so many tissues, causing in essence a noninflammatory developmental disorder of multiple organs, was a novel concept, and it raised the interesting prospect that other viruses might have similar effects. Surprisingly, however, only CMV and possibly HSV have been incriminated in embryonal-developmental neuropathology. A large number of other viruses (e.g., influenza, Epstein-Barr, hepatitis) have been implicated in human teratogenesis, but in none is the relationship beyond doubt.

It is now well established that most instances of congenital rubella infection occur in the first 10 weeks of gestation and that the earlier the infection occurs, the greater the risk to the fetus. However, there may be some risk beyond the first trimester, up to the 24th week, according to Hardy.

Following the experience of the massive rubella epidemics of 1964 and 1965, the congenital rubella syndrome has been expanded to include low birth weight; sensorineural deafness, sometimes unilateral (the most common complication); microphthalmia; pigmentary degeneration of the retina (salt-and-pepper chorioretinitis); glaucoma, cloudy corneas, and cataracts of special type (the latter two abnormalities usually cause visual impairment); hepatosplenomegaly, jaundice, and thrombocytopenic purpura; and patent ductus arteriosus or interventricular septal defect. There may be one, a few, or many of these abnormalities, in various combinations. The mental retardation is severe and may be accompanied by seizures and motor defects such as hemiplegia or spastic diplegia and rarely by seizures. Psychiatric symptoms, some resembling autism, are not infrequent.

Infection of the fetus after the first trimester results in a less impressive neonatal syndrome. The infant may seem lethargic and fail to thrive. The cranium is abnormally small. Only a cardiac

abnormality, deafness, or chorioretinitis may provide clues to the diagnosis. The CSF later may show an increase of mononuclear cells and an elevated protein. The infection may persist for a year or longer. Foci of calcification are rare, and CT scanning and MRI are of little help in diagnosis. The maternal infection may be so mild that it is passed off as minor; but even when it is evident, the fetus is spared in about 50 percent of cases. Diagnosis can be verified in the neonate by demonstrating IgM antibodies to the virus or by the isolation of the virus from the throat, urine, stool, or CSF. Also, the virus has been obtained from cells in the amniotic fluid. In subsequent pregnancies the fetus has been normal in our experience.

The *neuropathology* is of considerable interest. In the nervous system of abortuses (the abortion performed because of proven maternal rubella in the first trimester), R. D. Adams found no visible lesions by light microscopy, even though the virus had been isolated from the brain by Enders. At this period of development there is no inflammatory reaction because of the absence of polymorphonuclear leukocytes, lymphocytes, and other mononuclear cells in the fetus. At birth the brain is usually of normal size, and there may be no discernible lesions. In a few, a mild meningeal infiltration of lymphocytes as well as a few zones of necrosis and vasculitis with later calcification of vessels are seen, as are small hemorrhages, presumably related to the thrombocytopenia. Smallness of the brain and delay in myelination have been observed in children dying at 1 to 2 years of age. None of the brains in our series have been malformed. Rubella virus continues to be recoverable from the CSF for at least 18 months after birth. A delayed progressive rubella encephalitis in childhood is also known and is described on page 651. Our colleagues have had two cases, studied in serial sections by Yakovlev, that survived 5 to 6 years.

Since there is no treatment for the active infection, the obvious approach to the problem of congenital rubella infection is to make sure that every woman has been vaccinated against rubella or has antibodies as a result of infection prior to pregnancy. The widespread use of rubella vaccine has reduced the chance of major outbreaks, but sporadic infections continue to be seen, and outbreaks of epidemic proportions continue to occur in developing countries.

Congenital Cytomegalovirus Infection

For many years it was known that in the tissues of some infants who died in the first weeks and months of life there were swollen cells containing intranuclear and cytoplasmic inclusions. This cytologic change seemed related to the fatalities. In 1956 and 1957, three different laboratories isolated what has come to be called the *human cytomegalovirus* (see Weller). This has proved to be the most frequent intrauterine viral infection, rivaled in the current era only by HIV.

CMV disease is caused by a DNA virus, a member of the herpes group, and is widespread in the general population. Although cervicitis is common, the virus is probably transmitted to the fetus transplacentally. Infection of the fetus usually occurs in the first trimester of pregnancy, sometimes later, by way of an inapparent maternal viremia and infection of the placenta. The newborn can also be infected in the course of delivery or afterward by the mother's milk or by transfusions. However, only a small proportion of women known to harbor the virus give birth to infants with active infection. The likelihood of the fetus being infected is much greater if the seronegative mother becomes infected for the first time during pregnancy. Eighteen percent of infants born to

such mothers were symptomatic at birth, and 25 percent became blind, deaf, or mentally retarded within a few years (Fowler et al). In mothers with recurrent CMV infection, the infants were asymptomatic at birth, and only a few developed serious sequelae. Evidently, the presence of maternal antibodies before conception protects against congenital CMV infection.

Early infection of the fetus may result in a malformation of the cerebrum; later, there is only inflammatory necrosis in parts of the normally formed brain. In the low-birth-weight or full-term infant, the clinical picture is one of jaundice, petechiae, hematemesis, melena, direct hyperbilirubinemia, thrombocytopenia, hepatosplenomegaly, microcephaly, mental defect, and convulsions. Cells in the urine may show cytomegalic changes. There is a pleocytosis and an increased protein in the CSF. Disseminated inflammatory foci have been observed in the cerebrum, brainstem, and retinae. Here there were aggregates of lymphocytes, mononuclear cells, and plasma cells. The mononuclear histiocytes (microglial cells) contain inclusion bodies; some astrocytes are similarly affected. The granulomas later calcify, particularly in the periventricular regions. Often there is hydrocephalus.

Congenital CMV infections pose a much greater problem than rubella. There is no way of identifying the infected fetus prior to birth or to prevent inapparent infections in the pregnant woman. As indicated above, if the pregnant woman has measurable titers of antibodies to CMV at the time of conception, her infant is relatively protected. Moreover, some infected infants (with viruria) may appear normal at birth but develop neural deafness and mental retardation several years later. Viral replication in infected organs continues after the first year and health workers are at risk. A second child may be infected.

There is no known treatment. The difficulties in prenatal diagnosis of maternal infection preclude planned abortion. Routine serologic testing should be done on every young woman of childbearing age. Until an effective vaccine becomes available, pregnancy should be avoided if a sexual partner is infected.

Congenital HIV Infection and AIDS

In the United States, about 10 percent of cases of acquired immunodeficiency syndrome (AIDS) have occurred in women, almost all of them of childbearing age, and the rate of new cases is increasing at a faster rate among them than among men. The numbers are higher in many developing countries and particularly in parts of Africa. In children, practically all instances of AIDS come from an HIV-infected mother ("vertical transmission"). The infection may be acquired in utero, during delivery, or from breast-feeding. The relative importance of each of these modes of transmission has not been settled.

It is estimated that HIV infection and AIDS occur in 15 to 30 percent of infants born to HIV-seropositive mothers (see Prober and Gerson). Infected infants present special difficulties in diagnosis, and the infection runs a more accelerated course in them than in adults. In the perinatal period, infected and noninfected infants can only rarely be distinguished clinically, and laboratory diagnosis is hampered by the presence of maternally derived antibody to HIV. The initial clinical signs usually appear within a few months after birth; practically all infected infants become ill before their first birthday, and very few are asymptomatic beyond 3 years of age. Early signs consist of lymphadenopathy, splenomegaly, hepatomegaly, failure to thrive, oral candidiasis, and parotitis. In the European Collaborative Study, comprising 600 children born to HIV-

infected mothers, 83 percent of infected children showed laboratory or clinical features of HIV infection by 6 months of age. By 12 months, 26 percent had clinical symptoms of AIDS and 17 percent had died of HIV-related diseases. Once AIDS is established in children, it does not differ materially from the syndrome in adults (Chap. 33).

There is often a delay in the attainment of psychomotor milestones. In others, after a period of normal development, a psychomotor decline begins, with corticospinal or peripheral nerve signs, often with pleocytosis in the CSF. The typical giant-cell AIDS encephalitis, neuritis, and myelitis is easily distinguished from CMV encephalitis and toxoplasmosis.

Infected children are also subject to a variety of opportunistic infections, including bacterial meningitis, toxoplasmosis, CMV encephalitis, fungal infections (cryptococcosis, aspergillosis, candidiasis), herpes simplex, syphilis, zoster, and mycobacterial meningitis. There may also be vascular lesions, with infarction or hemorrhage and lymphoid neoplasia. These are discussed in Chaps. 32 and 33. To date there is little that one can do for these children, but this may be changing with the current use of three-drug antiretroviral therapy, as described in Chap. 33.

Congenital Toxoplasmosis

This tiny protozoan *Toxoplasma gondii*, occurring freely or in pseudocyst form, is a frequent cause of meningoencephalitis in utero or in the perinatal period of life. The disease exists in all parts of the United States but is more frequent in western European countries, particularly in those with hot, humid climates. The mother is most often infected by exposure to cat feces, handling uncooked infected mutton or other meat, or eating partially cooked meat, but she is nearly always asymptomatic or has only a mild fever and cervical lymphadenopathy.

The precise times of placental and fetal invasion are not known, but presumably they occur late in the gestational period. The clinical syndrome usually becomes manifest in the first days and weeks of postnatal life, when seizures, impaired alertness, hypotonia, weakness of the extremities, progressive hydrocephalus, and chorioretinitis appear. The retinal lesions consist of large pale areas of destroyed retina surrounded by deposits of pigment. If the infection is severe, the maculae are destroyed; optic atrophy and microphthalmos follow. In older infants, we have several times observed hemiplegias, first on one side and then on the other, followed by tension hydrocephalus. The latter is present in about one-third of the cases. The CSF contains a moderate number of white blood cells, mostly lymphocytes and mononuclear cells, and the protein content is in the range of 100 to 400 mg/dL (i.e., a higher protein content than all other neonatal infections except bacterial meningitis). The glucose values are normal. Less than 10 percent of infected children recover; the others are mentally retarded, with seizures and paralysis. In those without symptoms of infection at birth, the outcome is better.

Granulomatous masses and zones of inflammatory necrosis abut the ependyma and meninges. The organisms, 6 to 7 mm in length and 2 to 4 mm in width, are visible in and near the lesions. Microcysts may also be found, lying free in the tissues without surrounding inflammatory reaction. The necrotic lesions calcify rapidly and, after several weeks or months, are readily visible in plain films of the skull. These appear in periventricular and other regions of the brain as multiple nodular densities.

In adults, often in association with AIDS, the disease takes

the form of a rapidly evolving meningitis and multifocal encephalitis in conjunction with myocarditis, hepatitis, and polymyositis. This syndrome is described on page 623, as are the diagnostic tests and treatment. In the infant, infections such as rubella, syphilis, CMV disease, and herpes simplex must be considered in the differential diagnosis. The most reliable means of diagnosis is the IgM indirect fluorescent antibody test, performed on umbilical cord blood. Passive transfer of IgG antibody from mother to fetus takes place, but its presence in the latter is not proof of active infection.

In women who develop antibodies in the first 2 or 3 months of pregnancy, treatment with spiramycin (Rovamycin) prevents fetal infection. Once the fetus is infected, pyrimethamine and sulfadiazine must be used. A later second pregnancy is not affected.

Congenital Neurosyphilis

The clinical syndromes and pathologic reactions of congenital neurosyphilis of the newborn are similar to those of the adult, as described on pages 614 to 618. Such differences as exist are determined principally by the immaturity of the nervous system at the time of spirochetal invasion.

The syphilitic infection may be transmitted to the fetus at any time from the fourth to the seventh months. The fetus may die, with resulting miscarriage or stillbirth, or may survive only to be born with florid manifestations of secondary syphilis. The dissemination of the spirochetes throughout the body, the time of appearance of the secondary manifestations, and the time of formation of anti-syphilitic antibodies (reagin) in the blood are all governed by the same biologic principles that apply to adult syphilis.

At birth the spirochetemia may not have had time to cause syphilitic antibodies to appear; hence a negative Venereal Disease Research Laboratory (VDRL) reaction in umbilical cord blood does not exclude syphilis. In unselected groups of syphilitic mothers, 25 to 80 percent of fetuses are infected, and in 20 to 40 percent of those infected, the CNS is invaded, as judged by the finding of abnormal CSF. The types of congenital neurosyphilis (asymptomatic and symptomatic meningitis, meningovascular disease, hydrocephalus, general paresis, and tabes dorsalis) are the same as those in the adult except for the great rarity of tabes dorsalis. The classic Hutchinson triad (dental deformities, interstitial keratitis, and bilateral deafness) is infrequently observed in complete form. The sequence of neurologic syndromes is also the same as in the adult, all stemming basically from a chronic spirochetal meningitis. The infection may become symptomatic in the first weeks and months of postnatal life, meningovascular lesions and hydrocephalus reaching maximal frequency during the period from 9 months to 6 years. An early form of syphilitic meningoencephalitis may occur at 1 to 2 years and result in severe mental retardation. More often, a congenital paresis and tabes usually appear between the ninth and fifteenth years. The pathologic basis of the neurosyphilitic syndromes are discussed on page 614.

All neurologists observe fewer and fewer cases of congenital neurosyphilis as the years pass, but there may be a recrudescence of the disease in HIV-infected patients. If the syphilitic mother is treated before the fourth month of pregnancy, the fetus will not be infected. The affected infant may be normal at birth or exhibit only mucocutaneous lesions, hepatosplenomegaly, lymphadenopathy, and anemia. There are in the neonatal period no signs of meningeal invasion, or there may be only an asymptomatic meningitis. If the latter is actively treated until the CSF is normal, vascular lesions of brain and spinal cord, hydrocephalus, general paresis, and tabes

dorsalis will not develop. If cases of meningovascular syphilis, general paresis, and tabes dorsalis are treated for 3 to 4 weeks with penicillin until the CSF is rendered acellular and the protein reduced to normal, the neurologic disorder will be arrested and there is often functional improvement.

Congenital syphilis must be considered a potential albeit rare cause of epilepsy and mental retardation. Once the syphilitic infection has been treated in early life and rendered inactive (acellular CSF, normal protein), the occurrence of a congenital luetic infection can only be substantiated by an accurate history; the finding of the syphilitic stigmata in the eyes, teeth, and ears; or a positive serologic reaction in the CSF.

Treatment of syphilis in the child follows along the same lines as treatment of the syphilitic adult (page 618), with appropriate adjustment of dosage in accordance with the child's weight.

Other Viral and Bacterial Infections

Several other infections of late fetal life or the neonatal period are only mentioned here, for to describe them all would be tedious and would elucidate no new neurologic principles. Meningitis due to the small gram-positive rod *Listeria monocytogenes* may be acquired in the usual way, at the time of passage through an infected birth canal or in utero, as a complication of maternal and fetal septicemia due to this organism. In the latter case, it causes abortion or premature delivery. Neonatal bacterial meningitis is a particularly devastating and often fatal type of bacterial infection, not easily diagnosed unless the pediatrician is alert to the possibility of a silent meningitis in every case of neonatal infection (page 596).

Herpes simplex virus (HSV) encephalitis may destroy large parts of the infant brain, particularly of the temporal lobes, and is frequently fatal. Coxsackie B, polioviruses, other enteroviruses, and arboviruses (western equine) seem to be able to cross the placental barrier late in pregnancy and cause encephalitis or encephalomylitis in the near-term fetus. It is indistinguishable from the disease in the very young infant.

Herpes zoster may occur in utero, leaving cutaneous scars and retarding development. Or zoster may appear soon after birth, the infection having been contracted from the mother. Only later in childhood can varicella induce an autoimmune perivenous demyelination and possibly a direct infection, affecting predominantly the cerebellum (pages 641 and 790), or the now rare Reye syndrome.

Epstein-Barr virus is another not infrequent cause of meningoencephalitis. In some instances it may present as an aseptic meningitis or a Guillain-Barré type of acute polyneuritis. This infection tends to affect the nervous system of children rather than that of adults, but there are exceptions to this comment. It is estimated that approximately 2 percent of children and adolescents with this infection have some type of neurologic dysfunction; rarely will this be the only manifestation of the disease. Stupor, chorea, and aseptic meningitis were the main neurologic findings in the case reported by Friedland and Yahr, and acute cerebellar ataxia and deafness were observed in the case of Erzurum and associates (see also Chaps. 32 and 33).

EPILEPSIES OF INFANCY AND CHILDHOOD

The major types of seizure disorder have already been discussed in some detail in Chap. 16. In bringing them up here, attention is again drawn to the fact that epilepsy is mainly a disease of infancy

and childhood. Approximately 75 percent of epileptics fall into these age periods, and some of the most interesting and unique types of seizure are peculiar to these epochs of life. Epilepsies that are observed exclusively in infants and children are benign neonatal convulsions, benign myoclonic epilepsy of infancy, febrile seizures (both genetic and acquired), infantile spasms of West, absence seizures, the Lennox-Gastaut syndrome, rolandic and occipital paroxysms and other benign focal epilepsies, and the juvenile myoclonic epilepsies.

One principle that emerges is that the form taken by seizures in early life is in part age-linked. Neonatal seizures are predominantly partial or focal; infantile seizures take the form of myoclonic flexor (sometimes extensor) spasms; and the various forms of petit mal are essentially diseases of childhood (4 to 13 years). The motor phenomena of epilepsy in young children are often termed *myoclonic*, but this should not be confused with other, later-occurring epilepsies that are endowed with the same name. Further, certain epileptic states tend to occur only during certain epochs of life—one type of febrile seizures from 6 months to 6 years, generalized or temporal spike-wave activity with benign motor and complex partial seizures from 6 to 16 years, and juvenile myoclonic epilepsy in the mid- and late-adolescent years. In general, idiopathic epilepsy, so called because the cause cannot be determined, is predominantly a pediatric neurologic problem. This is not to say that seizures of unknown cause do not occur for the first time in adult life but rather that the onset of such seizures is far more frequent in childhood and tends to diminish once adulthood is reached.

The clinical characteristics of infantile and childhood seizures, including those of genetic origin, are fully described in Chap. 16.

SEVERE FORMS OF MENTAL RETARDATION

The subject of mental retardation was introduced in Chap. 28, where it was pointed out that two major categories of this disorder have been delineated. In one, and by far the more common group, the mental retardation is relatively mild, allowing the individual to benefit from training and education; it is often familial and is featured by a lack of definite neurologic abnormalities (except possibly a slightly higher incidence of seizures) and the absence of neuropathologic changes. A large part of this group, falling between 2 and 3 standard deviations below the normal mean IQ, probably are the lower end of the Gaussian curve of intelligence, the converse of which is genius. This group is, however, contaminated with a small number of defined diseases of the nervous system occurring in a less severe form, as was pointed out on page 513. In a second group, the degree of mental retardation is usually more severe (IQ of 50 to 70), and yet more so in the third group (IQ less than 50). Most of the cases in the second and third groups are nonfamilial, and a wide variety of neuropathologic changes are in evidence. The subdivisions are not absolute, for there are a few metabolic and developmental diseases in which mental retardation is profound yet with no somatic or neurologic abnormalities and, most importantly, well-defined neuropathologic changes are lacking. Here we refer to conditions such as Rett syndrome, autism, and the X-linked mental retardation syndromes (Renpenning and fragile-X types). In this chapter only these major types of *severe mental retardation* are described.

The overall frequency of severe mental retardation cannot be stated precisely. Rough estimates place the figure at 0.2 to 0.4 percent of the general population and at about 10 percent of the general

retarded segment of society. It is important to emphasize that in a large proportion of individuals with severe mental retardation, a particular congenital abnormality or anomaly of development cannot at present be traced to any of the disorders reviewed in the preceding pages. More precisely stated, when groups of such severely retarded patients are studied clinically, a reasonably accurate etiologic determination of the underlying brain disease can be made in only slightly more than half. According to Penrose, chromosomal abnormalities account for 15 percent, single-gene disorders for 7 percent, and environmental agents for 20 percent. Recent studies of the subtelomeric parts of chromosomes reportedly find abnormalities in another 7 percent of severely retarded children (Knight et al). No cause is found for the remaining cases. Males outnumber females 3 to 1. For purposes of comparison, our figures, obtained from a study of 1372 patients at the Walter E. Fernald School in the 1970s, are presented in Table 38-6.

From the neuropathologic standpoint, *the examination of the brains of the severely retarded by conventional histopathologic methods discloses lesions in approximately 90 percent, and in fully three-quarters an etiologic diagnosis can be determined or tentatively assigned*. Many of the remaining 10 percent of the “pathologically retarded” actually lack definite pathologic changes, but their brains are lighter in weight by 10 to 15 percent than age-matched normal brains. Interestingly, the proportion of vascular, hypoxic-ischemic, metabolic, and genetic lesions in this group of severely retarded individuals is much the same as is found in a group selected on the basis of “cerebral palsy.”

Here it is important to repeat a point made earlier and in Chap. 28, that a few of the severely disabled and a large majority of the mildly retarded do not have a recognizable cerebral pathology or exhibit any of the familiar and conventional signs of cerebral disease. Although the milder forms of mental retardation tend to be familial, this does not by itself separate them from the severe forms of mental retardation. There are several types of hereditary mental

Table 38-6
Causes of severe and mild mental retardation in 1372 patients at the W. E. Fernald State School

DISEASE CATEGORY	NUMBER OF PATIENTS		PERCENT OF ALL PATIENTS
	IQ<50	IQ>50	
Acquired destructive lesions	278	79	26.0
Chromosomal abnormalities	247	10	18.7
Multiple congenital anomalies	64	16	5.8
Developmental abnormality of brain	49	16	4.7
Metabolic and endocrine diseases	38	5	3.1
Progressive degenerative disease	5	7	0.9
Neurocutaneous diseases	4	0	0.3
Psychosis	7	6	1.0
Mentally retarded (cause unknown)	385	156	39.5

retardation, in which the retardation may be severe and in some of which there may be maldevelopment of the cerebral cortex. These are discussed further on.

Clinical Characteristics of the Severely Retarded

These cases can be broadly divided into four groups. In one large group, designated *dysmorphic retardation*, a variety of physical deformities, including microcephaly, is commonly present. In a second group, with *multiple system retardation*, the mental backwardness is linked to nonskeletal abnormalities (e.g., hepatosplenomegaly, hematologic and skin disorders), which provide reliable clues to the underlying somatic disease. In a third group, *neurologic retardation*, somatic abnormalities are lacking but a configuration of neurologic signs leads to the diagnosis. In the fourth group, and the most difficult one to clarify, that comprising *uncomplicated retardation*, there are no (or minimal) somatic, visceral, or neurologic abnormalities. One is then forced to turn to special features of the mental retardation itself for identification of the underlying

disease. Table 38-7 elaborates our classification of the types of mental retardation.

The profoundly retarded infant with a virtually untestable IQ is identified early in life because he does not sit, stand, or walk. If any one of these motor activities is acquired, it appears late and is imperfectly performed. Language never develops; at most a few spoken words or phrases are understood and fewer are uttered, or the patient only vocalizes in a meaningless way. Such a person may not even indicate bodily needs for food, drink, excretion, and so on. Usually the patient is continuously idle and interacts little with people and objects. Only the most primitive emotional reactions are exhibited, often without connection to an appropriate stimulus. Physical growth is usually retarded, nutrition may be poor, and susceptibility to infections is increased. Sphincteric control may never be attained, and if attained, is precarious.

When the mental defect is less severe than described above, falling into the IQ ranges of 20 to 45, or 45 to 70, there may be somatic neurologic abnormalities. If specific motor defects do not coexist, then sitting, standing, and walking are achieved but not at the expected times. The existence of a mental defect is most clearly

Table 38-7
Types of severe mental retardation

- I. Dysmorphic defect with somatic developmental abnormalities in nonnervous structures
 - A. Those affecting cranioskeletal structures
 - 1. Microcephaly
 - 2. Macrocephaly
 - 3. Hydrocephalus (including myelomeningocele with Chiari malformation and associated cerebral anomalies)
 - 4. Down syndrome
 - 5. Cretinism (congenital hypothyroidism)
 - 6. Mucopolysaccharidoses (Hurler, Hunter, and Sanfilippo types)
 - 7. Acrocephalosyndactyly (craniostenosis) and other craniosomatic abnormalities
 - 8. Arthrogryposis multiplex congenita (in certain cases)
 - 9. Rare specific syndromes: De Lange
 - 10. Dwarfism, short stature: Russel-Silver dwarf, Seckel bird-headed dwarf, Rubinstein-Taybi dwarf, Cockayne-Neel dwarf, etc.
 - 11. Hypertelorism, median cleft face syndromes, agenesis of corpus callosum
 - B. Those affecting nonskeletal structures
 - 1. Neurocutaneous syndromes: tuberous sclerosis, Sturge-Weber, neurofibromatosis
 - 2. Congenital rubella syndrome (deafness, blindness, congenital heart disease, small stature)
 - 3. Chromosomal disorders: Down syndrome, some cases of Klinefelter syndrome (XXY), XYY, Turner (XO) syndrome (occasionally), and others
 - 4. Laurence-Moon-Biedl syndrome (retinitis pigmentosa, obesity, polydactyly)
 - 5. Eye disorders: toxoplasmosis (chorioretinitis), galactosemia (cataract), congenital rubella
 - 6. Prader-Willi syndrome (obesity, hypogenitalism)
- II. Nondysmorphic mental defect without somatic anomalies but with cerebral and other neurologic abnormalities
 - A. Cerebral spastic diplegia
 - B. Cerebral hemiplegia, unilateral or bilateral
 - C. Congenital choreoathetosis or ataxia
 - 1. Kernicterus
 - 2. Status marmoratus
 - D. Congenital ataxia
 - E. Congenital atonic diplegia
 - F. Syndromes resulting from hypoglycemia, trauma, meningitis, and encephalitis
 - G. Associated with other neuromuscular abnormalities (muscular dystrophy, cerebellar ataxia, etc.)
 - H. Cerebral degenerative diseases (lipidoses)
 - I. Associated with inborn errors of metabolism (phenylketonuria, other aminoacidurias, organic acidurias, Lesch-Nyhan syndrome)
 - J. Congenital infections (some cases of congenital syphilis, cytomegalic inclusion disease)
- III. Genetic mental defect of indeterminate type with minor or no signs of somatic abnormality or neurologic disorder
 - A. Infantile autism, Rett, Williams, fragile X, Partington, and Rett syndromes

evidenced by a delay in psychomotor development and a failure to speak by the second or third postnatal year. The patient does not acquire the usual household and play activities as well as other children. However, delay in speech development must not, by itself, be taken as a mark of mental retardation, for in some children a unique delay in speech can be an isolated abnormality (see Chap. 28), with subsequent normal development of speech and mental ability. Toilet training may be difficult to accomplish in the retarded child, but, again, bed-wetting may be a problem in an otherwise normal child. Also, the deaf child may have to be considered separately; here the problem becomes apparent by an indifference to noise and reduced vocalization (stereotypy of babbling).

More searching analyses of cognitive functions in the moderately retarded child have been undertaken by O'Connor and Hermelin, by Pulsifer, and by others. These authors have measured efficiency of visual and auditory perception, adequacy of communication, relations between language development and thought, cross-modal sensory encoding, alertness, attention, and memory. It was concluded that none of these functions was specifically impaired. Instead, the retarded child could not properly encode new information because the memory systems and the stock of past assimilated knowledge were insufficient to provide a framework of items and categories with which new information could be integrated. Some patients also seemed unable, perhaps because of this, to extract from perceived material selective features that could be interpreted. Further, they were unable to deal with an array of sensory experiences like normal children. The complexity of these mental operations, which we would reduce to a global failure of the normal processes of apperception and integration, has been called by Piaget a failure of assimilation and accommodation. This type of inadequacy is common to many different diseases, but in each there are almost certainly other subtle differences that are just now being analyzed by neuropsychologists.

However, within the spectrum of mental retardation, apart from cognitive impairments, there are curious differences in behavior and personality, even in those with more or less the same IQ. Some individuals with moderately severe retardation are pleasant and amiable and achieve a rather satisfactory social adjustment. This is particularly notable in patients with Down and Williams syndromes. At the opposite end of the behavioral scale are the syndromes of autism and that of Smith-Magenis and of DeLange, in which the individual fails to manifest normal interpersonal social contact, including communicative language. The phenylketonuric child is usually irritable, unaffectionate, and implacable, and the same is said of certain other forms of retardation, such as those with the DeLange syndrome, discussed earlier in the section on retardation with dwarfism.

Regarding differences in activity levels, many retarded individuals are slow, clumsy, and relatively akinetic. Others, as many as half, display an incessant hyperactivity characterized by a restless, seemingly inquisitive searching of the environment. When thwarted, they may exhibit a low frustration tolerance. They may be destructive and recklessly fearless and impervious to the risk of injury. Some exhibit a peculiar anhedonia that renders them indifferent to both punishment and reward. Other aberrant types of behavior, such as violent aggressiveness and self-mutilation, are common.

Rhythmic rocking, head-banging, incessant arm movements—so-called *rhythmias* or *movement stereotypies*—are observed in the majority of those who are severely and moderately severely retarded. These movements are maintained hour after hour

without fatigue and may be accompanied by breathing sounds, squeals, and other exclamations. A number of them tend to be particularly common in certain forms of retardation: hand-flapping in autism, hand-wringing in Rett syndrome, and hand-waving in Down syndrome and other disorders. Self-stimulation, even hurtful—such as striking the forehead or ears or biting the fingers and forearms—seems to be compulsive or perhaps to provide some sort of satisfaction. It is not that these rhythmias are by themselves abnormal, for some of them occur for brief periods in normal babies, but that they persist. Nevertheless, many moderately retarded persons, when assigned to a simple task such as putting envelopes in a box, can continue this activity under supervision for several hours.

In the least severe types of retardation, all the mental activities are intact but subnormal. The point to be made is that all aspects of intellectual life, personality, and deportment are affected in slightly but differing degrees and that these effects have a neurologic basis. There is more than a hint that in particular diseases, because of their anatomy, the cognitive experience, affective life, and behavior are affected in special ways.

The group of moderately retarded, like the severely retarded, is divisible into groups with somatic systemic and neurologic abnormalities, though the proportions are not the same. There are fewer of the dysmorphic type and more of the nondysmorphic, nonneurologic group.

Etiology of Severe Mental Retardation From Table 38-1 it is obvious that many diseases can blight the development and maturation of the brain, leaving it in an arrested state. Some of these are acquired and some are congenital and hereditary. Some affect all parts of the organism, giving rise to associated dermal, skeletal, and visceral abnormalities, while others affect only the nervous system in particular patterns. With respect especially to the *milder degrees of mental retardation*, in all populations thus far studied, as mentioned above, infants of extremely low birth weight are more likely to have disabilities, brain abnormalities, and poorer language development and scholastic achievement. Mild mental retardation also tends to correlate with lower social status, which must relate in some manner to biological factors, as pointed out in the Scottish Low-Birth-Weight Study. Viral and spirochetal infections and parturitional accidents are other common causes. They act acutely and are theoretically preventable.

The factor of malnutrition during the fetal or infantile period of life as a cause of severe mental retardation has received considerable attention because it is a worldwide problem. Animal experiments by Winick and others have demonstrated that severe undernutrition in early life leads to behavioral abnormalities and biochemical and morphologic changes in the brain, which may be permanent (see Chap. 41). Galler studied a group of infants in Barbados who were severely malnourished during the first year of life and then given an adequate diet. These children were followed to adulthood and compared with normally nourished siblings. Galler observed no effect on physical growth, but there were persistent attention deficits in 60 percent of the undernourished group and in only 15 percent of controls. The IQ scores of the former were also lower. Unfortunately, genetic factors could not be completely controlled. In general, it may be said that the data showing mental retardation to be caused by malnutrition, while suggestive, are far from convincing.

Severe protein-calorie malnutrition in the first 8 months of life, which induces kwashiorkor, was reported to retard mental de-

velopment. However, such patients are said to regain mental function when fed. The authors have been impressed with the ability of the nervous system to withstand the effects of nutritional deficiency, perhaps better than any other organ.

The action of exogenous toxins during pregnancy is another factor to be considered. Severe maternal alcoholism has been linked to a dysmorphic syndrome and mental retardation, but the findings of several studies have not been consistent (see Chap. 42); a similar problem attaches to maternal exposure to anticonvulsant medications (see Chap. 16). Surprisingly, maternal addiction to opiates, while causing an opiate withdrawal in infants for weeks or even months (Wilson et al), seems not to result in permanent injury to the nervous system. The importance of exposure to extremely small amounts of environmental lead is also controversial.

The effect of psychologic deprivation on cognitive development has been of interest. Following the observations that complete isolation of young female monkeys had a devastating effect on their later sexual and nurturing behavior, the idea became popular that such deprivation might cause faulty mental development in humans. Orphaned and neglected babies were found to be inactive, apathetic, and backward in comparison with those who were constantly stimulated by caring mothers. But surprisingly, when nurtured properly at a later time, these babies soon caught up with their peers. This general idea of psychologic deprivation has been the basis of many interesting educational programs for poor and neglected children. To this day, however, it has not been proven that sensory, emotional, and psychologic deprivations of a degree observed in humans are the causes of severe mental retardation or repeated scholastic failure. However, the problem is a complex one, and the arguments pro and con have been carefully elaborated by Haywood and Wachs. The controversies regarding the effects of prematurity, maternal hypertension, and eclampsia, which are often associated with neonatal cerebral pathology and retarded psychomotor development, have been mentioned earlier in this chapter.

The genetic types of severe mental retardation (Down syndrome, fragile X, Prader-Willi, etc.), including the novel type associated with subtelomeric abnormalities, have been discussed in an earlier section.

Differentiation of Types of Retardation: Clinical Approach

As a particular guide to the pediatrician and neurologist who must assume responsibility for the diagnosis and management of backward children harboring a wide array of diseases and maldevelopments of the nervous system, the following clinical approach is suggested. First, as already described, there is an advantage in setting aside as one large group those who are only mildly retarded from those who have been severely delayed in psychomotor development since early life. With regard to the former group, having no obvious neurologic signs or physical stigmata, one should nevertheless initiate a search for the common metabolic, chromosomal, and infective diseases. In this large group one must be sure that their deficit is a general one and not one of hearing, poor sight, or the special isolated language and attention deficits described in Chaps. 23 and 28.

For patients with moderately severe and very severe cognitive deficits, one begins with a careful physical examination, searching specifically for somatic stigmata and neurologic signs. Abnormalities of eyes, nose, lips, ears, fingers, and toes are particularly important, as are head circumference and a variety of neurologic ab-

normalities, as outlined in Table 38-7. Data so obtained allow classification into one of three categories, as follows:

1. *In those with somatic abnormalities* (with or without obvious neurologic signs), one assumes the presence of a maldevelopment of the brain, possibly caused by a chromosomal abnormality. The psychomotor retardation is usually severe and often nongenetic and, as a rule, has a well-defined neuropathology. Diagnosis is determined by the gestalt of physical signs. The possible maldevelopments are numerous and diverse and have been summarized in Tables 38-1 and 38-7; some of the main ones have been described earlier in the chapter. One inevitably turns to the several atlases to delineate the syndromes (Holmes et al; Jones).
2. In the group in which the *abnormalities are confined to the nervous system*, attention is focused on a larger number of diseases, many due to exogenous factors such as perinatal hypoxia-ischemia, pre- or postnatal infections, trauma, and so on. There are usually conspicuous neurologic signs. The degree of mental retardation is variable, depending on the location and extent of a demonstrable neuropathology. Usually the family history is negative, but careful questioning of parents regarding the pregnancy, delivery, and early postnatal period and examination of hospital records from birth may disclose the nature of the neurologic insult.
3. The third category of retardates is one in which *neither somatic anomalies nor focal neurologic signs* are present, or they are minimal. The more severely retarded of this special group are represented by the following disease states: autism (Asperger-Kanner syndrome), the Rett and Williams syndromes, and the fragile X and Renpenning syndromes. All of these but autism are now known to have a genetic basis, as noted earlier in the chapter, and are described together below.

The practical importance of this clinical approach is that it directs the intelligent use of laboratory procedures for confirmation of the diagnosis. CT scanning and MRI are useful in clarifying maldevelopment and neurologic diseases but are seldom helpful in the third group of cases. EEG confirms seizure discharges when there is uncertainty as to the nature of episodic neural dysfunction. Karyotyping and genetic studies are useful in group 1 and rarely in group 2 patients.

The major pitfall to be avoided in this clinical approach is in mistaking a hereditary metabolic disease for a developmental one. Here one is helped by the fact that manifestations of the metabolic diseases are not usually present in the first days of life; they appear later and are progressive and often associated with visceral abnormalities. However, some metabolic diseases are of such slow progression that they appear almost stable, especially the late-onset ones, such as one type of metachromatic leukodystrophy, late-onset Krabbe leukodystrophy, adult adrenoleukodystrophy, and adult hexosaminidase deficiency (see Chap. 37).

Hereditary Mental Retardations

Fragile X Syndrome (See page 864) Great interest has been evinced in this syndrome, which some geneticists hold accountable, at least in part, for the preponderance of males among institutionalized retarded individuals. A large kindred in which mental retardation was inherited in an X-linked pattern was first reported by

Martin and Bell in 1943. It was in such a family, with X-linked mental retardation, that Lubs, in 1969, discovered a fragile site at the distal end of the long arm of the X chromosome; subsequently it was established that there is an unstable inherited CGG repeating sequence at this site, which leads to breakage, as discussed previously. At first, it was assumed that the fragile X syndrome was only an example of the Renpenning syndrome (an X-linked hereditary mental retardation in males—see below), until it was pointed out that in this latter condition, stature was reduced, as was the cranial circumference, and further that the X chromosomes of the Renpenning patients were normal. The nature of chromosomal breakage is given on page 864.

In some series, fully 10 percent of mentally retarded males have this fragile X chromosomal abnormality, although 2 to 4 percent is more accurate according to others. Females are sometimes affected, but their mental function is only slightly reduced. Affected males have only mild dysmorphic features (large ears, broad forehead, elongated face, and enlarged testes) that may not become obvious until puberty. Others are somatically normal. Behavioral problems of one sort or another are almost universal. Pulsifer, whose review of the neuropsychologic aspects of mental retardation is recommended, lists self-injurious, hyperactive, and impulsive behaviors as the most common. The hand-flapping that is more characteristic of autism may be seen.

Rett Syndrome (See page 965) This is yet another hereditary form of mental retardation, but affecting girls. None of the cases in the extensive studies of Hagberg and coworkers were male. The responsible spontaneous mutation has been shown to relate to a defect at chromosomal site Xq28, making it one of the X-linked mental retardations. A fatal outcome in boys due to a severe neonatal encephalopathy explains the expression of the disease only in girls, who are mosaics for the mutation. The involved gene, MECP2, is responsible for suppressing various other genes at critical stages of development (see Dunn and MacLeod). It has this effect by binding to methylated DNA. Defective function of the gene leads to an alteration in synaptogenesis and neural connectivity (Neul and Zoghbi). Severe inactivation of gene expression causes classic Rett syndrome, but it has become apparent that incomplete expression and mosaicism lead to a number of partial syndromes, including nonspecific mental retardation, tremor, psychiatric disturbances, and autism-like presentations.

Prevalence studies from Sweden indicate an occurrence of 1 per 10,000 girls; thus Rett syndrome is more common than phenylketonuria. While most cases appear to be sporadic, there is a high familial incidence and some degree of concordance in twins (this is still uncertain).

The syndrome is characterized clinically by withdrawn behavior that simulates autism, dementia, ataxia, loss of purposeful hand movements, and respiratory irregularities. Highly characteristic of this syndrome is a period of 6 to 18 months of normal development followed by the rapid appearance and progression of all these signs, and then by relative stability for decades. Spasticity, muscle wasting, scoliosis, and lower limb deformities may become evident in the late stages of the illness. Hand-wringing and similar stereotypes are very typical features (and are different in subtle ways from the hand-flapping of autistic children).

Armstrong and Naidu, who have reviewed the neuropathology of Rett syndrome, have drawn attention to a number of subtle cortical abnormalities, most of which are consistent with disruption of the postnatal integrative phase of cerebral development; however,

not all cases showed these abnormalities. There is generally a decrease in brain size, most marked frontally. Dendritic branching is reduced in several areas. The MRI scan is ostensibly normal, but some patients have a frontal or cerebellar atrophy in their teenage years.

Partington Syndrome This is yet another X-linked type of mental retardation, which in its fully expressed form, is associated with prominent dystonia of the hands and sometimes ataxia. Like Rett syndrome, discussed above, variations in gene expression are found to have other syndromes including myoclonic epilepsy, West syndrome, autism, and nonspecific retardation as well as lissencephaly. The mutated gene, termed Aristaless-related homeobox (ARX), is involved with regulation of protein-DNA interactions. The subject is reviewed by Sherr.

Renpenning Syndrome A similar type of hereditary, male-sex-linked mental retardation has been described by Renpenning (see page 515). The originally described family comprised 21 males in two generations of Mennonites in western Canada whose IQs ranged from 30 to 40. As with the fragile X syndrome, female siblings may show slight degrees of retardation. Affected members were small in stature and slightly microcephalic but otherwise free of somatic and neurologic abnormalities.

Williams Syndrome This inherited form of mental retardation, which is manifest in both males and females, has also been mentioned earlier, on page 864, in relation to the chromosomal abnormalities. It is characterized by mild mental retardation but with striking retention and even precocity or superiority of musical aptitude and social amiability. In some instances a retained facility for writing permits the production of long written descriptions; yet at the same time these subjects are barely able to draw simple objects. The child is physically retarded and has minor but distinctive somatic changes (wide mouth, almond-shaped eyes, upturned nose, small pointed ears), together imparting an “elfin appearance.” The child is unusually sensitive to auditory stimuli. There is a delay in the acquisition of communicative speech and defects in visual, spatial, and motor skills, making these children seem more backward than they actually are. Striking sociability and empathy sets them apart; they represent virtually the converse of autism in this respect. Memory for musical scores—such as memorizing parts of a complete symphony after one hearing—may be prodigious. By the use of high-resolution cytogenetics, the disease has been traced in 90 percent of cases to a microdeletion on chromosome 7 in the region of the gene that controls the production of elastin (Nickerson et al). This is of interest because an index feature of these cases is a supravalvular aortic stenosis. It is not known whether there is a characteristic brain pathology, but one patient of Golden and colleagues, examined at 35 years of age, showed no cerebral abnormalities except for Alzheimer changes, mainly plaque formation in the entorhinal cortex and amygdala.

Doublecortin Mutations Among the disorders of neuronal migration, lissencephaly and the related disorder of subcortical band heterotopia are usually associated with severe defects in mental development. However, in female carriers, other mutations in the doublecortin gene (DCX) on the X-chromosome have given rise to mild nondysmorphic mental retardation and cryptogenic epilepsy (see Guerrini and colleagues). Thus this disorder joins the group of X-linked mental retardations with minimal dysmorphic features

and has implications for the understanding of X-chromosome inactivation in female carriers.

Autism (Kanner-Asperger Syndrome; Autistic Spectrum Disorders)

This condition was described almost simultaneously by Kanner in Baltimore (in 1943) and Asperger in Vienna (in 1944). Among the large group of retarded children, Kanner observed exceptional ones who appeared to be *asocial, lacking in communicative skills both verbal and nonverbal, and committed to repetitive ritualistic behaviors*. At the same time certain intellectual capacities—such as focused attention, retentive memory, skilled sensory and motor aptitudes, and capacity for visuospatial perception—were often retained or overly developed. In other words, the disorder pervaded only certain aspects of mental development. It is the gestalt of negative and positive aptitudes that sets this syndrome apart from other types of retardation. Kanner incorrectly ascribed the condition to psychosocial factors—such as a cold, aloof parent—and regarded it as a psychopathy. The implication that these children are literally “autistic”—i.e., that they have a rich inner psychic life or dream world out of relation to reality—is an assumption wholly without foundation. Asperger, whose observations included somewhat older children, less completely disabled, later ascribed the retardation (also incorrectly) to a special metabolic disease, possibly related to hyperammonemia. Opinion varied as to the relationship between the severe Kanner syndrome and the less severe Asperger syndrome. The authors have taken the position that these forms of autism represent a single syndrome of varying severity, with similar pathologic underpinnings possibly of multiple etiologies, including genetic. Some 1 percent are of normal or superior intelligence.

For reasons mentioned above, the term *autism*, drawn from psychiatry, is inappropriate but is firmly embedded in the medical lexicon. Despite many claims to the contrary, there is absolutely no evidence of a psychogenesis. (However, as Rapin points out, behavioral modification and special education are beneficial for the less severely affected.) At one time the disorder was referred to as childhood schizophrenia, but the afflicted individuals do not resemble schizophrenics, even when they reach adult years. The very early onset (preschool) of autism, the lack of delusional thinking, and different inheritance patterns are additional points against this being a type of childhood schizophrenia. Moreover, the manifestations of autism change to some extent in the course of development—a characteristic of what is called, for lack of a better label here and in Rett syndrome, a neurodevelopmental disorder.

The overall prevalence of the autistic state has been calculated at 4.5 to 20 per 10,000. Although there is said to be no familial tendency to autism, this is almost certainly incorrect; we have seen the disease in both of identical twins and in brothers, and small familial subgroups are known to exist. Autistic traits, without the full syndrome, are being found with increasing frequency in sibs and other family members, suggesting a polygenic inheritance. DeMyer found that 4 out of 11 monozygotic twins were concordant for autism and that siblings have a 50 times greater risk of developing the disorder than normal children. Bailey and also LeCouteur and associates have reported a concordance rate in monozygotic twins of 71 percent for the autistic spectrum disorder (see below) and 92 percent for an even broader phenotype of disordered social communication and stereotypic or obsessive behaviors. DeLong finds an increased incidence of manic-depressive disease in the

families of one group of autistic children and superior mathematical aptitudes in other family members.

Clinical Features The autistic child is ostensibly normal at birth and may continue to be normal in achieving early behavioral sequences until 18 to 24 months of age. Then an alarming regression occurs. In some instances the abnormality appears even before the first birthday and is identified as abnormal in some way by the mother; or, if there had been a previously autistic child, she recognizes the early behavioral characteristics of the disorder. The level of activity is reduced or increased. There may be less crying and an apparent indifference to surroundings. Toys are ignored or held tenaciously. Cuddling may be resisted. Motor developments, on the other hand, proceed normally and may even be precocious. Later there may be an unusual sensitivity to all modes of sensory stimulation. Occasionally the onset appears to have a relationship to an injury or an upsetting experience.

Regardless of the time and rapidity of onset, the autistic child exhibits a disregard for other persons; this is typically quite striking but can be subtle in milder cases. Little or no eye contact is made, and the child is no more interested in another person than in an article of furniture. Proffered toys are manipulated cleverly, placed in varying lines, or rejected. Insistence on constancy of environment may reach a point where the patient becomes distraught if even a single one of his possessions has been moved from its original place and remains distressed until it is replaced. If speech develops at all, it is highly automatic (echolalic) and not used effectively to communicate. A repertoire of elaborate stereotyped movements—such as whirling of the body, manipulating an object, toe-walking, and particularly hand-flapping are characteristic. Spinning toys or running water may hold a strange fascination for the child.

It is important to point out, however, that in any sizable group of autistic children *there is a wide range of deficits in sociability, drive, affect, and communicative (verbal and gestural behavior) ability*, ranging from the averbal, completely isolated state to one showing considerable language skill and some capacity for attachment to certain people and for scholastic achievement. In this higher-functioning group, taken to typify the Asperger syndrome, the child may be unusually adept or even supernormal in reading, calculating, drawing, or memorizing (“idiot savant”) while still having difficulty in adjusting socially and emotionally to others. Many are clumsy and inept in athletic activities. The IQ of the majority is below 70 and in 20 percent it is below 35; 1 percent, however, have normal or superior intelligence as already noted. The least degree of deficit allows success in a professional field but with handicap in the social sphere. We take the current emphasis on the term *autistic spectrum disorders* to reflect a concept that each of the core elements of autism (in social, language, cognitive, and behavioral domains) may occur in widely varying degrees of severity. This view permits a syndromic diagnosis of autism in patients with coexisting elements of other disorders, such as attention-deficit disorder and manic-depressive or obsessive-compulsive disorders and expands the diagnosis to many children who are highly functional except for gaze aversion and other “soft signs,” called “pervasive developmental disorder” (Filipek). The authors’ only concern is that the clinical value of the term *autism* may presume too much about the etiology.

Rapin, drawing on a large clinical experience with autism, has carefully documented its linguistic, cognitive, and behavioral features. She uses the term *semantic-pragmatic disorder* to designate

the characteristic problem with language and behavior and to distinguish it from other forms of developmental disorders and mental retardation. There is a striking ability to understand isolated facts but not to comprehend concepts or conceptual groupings; therefore these children and adults seem to have difficulty generalizing from an idea. Temple Grandin, a patient with a high-functioning Asperger type of autism (who has written of her experiences and has been described by Sacks) indicates that she thinks in pictures rather than in a semantic language. She reports a curious comfort from being tightly swaddled and has a highly developed emotional sensitivity to the experiences of cattle, which has allowed her success in reforming and designing abattoirs.

Elements of autism, but not the whole syndrome with its positive and negative attributes, may appear in other diseases that interfere with brain development, specifically fragile X and Rett syndromes, and fragmentary similarities are found in a few children with phenylketonuria, tuberous sclerosis, Angelman syndrome, and, rarely, Down syndrome—but these patients are easily distinguished from those with the far more common type of autism. Bolton and Griffiths have made the intriguing observation that autistic traits in patients with tuberous sclerosis correspond to the finding of tubers in the temporal lobe, and DeLong and Heinz point out that patients with seizures from bilateral (but not unilateral) hippocampal sclerosis may fail to develop (or may lose) language ability as well as failing to acquire social skills after a period of normal development, in a manner similar to idiopathic autism.

Etiology and Pathology of Autism The basis of childhood autism is as much a mystery today as it was when Kanner and Asperger described it. Most of these children are physically normal except for a slightly larger head size, on average, but with no other somatic anomalies. Despite instances in which the onset of mental and behavioral regression seems to be quite sudden, no environmental factors, including the often mentioned measles-mumps-rubella (MMR) vaccination, mercury exposure, and food allergies, have been credibly connected to autism.

The EEG is normal, as is CT or MRI. The significance of cerebellar vermal changes, reported originally by Courchesne et al, remains to be determined (Filipek). In the few brains examined postmortem, no lesions of any of the conventional types have been found. In five brains studied in serial sections by Bauman and Kemper, smallness of neurons and increased packing density were observed in the medial temporal areas (hippocampus, subiculum, entorhinal cortex), amygdala and septal nuclei, and mammillary bodies. In a subsequent review of the neuropathology, Kemper and Bauman concluded that three changes stood out: a curtailment of the normal development of neurons in the limbic system; a decrease in the number of Purkinje cells that appears to be congenital; and age-related changes in the size and number of the neurons in the diagonal band of Broca (located in the basal frontal and septal region) as well as in the cerebellar nuclei and inferior olive. The latter changes were inferred from studying the brains of autistic children who died at different ages, and they gave the appearance of a progressive or ongoing pathology that continues into adult life. These findings are in keeping with the concept of autism as a neurodevelopmental disorder, but they allow only speculation regarding the derivation of the clinical features of the disease. An increased concentration of platelet serotonin and low serum serotonin is detected in many but not all patients; also, serum oxytocin is reduced. The biologic significance of these findings is unclear. A gene on chromosome 7q has been found by several groups and is

believed to confer a susceptibility to autism. Several other genetic loci have been implicated, suggesting that this disease reflects an interplay between polymorphisms in multiple genes, possibly influenced by environmental factors (Muhle et al).

Course, Treatment, and Prognosis The disease is essentially nonprogressive, although some patients, as they grow older, begin to manifest additional visuoperceptive or auditory defects. In the typical or classic case, the outcome is bleak, although less affected children show improvement in social relationships and schoolwork when given a serotonin reuptake inhibitor, sometimes in very small doses (DeLong; Filipek, personal communication). Administration of the peptide secretin had produced a number of anecdotal successes, but this could not be reproduced in controlled studies (Sandler et al).

More recently, selective serotonin reuptake inhibitors (e.g., fluoxetine, citalopram) have also shown some benefit in managing repetitive behaviors and mood swings. Medications in this class are being widely prescribed to autistic children. In addition, serious behavioral changes such as self-injurious activities, aggression, and severe tantrums have been treated with drugs such as risperidone. These almost certainly represent a therapeutic advance; but, as pointed out by Hollander and colleagues in their review of the drug treatment of autism, the patients studied were selected for the severity and type of their symptoms; for this reason, these medications cannot be expected to be of help to all autistic individuals.

According to Eisenberg, who reviewed many of Kanner's original cases and followed many other cases into adult life, one-third never spoke and remained social isolates, one-third acquired a rudimentary language devoid of communicative value, and the remainder were functional to various degrees, possessing an affected, stilted, colorless speech. It is in the latter group, representing the mildest degrees of autism, that one finds the eccentrics, the mirthless, flat personalities, unable to adapt socially and habitually avoiding eye contact but sometimes possessing certain unusual aptitudes in memory, mathematics, factual knowledge, history, and science. Rutter, who has written extensively on the subject, says that the degree of language impairment and lowered intelligence predicts outcome; those who do not speak by 5 years of age never learn to speak well.

Management of Mental Retardation

Since there is little or no possibility of treating most of the diseases underlying mental retardation and there is no way of restoring function to a nervous system that is developmentally subnormal, the objective is to assist in planning for the patient's care, training, education, and social adjustment. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he or she can acquire, to the fullest extent possible, good work habits and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life: special schooling may enable them to learn skills useful in a vocation. Social factors that contribute to underachievement must be sought and eliminated if possible.

If the IQ is below 20, institutionalization is almost inevitable, for few families can provide the long-term custodial care that is needed. Well-run institutions are usually better than community homes because they offer many more facilities (medical, educa-

tional, recreational). Often institutional care is necessary for individuals with IQs of 20 to 50. Patients in this group, if stable in temperament and relatively well adjusted to society, can work under supervision, but they rarely become vocationally independent. For the more severely retarded, special training in hygiene and self-care is the most that can be expected.

Great care must be exercised in recommending institutionalization. Whereas the need will be all too apparent in the gravely retarded by the first or second year of life, the less severely affected are difficult to evaluate at an early age. As stated earlier, psycho-

logic tests alone are not altogether trustworthy. It is best to observe the patient over a period of time. As noted in Chap. 28, the method of evaluation suggested long ago by Fernald has a ring of soundness, albeit in quite dated terms. It should include observations of (1) the physical, medical, and neurologic findings; (2) family background; (3) developmental history; (4) school progress or lack thereof; (5) performance tests; (6) social behavior; (7) industrial efficiency; (8) behavioral disinhibition, which was called in Fernald's time "moral behavior"; and (9) intelligence as measured by psychological tests.

CHAPTER 39

DEGENERATIVE DISEASES OF THE NERVOUS SYSTEM

The adjective *degenerative* has no great appeal to the modern neurologist. For one thing, it has an unpleasant nonmedical connotation, referring as it does to a state of moral turpitude or deviant behavior. More important, it is not a satisfactory term medically, since it implies an inexplicable decline from a previous level of normalcy to a lower level of function—an ambiguous conceptualization of disease that satisfies neither theoretician nor scientist.

It is becoming increasingly evident that many of the diseases included in this category depend on genetic factors, or at least they appear in more than one member of the same family, in which case they are more properly designated as *heredodegenerative*. Even more diseases, not differing in any fundamental way from the heredodegenerative ones, occur sporadically, i.e., as isolated instances in given families. For diseases of this type, Gowers in 1902 suggested the term *abiotrophy*, by which he meant a lack of “vital endurance” of the affected neurons, resulting in their premature death. This concept embodies an untested, unproven hypothesis—that aging and degenerative changes of cells are based on the same process. Understandably, contemporary neuropathologists are reluctant to attribute to simple aging the diverse processes of cellular diseases that are constantly being revealed by ultrastructural and molecular genetic techniques.

The reader may be perplexed by the inconsistent use of the terms *atrophy* and *degeneration*, both of which are applied to diseases of this category. Spatz argued that on purely histopathologic grounds they are different. *Atrophy* specifies a gradual wasting and loss of a system of neurons, leaving in their wake no degradative products and only a sparsely cellular, fibrous gliosis. *Degeneration* refers to a more rapid process of neuronal, myelin, or tissue breakdown, the degradative products of which evoke a more vigorous reaction of phagocytosis and cellular astrogliosis. The difference lies in both the speed and the type of breakdown. It is of some interest that many of the diseases characterized by degeneration, in Spatz’s sense of the term, are now known to be of metabolic origin, while very few of the purely atrophic ones have been shown to have a metabolic basis.

There are also, within recent memory, several examples of diseases that were formerly classed as degenerative but are now known to have a metabolic, toxic, or nutritional basis or to be caused by a “slow virus” or a nonviral transmissible agent. It seems reasonable to expect that with increasing knowledge, more and more diseases whose causes are now unknown will find their way into these categories.

As was pointed out in Chap. 29, on aging, more than half of the normal life cycle of the organism involves a slow deterioration of organ function. Such changes in the nervous system are manifest in every sensory and motor system and in all cerebral functions. The basis of these aging changes is theoretically at the neuronal level, but it is not fully understood. A fundamental problem is the distinction of these aging deteriorations from degenerative disease. When the latter appears in adult life, one must assume that the clinical presentation is modified to some extent by life-cycle phenomena—the patient’s function being a gestalt of both processes.

Their separation is of fundamental importance in diagnosis and therapeutics.

In recent times much new and essential information has been gained regarding the biologic derangements that lead to neuronal death and dysfunction by investigating the inherited forms of degenerative diseases. The application of the techniques of molecular genetics to the field of neurodegenerative disease have given stunning results. Even when the hereditary forms of a degenerative condition are rare in comparison to sporadic types and do not entirely conform on clinical grounds to idiopathic disease, general principles of cellular biology have exposed mechanisms common to both familial and sporadic forms of the same disorder. This approach holds great promise for effective treatment of what heretofore have been considered progressive and incurable diseases. For these reasons, and because the well educated neurologist should have some understanding of this evolving field, there is in this chapter more emphasis on mutations that cause degenerative neurologic conditions than had been given in previous editions of the book.

In view of this emphasis, it has been proposed that all degenerative diseases be classified according to their genetic and molecular abnormalities. However, when one notes the diversity of pathologic change that may accompany a single, seemingly unitary gene abnormality or, reciprocally, the diversity of genetic defects that may underlie a single phenotype, this type of classification, while informative, does not prove immediately helpful to the clinician. In other words, the practice of creating new disease categories to encompass all of the molecular and pathologic changes associated with a particular type of neuronal degeneration offers no great advantage in practice. After all, the patient does not complain of a particular cellular pathology. We believe the only valid approach for the clinician is through an awareness of constellations of clinical features. Restated, until such time as the causation of the degenerative neurologic diseases is known, there must be a name and a place for a group of diseases that have no known cause and are united only by the common attribute of gradually progressive disintegration of part or parts of the nervous system. In deference to traditional practice, these diseases are collected here under the rubric *degenerative diseases*. Nonetheless, as already mentioned, the knowledgeable clinician should be aware of those diseases that are attributable entirely to a gene mutation as well as the ongoing endeavors to understand the cellular mechanisms being exposed as a result of the study of genetic forms of neurologic disease.

General Clinical Characteristics of Degenerative Diseases

The diseases included in the degenerative category have two outstanding characteristics: (1) *they tend to affect specific parts or functional systems of the nervous system and (2) they begin insidiously, after a long period of normal nervous system function, and pursue a gradually progressive course that continues for many*

years, often a decade or longer. In respect to their temporal evolution, these diseases differ from most of the metabolic and slow viral disorders. Frequently it is impossible to assign a date of onset. Sometimes, the patient or the patient's family gives a history of abrupt appearance of disability, particularly if some injury, infection, surgical procedure, or other memorable event coincided with the initial symptoms. Often a skillfully taken history will reveal that the patient or family had been aware of a pre-existent condition, the subtle symptoms of which had been present for some time but had attracted little attention. Whether trauma or other stress can actually evoke or aggravate a degenerative disease is a question that cannot be answered with absolute certainty. Anyone who states otherwise must offer evidence that at present is purely anecdotal. Instead, these degenerative disease processes by their very nature appear to develop de novo, without relation to known antecedent events, and their symptomatic expressions are late events in the pathologic process, occurring only when the degree of neuronal loss reaches or exceeds the "safety factor" for the functioning of a particular neuronal system. Irreversibility of clinical manifestations is another feature common to all the neurodegenerative conditions.

The *familial occurrence* of disease is of great importance both clinically and for scientific reasons, as just mentioned, but it must be emphasized again that such information is often difficult to obtain on first contact with the patient. The family may be small or widely scattered, so that the patient is unaware of the health of other members. The patient or the patient's relatives may be ashamed to admit that a neurologic disease has "tainted" the family. Furthermore, it may not be realized that an illness is hereditary if other members of the family have a much more or much less severe form of the disorder than the patient. Sometimes, in the latter case, only the careful examination of other family members will disclose the presence of a hereditary disease. Also, it should be remembered that familial occurrence of a disease does not necessarily mean that it is inherited but may indicate instead that more than one member of a family had been exposed to the same infectious or toxic agent.

As a rule, the degenerative diseases of the nervous system run a *ceaselessly progressive course* and with few exceptions are uninfluenced by any medical or surgical measures, so that dealing with a patient with this type of illness may be an anguishing experience for all concerned. However, some of these diseases are characterized by periods of relative stability; moreover, many symptoms (e.g., those of Parkinson disease) can be alleviated by skillful management, and the physician's interest and advice may be of great help.

General Pathologic and Pathogenic Features

Most of the degenerative diseases are characterized by the *selective involvement of anatomically and physiologically related systems of neurons*. This feature is exemplified by amyotrophic lateral sclerosis (ALS), in which the pathologic process is limited to motor neurons of the cerebral cortex, brainstem, and spinal cord, and by the progressive ataxias, in which only the Purkinje cells of the cerebellum are affected. Many other examples could be cited (e.g., Friedreich ataxia, Parkinson disease) in which several discrete neuronal systems disintegrate, leaving others unscathed. These degenerative diseases have therefore been called *system atrophies* or *systemic neuronal atrophies*. The selective vulnerability of certain

systems of neurons is not an exclusive property of the degenerative diseases; several different disease processes of known cause have similarly circumscribed effects on the nervous system. Diphtheria toxin, for instance, selectively affects the myelin of the peripheral nerves near the spinal ganglia, and triorthocresyl phosphate affects both the corticospinal tracts of the spinal cord and the spinal motor neurons. Other examples are the special vulnerability of the Purkinje cells to hyperthermia, the cerebellar granule cells to methyl mercury compounds, the basal ganglionic neurons to manganese, and the hippocampal neurons to anoxia. On the other hand, in Alzheimer disease and some other degenerative diseases, the pathologic changes are somewhat less selective and eventually more diffuse, but still restricted largely to neurons in the cerebral cortex. Even then, there is an early proclivity to involve certain neurons, namely those of the hippocampus and related structures.

As one would expect of any pathologic process that is based on the slow wasting and loss of neurons, not only the cell bodies but also their dendrites, axons, and myelin sheaths disappear—unaccompanied by an intense tissue reaction or cellular response because of the slowness of the process. The cerebrospinal fluid (CSF), therefore, shows little if any change—or at most a slight increase in protein content. Moreover, since these diseases invariably result in tissue loss (rather than in new tissue formation, as occurs with neoplasms or inflammations), *radiologic examination shows either no change or a volumetric reduction (atrophy)* with a corresponding enlargement of the CSF compartments. These radiologic findings help distinguish the neuronal atrophies from other large classes of progressive disease of the nervous system—namely, tumors, infections, and other processes of inflammatory type.

The terms *atrophy* and *degeneration* describe phenomena that are manifest in systems or subsets of neurons, and they apply to the entire class of degenerative diseases of the nervous system, both sporadic and genetic types. At the cellular level, several processes characterize the death of individual cells. The term *apoptosis* has been borrowed from embryology to specify many of the diverse mechanisms that lead to neuronal degeneration. The original meaning of the term refers to the naturally occurring cell death during development and involves the expression of genes that cause a reduction in the number of neurons over a short period of time (i.e., "programmed" cell death), leaving no trace of a pathologic reaction. The process of pathologic neuronal degeneration is quite different in that it refers to a series of changes in mature neurons that occur over a protracted period of time, leading to cell death and often leaving a discrete glial scar. In many models, this process can involve activation of programmed cell death genes, although the time course and cellular morphology are not apoptotic in the original sense of the term. Probably, mechanisms other than programmed cell death will prove central to understanding the degenerative diseases, and it is becoming apparent that the clinical features of these conditions are manifest even before cellular destruction occurs. For example, interference with synaptic signaling and dysfunction of supporting glial cells are equally important features.

Finally, it will become apparent in the following discussion that a common theme in the modern study of degenerative diseases is that of aggregation of normal cellular proteins such as amyloid, synuclein, ubiquitin, and huntingtin. In some cases, the protein is overproduced as a result of the simple fact of a triplication or overactivity of its gene. In other instances, enzymatic cleavage of a normal precursor protein yields a product with physical properties

that lead to aggregation (as happens with amyloid in Alzheimer disease) or, in others, there may be failure of the normal mechanisms of protein removal, resulting in the accumulation of a normal cellular protein. The biologic and the physicochemical properties of these proteins have therefore assumed great importance. The mechanisms by which these various proteins interfere with cellular function and ultimately cause cell death is an area of modern research.

CLINICAL CLASSIFICATION

Since grouping of the degenerative diseases in terms of etiology is not currently possible (except that in some hereditary or genetic factor can be recognized), we resort, for practical purposes, to a division based on the presenting clinical syndromes and their pathologic anatomy. Although this is the most elementary mode of classification of naturally occurring phenomena, it is a necessary prelude to diagnosis and scientific study and preferable to a haphazard listing of diseases by the names of the neurologists or neuropathologists who first described them. For reasons given in the introduction to this chapter, this approach is also preferable to genetic classifications in analyzing the problem presented by an individual patient.

- I. Syndrome of progressive dementia, other neurologic signs being absent or inconspicuous
 - A. Diffuse cerebral atrophy
 - 1. Alzheimer disease
 - 2. Diffuse cerebral cortical atrophy of non-Alzheimer type
 - 3. Some cases of Lewy body dementia
 - B. Circumscribed cerebral atrophies
 - 1. Pick disease (lobar sclerosis)
 - 2. Frontotemporal dementia
- II. Syndrome of progressive dementia in combination with other neurologic abnormalities
 - A. Huntington chorea
 - B. Lewy body disease
 - C. Some cases of Parkinson disease
 - D. Corticobasal ganglionic degeneration
 - E. Cortical-striatal-spinal degeneration (Jakob) and the dementia–Parkinson–amyotrophic lateral sclerosis complex (Guamanian and others)
 - F. Cerebrocerebellar degeneration
 - G. Familial dementia with spastic paraparesis, amyotrophy, or myoclonus
 - H. Polyglucosan body disease
 - I. Frontotemporal dementia with parkinsonism or ALS
 - J. Primary progressive aphasia
- III. Syndrome of disordered posture and movement
 - A. Parkinson disease
 - B. Striatonigral degeneration with or without autonomic failure (Shy-Drager syndrome) and olivopontocerebellar atrophy (multiple system atrophy)
 - C. Progressive supranuclear palsy
 - D. Dystonia musculorum deformans (torsion spasm)
 - E. Hallervorden-Spatz disease
 - F. Huntington chorea
 - G. Other inherited choreas
 - H. Corticobasal ganglionic degeneration
 - I. Lewy body disease
- J. Dentatorubropallidoluysian degeneration (DRPLA)
- K. Restricted dystonias, including spasmodic torticollis and Meige syndrome
- L. Familial tremors, essential tremor
- M. Multiple tic disease (Gilles de la Tourette syndrome)
- N. Acanthocytic chorea
- IV. Syndrome of progressive ataxia
 - A. Spinocerebellar ataxias (early onset)
 - 1. Friedreich ataxia
 - 2. Non-Friedreich, early-onset ataxia (with retained reflexes, hypogonadism, myoclonus, and other disorders)
 - B. Cerebellar cortical ataxias
 - 1. Holmes type of familial pure cerebellar-olivary atrophy
 - 2. Late-onset cerebellar atrophy of Marie, Foix, and Alajouanine
 - C. Complicated cerebellar ataxias (later-onset ataxia with brainstem and other neurologic disorders)
 - 1. Olivopontocerebellar degenerations (OPCA)
 - a. Clinically pure (Déjerine-Thomas type)
 - b. With extrapyramidal and autonomic degeneration (multiple system atrophy)
 - c. Conjoined with spinocerebellar degeneration (Menzel type)
 - 2. Dentatorubral degeneration (Ramsay Hunt type)
 - 3. Dentatorubropallidoluysian atrophy (DRPLA)
 - 4. Machado-Joseph-Azorean disease
 - 5. Other complicated late-onset, autosomal dominant ataxias (including Harding's types 1, 2, and 3) with pigmentary retinopathy, ophthalmoplegia, slow eye movements, polyneuropathy, optic atrophy, deafness, extrapyramidal features, and dementia
 - V. Syndrome of slowly developing muscular weakness and atrophy
 - A. Motor disorders with amyotrophy: motor system disease
 - 1. Amyotrophic lateral sclerosis
 - 2. Progressive spinal muscular atrophy
 - 3. Progressive bulbar palsy
 - 4. Hereditary forms of progressive muscular atrophy and spastic paraparesis
 - 5. Motor neuron disease with frontotemporal dementia
 - B. Spastic paraparesis without amyotrophy
 - 1. Primary lateral sclerosis
 - 2. Hereditary spastic paraparesis (Strümpell-Lorrain)
 - VI. Sensory and sensorimotor disorders (neuropathies) (See Chap. 46)
 - A. Hereditary sensorimotor neuropathies—peroneal muscular atrophy (Charcot-Marie-Tooth); hypertrophic interstitial polyneuropathy (Déjerine-Sottas); and others
 - VII. Syndrome of progressive blindness or ophthalmoplegia with or without other neurologic disorders
 - A. Pigmentary degeneration of retina (retinitis pigmentosa)
 - B. Stargardt disease
 - C. Mitochondrial disorders sometimes classified as degenerative

1. Progressive external ophthalmoplegia with or without deafness or other system atrophies (Kearns-Sayre syndrome)
2. Leber hereditary optic neuropathy

VIII. Syndromes characterized by neurosensory deafness (See Chap. 15)

- A. Pure neurosensory deafness
- B. Hereditary hearing loss with retinal diseases
- C. Hereditary hearing loss with system atrophies of the nervous system

DISEASES CHARACTERIZED MAINLY BY PROGRESSIVE DEMENTIA

Alzheimer Disease

This is the most common and important degenerative disease of the brain, having to an increasing degree an immense societal impact. Some aspects of the intellectual deterioration that characterizes this disease have already been described in Chap. 21, under "The Neurology of Dementia," and the relationship of this disease to the aging process has been fully discussed in Chap. 29. There it was pointed out that some degree of shrinkage in size and weight of the brain, i.e., "atrophy," is an inevitable accompaniment of advancing age, but that these changes alone are of relatively slight clinical significance and uncertain structural basis (e.g., whether the loss of brain weight is due to a simple depletion of neurons). By contrast, severe degrees of diffuse cerebral atrophy that evolve over a few years are invariably associated with dementia, and the underlying pathologic changes in these cases most often prove to be those of Alzheimer disease. As also commented in Chap. 29, the rate of cerebral atrophy, specifically of the hippocampus and medial parts of the temporal lobes, is accelerated in the early stages of Alzheimer disease, and longitudinal studies by magnetic resonance imaging (MRI) can identify individuals who will subsequently develop the disease (Rusinick). These observations have significance in relation to future treatment of Alzheimer disease at a stage of potential reversibility.

The now outdated practice of giving Alzheimer disease and senile dementia the status of separate diseases was attributable to the relatively young age (51 years) of the patient originally studied by Alois Alzheimer in 1907. Such a division is illogical, since the two conditions, except for their age of onset, are clinically and pathologically indistinguishable. There is, in fact, a smooth, exponential, age-dependent increase in incidence after 40 years of age. Whether it is useful to classify separately the differing heredofamilial forms of Alzheimer disease is an open question, but these occur infrequently enough that they need not be differentiated from the native disease for the purposes of clinical work.

Epidemiology Although Alzheimer disease has been described at every period of adult life, the majority of patients are in their sixties or older; a relatively small number have been in their late fifties or younger. It is one of the most frequent mental illnesses, making up some 20 percent of all patients in psychiatric hospitals and a far larger proportion in nursing homes. In the United States, in 17 series comprising 15,000 persons over the age of 60 years, the mean incidence of moderate to severe dementia was calculated to be 4.8 percent (Wang). In Rochester, Minnesota, the incidence rate for dementia in general is 187 cases per 100,000 population

per year, and for Alzheimer disease, 123 cases per 100,000 annually (Schoenberg et al).

These staggering statistics may be viewed from another perspective. The incidence rate of clinically diagnosed Alzheimer disease is similar throughout the world, and it increases comparably with age, approximating 3 new cases yearly per 100,000 persons below age 60 and 125 new cases per 100,000 of those over 60. The prevalence of the disease per 100,000 population is near 300 in the group aged 60 to 69; it is 3200 in the 70-to-79 group and 10,800 in those over age 80. In the year 2000, there were an estimated 2 million persons with Alzheimer disease in the United States. Prevalence rates, which depend also on overall mortality, are three times higher in women, although it does appear that the incidence of new cases is only slightly disproportionate in women. The survival of patients with Alzheimer disease is reduced to half the expected rate, mainly because of respiratory and cardiovascular causes and inattention but also for other reasons that are not entirely clear.

Several putative epidemiologic risk factors for Alzheimer disease—such as birth order, mother's age at birth, family history of Down syndrome, or head injury—seem marginal at best and in some instances may be due to selection bias. Whether low educational attainment is a risk factor for the development of Alzheimer disease or, conversely, whether cognitively demanding occupations protect against dementia has not been settled, but some provocative data indicating that this may be so have been presented in Chap. 21 (Katzman; Cobb et al).

The *familial occurrence* of Alzheimer disease has been well established. In fewer than 1 percent of such cases there is a dominant inheritance pattern (Nee et al, Goudsmit et al; see further on, in the section on pathogenesis). Reports of substantial familial aggregations of dementia without a specific pattern of inheritance also suggest the operation of more than one genetic factor. Several studies have documented a significant increase in the risk of ostensibly sporadic Alzheimer disease among first-degree relatives of patients with this disorder. Again, this risk is disproportionately greater in females, adding to the evidence that women in general are at slightly higher risk for Alzheimer disease (Silverman et al). Li and coworkers have provided evidence that patients with an earlier age of onset of Alzheimer disease (before age 70) are more likely to have relatives with the disease than are patients with later onset. Genetic studies are difficult because the disease does not appear at the same age in a given proband. Even in identical twins, it may develop at the age of 60 years in one of the pair and at 80 years in the other. Death from other diseases may prevent its detection.

Clinical Features (See also Chap. 21) The onset of mental changes is usually so insidious that neither the family nor the patient can date the time of its beginning. Occasionally, however, it is brought to attention by an unusual degree of confusion in relation to a febrile illness, an operation, mild head injury, or the taking of medication. Other patients may present with complaints of dizziness, mental foginess, nondescript headaches, or other vaguely expressed and changeable somatic symptoms.

The gradual development of forgetfulness is the major symptom. Small day-to-day happenings are not remembered. Seldom-used names are particularly elusive. Little-used words from an earlier period of life also tend to be lost. Appointments are forgotten and possessions misplaced. Questions are repeated again and again, the patient having forgotten what was just discussed. It is said that remote memories are preserved and recent ones lost (Ribot's law of memory), but this is only relatively true; it is difficult to check

the accuracy of ancient memories. Albert and associates, who tested the patient's recognition of dated political events and pictures of prominent people past and present, found that some degree of memory loss extends to all decades of life (neuropsychologic testing is discussed further on).

Once the memory disorder has become pronounced, other failures in cerebral function become increasingly apparent. The patient's speech is halting because of failure to recall the needed word. The same difficulty interrupts writing. Vocabulary becomes restricted and expressive language stereotyped and inflexible. Comprehension of spoken words seems at first to be preserved, until it is observed that the patient does not carry out a complicated request; even then it is uncertain whether the request was not understood because of inattention or was forgotten. Almost imperceptible at first, these disturbances of language become more apparent as the disease progresses. The range of vocabulary and the accuracy of spelling are reduced. Finally, after many years of illness, there is a failure to speak in full sentences; the finding of words requires a continuous search; and little that is said or written is fully comprehended. There is a tendency to repeat a question before answering it, and later there may be a rather dramatic repetition of every spoken phrase (*echolalia*). The deterioration of verbal skills has by then progressed beyond a groping for names and common nouns to an obvious anomic aphasia. Other elements of receptive and executive aphasia are later added, but discrete aphasias of the Broca or Wernicke type are characteristically lacking. In general there is a paucity of speech and a quantitative reduction in mentation.

Skill in arithmetic suffers a similar deterioration. Faults in balancing the checkbook, mistakes in figuring the price of items and in making the correct change—all these and others progress to a point where the patient can no longer carry out the simplest calculations (*acalculia* or *dyscalculia*).

In some patients, visuospatial orientation becomes defective. The car cannot be parked; the arms do not find the correct sleeves of the jacket or shirt; the corners of the tablecloth cannot be oriented with the corners of the table; the patient turns in the wrong direction on the way home or becomes lost. The route from one place to another cannot be described, nor can given directions be understood. As this state worsens, the simplest of geometric forms and patterns cannot be copied.

Late in the course of the illness, the patient forgets how to use common objects and tools while retaining the necessary motor power and coordination for these activities. The razor is no longer correctly applied to the face; the latch of the door cannot be unfastened; and eating utensils are used awkwardly. Finally, only the most habitual and virtually automatic actions are preserved. Tests of commanded and demonstrated actions cannot be executed or imitated. *Ideational* and *ideomotor apraxia* are the terms applied to the advanced forms of this motor incapacity (pages 48 and 402).

As these many amnesic, aphasic, agnosic, and apraxic deficits declare themselves, the patient at first seems unchanged in overall motility, behavior, temperament, and conduct. Social graces, whatever they were, are retained in the initial phase of the illness, but troublesome alterations gradually appear in this sphere as well. Imprudent business deals may be made. Restlessness and agitation or their opposites—*inertia* and *placidity*—become evident. Dressing, shaving, and bathing are neglected. Anxieties and phobias, particularly fear of being left alone, may emerge. A disturbance of the normal day and night sleep patterns is prominent in some pa-

tients. A poorly organized paranoid delusional state, sometimes with hallucinations, may become manifest. The patient may suspect his elderly wife of having an illicit relationship or his children of stealing his possessions. A stable marriage may be disrupted by the patient's infatuation with a younger person or by sexual indiscretions, which may astonish the community. The patient's affect coarsens; he is more egocentric and indifferent to the feelings and reactions of others. A gluttonous appetite sometimes develops, but more often eating is neglected, with gradual weight loss. Later, grasping and sucking reflexes and other signs of frontal lobe disorder are readily elicited (Neary et al), sphincteric continence fails, and the patient sinks into a state of relative akinesia and mutism, as described in Chap. 21.

Difficulty in locomotion, a kind of unsteadiness with shortened steps but with only slight motor weakness and rigidity, frequently supervenes. Elements of parkinsonian akinesia and rigidity and a fine tremor can be perceived in patients with advanced motor disability. Ultimately the patient loses the ability to stand and walk, being forced to lie inert in bed and having to be fed and bathed, and the legs may curl into a fixed posture of paraplegia in flexion (persistent vegetative state; page 304).

The symptomatic course of this tragic illness usually extends over a period of 5 or more years, but judging from studies of Down cases, the pathologic course has a much longer asymptomatic duration. This concept is supported by the detailed studies of Linn and colleagues, who found that a lengthy "preclinical" period (7 years or more) of stepwise decline in memory and attention span preceded the clinical diagnosis. Surprisingly, throughout this period, corticospinal and corticosensory functions, visual acuity, ocular movements, and visual fields remain relatively intact. If there is hemiplegia, homonymous hemianopia, etc., either the diagnosis of Alzheimer disease is incorrect or the disease has been complicated by a stroke, tumor, or subdural hematoma. Exceptions to this statement are rare. The tendon reflexes are little altered and the plantar reflexes almost always remain flexor. There is no true sensory or cerebellar ataxia. Convulsions are rare until late in the illness, when up to 5 percent of patients reportedly have infrequent seizures. Occasionally, widespread myoclonic jerks or mild choreoathetotic movements are observed late in the illness. Grand mal seizures occur in a small number of patients during the end stages of the disease. Eventually, with the patient in a bedfast state, an intercurrent infection such as aspiration pneumonia or some other disease mercifully terminates life.

The sequence of neurologic disabilities may not follow this described order, and one or another deficit may take precedence, presumably because the disease process, after becoming manifest in the memory cortex of the temporal lobes, may affect one particular part of the associative cortex earlier or more severely in one patient than in another. This allows a relatively restricted deficit to become the source of early medical complaint long before the full syndrome of dementia has declared itself. We have observed four limited deficits of this type, as follows:

1. *Korsakoff amnesia state*. The early stages of Alzheimer disease are usually dominated by a disproportionate failure of retentive memory, with integrity of other cognitive abilities. This may be the sole difficulty for years. In such patients, immediate memory (essentially a measure of attention), tested by the capacity to repeat a series of numbers or words, is essentially intact; it is the short- and long-term (retentive) memory that fails. Retentive memory may become impaired

- to the point where the patient can recall nothing of what she had learned a minute or two previously. Yet as a business executive, for example, he may continue to make acceptable decisions if the work utilizes long-established habit patterns and practices. In such cases, the temporal horns tend to be enlarged more than the rest of the ventricular system, reflecting the disproportionate atrophy of the inferomedial temporal lobes.
2. *Dysnomia.* The forgetting of words, especially proper names, may first bring the patient to a neurologist. Later the difficulty involves common nouns and progresses to the point where fluency of speech is seriously impaired. Every sentence is broken by a pause and search for the wanted word; if this is not found, a circumlocution is substituted or the sentence is left unfinished. When the patient is given a choice of words, including the one that was missed, there may be a failure of recognition. Repetition of the spoken words of others, at first flawless, later brings out a lesser degree of the same difficulty. A useful test for the failure to find names (*dysnomia*), which is probably the most common abnormality of language in this disease, is the category-fluency test. The naming defect is evident with even simple tests, e.g., asking the patient to generate a list of farm animals or car brands—a test that may elicit only three or four responses. A more extensive examination entails asking the patient to name as many items as possible in each of three categories in 1 min—vegetables, tools, and clothing. Alzheimer patients fall below a score of 50 items. Other components of language may be relatively intact, but before long it is evident that the patient does not understand all that he hears or reads. In contrast, nonverbal memory and the ability to calculate and make simple judgments may still be preserved. Duplicating our own experience, Mesulam and Chawluk and their colleagues have described patients in whom an aphasic disorder began with anomia and eventually affected reading, writing, and comprehension without the additional intellectual and behavioral disturbances of dementia. In our own observation, such patients, if followed for a sufficiently long period, develop a more general dementia, sometimes as long as 5 years or more after the onset of aphasia. This syndrome of “primary progressive aphasia” also represents a focal degenerative disorder (lobar atrophy of Pick or frontotemporal dementia), distinct from Alzheimer disease (Lippa et al, Kirshner et al). Usually the electroencephalogram (EEG) is normal or shows only a mild degree of left frontotemporal slowing, but MRI may disclose a focal atrophy of the language areas (Caselli et al).
 3. *Visuospatial disorientation.* Parieto-occipital functions are sometimes deranged in the course of Alzheimer disease and may fail while other functions are relatively preserved. This has been termed “posterior cortical dementia” (see Renner et al). As remarked above and in Chap. 22, prosopagnosia (impaired facial recognition), losing one’s way in familiar surroundings or inability to interpret a road map, to distinguish right from left, or to park or garage a car, and difficulty in setting the table or dressing are all manifestations of a special failure to orient the schema of one’s body with that of surrounding space. Exceptionally there is a neglect of stimuli in one visual field. Some of these patients develop the Balint syndrome or Gerstmann syndrome (Tang-Wai et al).
 4. *Paranoia and other personality changes.* Frequently, at some

point in the development of senile dementia, the most prominent event is the occurrence of paranoia or bizarre behavior. This may appear before the more obvious memory or language defects announce themselves. The patient becomes convinced that relatives are stealing his possessions or that an elderly and even infirm spouse is guilty of infidelity. He may hide his belongings, even relatively worthless ones, and go about spying on family members. Hostilities arise, and wills may be altered irrationally. Many of these patients are constantly worried, tense, and agitated. Of course, paranoid delusions may be part of a depressive psychosis and of other dementias, but most of the senile patients in whom paranoia is the presenting problem seem not to be depressed, and their cognitive functions are for a time relatively well preserved. It is tempting to think that a very early degenerative change of the limbic cortices has exposed a lifelong trait of suspiciousness, but this is purely hypothetical. Sometimes other oddities of behavior will announce the oncoming dementia. Social indiscretions, rejection of an old friend, embarking on an imprudent financial venture, or an amorous pursuit that is out of character are examples of these types of behavioral change.

Some clinicians attempt to subdivide the Alzheimer dementia syndrome into subtypes. Amnesic defect without lexical-semantic abnormalities represents more than 50 percent of cases. Chin and coworkers observed more prevalent and severe language disorder and more rapid progression in early-onset familial cases. Others point to a disproportionately severe defect in praxic functions and a greater tendency to abnormal EEG findings in such cases. Whether such distinctions represent fundamental differences in the disease process is questionable.

It has been our impression that each of the restricted clinical disorders described above is only *relatively pure*. Careful testing of mental function—and this is of diagnostic importance—frequently discloses subtle abnormalities in several cognitive spheres. Initially, most patients have a disproportionate disorder of the temporoparietal cortices, reflected by an earlier impairment on the performance parts of the Wechsler Adult Intelligence Scale. Within several months to a year or two, the more generalized aspects of mental deterioration become apparent, and the aphasic-agnosic-apraxic aspects of the syndrome become increasingly prominent. If one of the foregoing restricted deficits remains uncomplicated over a period of years, one is justified in suspecting some cause other than Alzheimer disease, such as Binswanger disease, hydrocephalus, frontotemporal dementia (see further on), or embolic infarction of one part of the temporal or parietal lobe. Also, as stated earlier, a hemianopic visual field defect, cortical sensory loss, or hemiparesis is seldom if ever due to Alzheimer disease. However, more complex disturbances of visual perception—taking the form of impaired recognition of objects (*object agnosia*) or faces (*prosopagnosia*), visual scanning, color identification, stereoaquity, separation of figures from background, and hand-eye coordination—are frequent in the more advanced stages (Mendez et al). Rarely there is a partial or even a complete Balint syndrome.

While it is true that most patients with Alzheimer disease walk normally until relatively late in their illness, infrequently a short-stepped gait and imbalance draw attention to the disease and worsen slowly for several years before cognitive manifestations become evident. The general decrepitude in appearance that accom-

panies the middle and late stages of the disease in many patients was commented on in Chap. 21.

For research purposes and to establish certain inclusive and exclusive criteria for the diagnosis of Alzheimer disease, a work group of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Diseases Association (ADRDA) have proposed the following diagnostic criteria: (1) dementia defined by clinical examination, the Mini-Mental Scale (page 382), the Blessed Dementia Scale, or similar mental status examination; (2) age of patient (over 40 years); (3) deficits in two or more areas of cognition and progressive worsening of memory and other cognitive functions—such as language, perception, and motor skills (praxis); (4) absence of disturbed consciousness; and (5) exclusion of other brain diseases (McKhann et al; Tierney et al). Using these criteria, the correct diagnosis is achieved in more than 85 percent of patients. Most cases are identifiable without resorting to restrictive criteria such as these, especially if the patient is observed serially over a period of months or years.

Pathology In the advanced stages of the disease, the brain presents a diffusely atrophied appearance and its weight is usually reduced by 20 percent or more. Cerebral convolutions are narrowed and sulci are widened. The third and lateral ventricles are symmetrically enlarged to a varying degree. Usually the atrophic process involves the frontal, temporal, and parietal lobes, but cases vary considerably. The extreme atrophy of the hippocampus—the most prominent finding, visible on MRI (mainly coronal images)—is diagnostic in the proper clinical circumstances. Microscopically, there is widespread loss of nerve cells. Early in the disease this is most pronounced in layer II of the entorhinal cortex. In addition to pronounced neuronal loss in the hippocampus, adjacent parts of the medial temporal cortex—namely, the parahippocampal gyri and subiculum—are affected. The anterior nuclei of the thalamus, septal nuclei, and diagonal band of Broca, amygdala, and particular brainstem parts of the monoaminergic systems are also depleted. The cholinergic neurons of the nucleus basalis of Meynert (the substantia innominata) and locus ceruleus are also reduced in number, a finding that at one time aroused great interest because of its putative role in memory loss (see below). In the cerebral cortex, the cell loss predominantly affects the large pyramidal neurons. Residual neurons are observed to have lost volume and ribonucleoprotein; their dendrites are diminished and crowd upon one another owing to the loss of synapses and neuropil. Astrocytic proliferation follows as a compensatory or reparative process, most prominent in layers III and V.

In addition, three microscopic changes give this disease its distinctive character (Fig. 39-1): (1) The presence within the nerve cell cytoplasm of thick, fiber-like strands of silver-staining material, often in the form of loops, coils, or tangled masses (Alzheimer neurofibrillary changes or “tangles”). These strands are composed of a hyperphosphorylated form of the microtubular protein “tau” and appear as pairs of helical filaments when studied ultrastructurally. (2) Spherical deposits of amorphous material scattered throughout the cerebral cortex and most easily seen with periodic acid-Schiff (PAS) and silver-staining methods; the core of the aggregates is the protein amyloid, surrounded by degenerating nerve terminals (*senile* or *neuritic plaques*). Amyloid is also scattered throughout the cerebral cortex in a nascent “diffuse” form, without organization or core formation and appreciated mainly by immunohistochemical methods, as well as in the walls of small blood

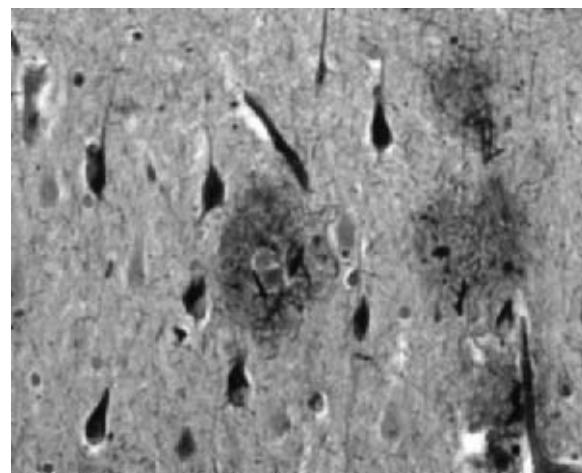

Figure 39-1. Photomicrograph (B&W) of Alzheimer amyloid plaque and neurofibrillary tangle.

vessels near the plaques—so-called congophilic angiopathy. (3) *Granulovacuolar degeneration* of neurons, most evident in the pyramidal layer of the hippocampus.

Neuritic plaques and neurofibrillary changes are found in all the association areas of the cerebral cortex, but it is the neurofibrillary tangles and neuronal alterations and loss, not the plaques, that correlate best with the severity of the dementia (Arriagada et al). If any part of the brain is disproportionately affected, it is the hippocampus, particularly the CA1 and CA2 zones (of Lorente de Nó) and the entorhinal cortex, subiculum, and amygdala. These parts have abundant connections with other parts of the temporal lobe cortex and dentate gyrus of the hippocampus and undoubtedly account for the amnesic component of the dementia. The parietal lobes are another favored site. Only a few tangles and plaques are found in the hypothalamus, thalamus, periaqueductal region, pontine tegmentum, and granule-cell layer of the cerebellum.

Experienced neuropathologists recognize a form of Alzheimer disease, particularly in older patients (75 years), in which there are senile plaques but few or no neuronal tangles (over 20 percent of 150 cases reported by Joachim et al). Another problem for the neuropathologist is to distinguish between the normal aged brain and that of Alzheimer disease. It is not unusual to find a scattering of senile plaques in individuals who were thought to be mentally normal during life. Henderson and Hubbard studied 27 demented individuals aged 64 to 92 years and 20 age-matched, nondemented controls. In the former, 3 to 38 percent of the hippocampal neurons contained neurofibrillary tangles; in all but 2 of the controls, the number of hippocampal neurons with tangles fell below 2.5 percent. Hence, the difference between plaques and tangles in the aging brain and in Alzheimer disease is largely quantitative.

Also of interest is the observation of Joachim and associates that 18 percent of Alzheimer cases had sufficient neuronal loss and Lewy bodies in the substantia nigra to justify a diagnosis on histopathologic grounds of Parkinson disease. Leverenz and Sumi found that 25 percent of their Alzheimer patients showed the pathologic (and clinical) changes of Parkinson disease—a much higher incidence than can be attributed to chance. Similarly, of 11 patients with progressive supranuclear palsy (discussed further on) reported by Gearing and coworkers, 10 were demented and 5 had the neuropathologic features of Alzheimer disease. These mixed cases, including those patients with Pick disease, present problems

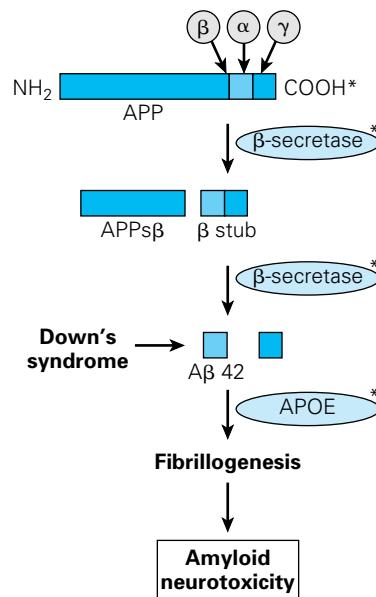

not only of classification but also in understanding the neurobiology of these degenerative diseases. This subject is discussed further on in the section on Parkinson disease.

It is of historical interest that Alzheimer was not the first to describe plaques, one of the hallmarks of this pathologic state. These miliary lesions ("Herdchen") had been observed in senile brains by Blocq and Marinesco in 1892 and were named *senile plaques* by Simchowicz in 1910. In 1907, Alzheimer described the case of a 51-year-old woman who died after a 5-year illness characterized by progressive dementia. Throughout the cerebral cortex he found the characteristic plaques, but he also noted—thanks to the use of Bielschowsky's newly devised silver impregnation method—a clumping and distortion of fibrils in the neuronal cytoplasm, the neurofibrillary change that now, appropriately, carries Alzheimer's name.

Pathogenesis Careful analyses of the "senile" plaques and neuronal fibrillary changes have been made in the last few decades in an attempt to elucidate the mechanism of Alzheimer disease. Several histologic techniques assist in this endeavor, including refined methods for silver impregnation that stain both amyloid and its main constituent (amyloid β protein, or A β); immunostaining using antibodies specific to such proteins as ubiquitin, neuronal tau protein, and amyloid β protein; and visualization of beta-pleated protein sheets using thioflavine S and Congo red with ultraviolet and polarized light. Tau is a discrete cytoskeletal protein that promotes the assembly of microtubules, stabilizes their structure, and participates in synaptic plasticity in a yet to be defined manner. In the pathologic circumstances of Alzheimer disease, progressive supranuclear palsy, and frontotemporal dementia (see further on), tau is hyperphosphorylated and aggregates, resulting in an overloading of the perikarya and neurites with paired helical filaments comprising neurofibrillary tangles. Electrophoretically, tau moves with the β_2 -globulins and is thought to function as a transferrin, i.e., it binds iron and delivers it to the cell. Its concentration can be measured in the CSF and serum, but this has not yet proven to be useful as a diagnostic test.

The A β protein is a small portion of a larger entity, the *amyloid-protein precursor* (APP), which is normally bound to neuronal membranes. As shown in Fig. 39-2, the A β protein is cleaved from APP by the action of proteases termed α , β , and γ secretase. One current hypothesis, developed by Selkoe and others, focuses on the manner in which APP is cleaved by these enzymes to give rise to different-length residues of A β . During normal cellular metabolism, APP is cleaved by either α or β secretase. The products are then cleaved by the γ isoform. The sequential cleavage by α and then γ produces tiny fragments that are not toxic to neurons. However, sequential cleavage by β and then γ results in a 40-amino acid product, A β_{40} , and a longer 42-amino acid form. The latter A β_{42} form is toxic in several models of Alzheimer disease, and it is proposed that the ratio of A β_{42} to A β_{40} is critical to the neuronal toxicity of amyloid.

Several pieces of evidence favor the view that elevation of the levels of A β_{42} leads to aggregation of amyloid and then to neuronal toxicity. It appears that the diffuse deposition of A β_{42} precedes the formation of better-defined neurofibrils and plaques. The fact that the gene coding for APP is located on chromosome 21, one of the regions linked to one type of familial Alzheimer disease, and that this chromosome is duplicated in the Down syndrome, in which Alzheimer changes almost inevitably occur with aging (see further on), suggests that the overproduction of amyloid and all its A β

*Mutations in APP, β or γ -secretase and the APOE-4 allele enhance toxicity.

Figure 39-2. Diagram of proteolysis of amyloid precursor protein (APP). When APP is cleaved sequentially by β secretase and then γ secretase, the resulting amyloid protein can be 40 (A β_{40}) or 42 (A β_{42}) amino acids in length. The latter favors the formation of aggregated fibrillary amyloid protein (fibrillogenesis) rather than normal APP degradation. The fibrillary form of amyloid is neurotoxic, a mechanism favored as the cause of cell damage in Alzheimer disease. Formation of A β_{42} is promoted by mutations, either in the APP gene itself or in the presenilins. In Down syndrome, excess production of APP and its product A β_{42} is caused by triplication of the long arm of chromosome 21, the location of the APP gene. The ApoE4 allele is associated with inadequate clearance of A β_{42} and is another mechanism that promotes fibrillogenesis. (Modified by permission from Sisodia SS, St. George-Hyslop PH: γ -Secretase, notch, A β and Alzheimer's disease: Where do the presenilins fit in? *Nat Rev Neurosci* 3:281–290, 2002.)

residues are causative factors in the disease. Furthermore, the ratio of A β_{42} to A β_{40} is increased in Down syndrome. Another suggestive connection has been the finding that there are genetic defects in the genes encoding APP and in a pair of endosomal proteins termed *presenilin 1* and *2* in some familial forms of Alzheimer disease. The presenilins interact with or may be a component of γ secretase, the enzyme that produces the A β_{42} fragment. Mutations of presenilin 1 and 2 also increase the relative levels of A β_{42} . It should be noted that mutations of the APP and presenilin genes explain fewer than 0.1 percent of Alzheimer cases (Terry). Transgenic mice that express human Alzheimer disease-associated mutations in APP or presenilin genes develop plaques with A β_{42} but not neurofibrillary tangles. There is also a provocative relationship between certain circulating proteins, particularly β -amyloid and selected isoforms of the ApoE lipoproteins, as discussed further on. The current notions of amyloid metabolism and the role of A β_{42} are summarized in Fig. 39-2. Many of the relationships and mechanisms depicted in the figure are derived from the understanding of genetic forms of Alzheimer disease; the extent to which they will be implicated in the idiopathic disease is not known. However, some form of disruption in these mechanisms are likely to be involved in the sporadic disease.

It must be emphasized, however, that there is some uncertainty regarding the relationship of amyloid deposition to the loss of neurons and brain atrophy. In their review, Hardy and Selkoe, authoritative investigators in this field, have pointed out that "Although the amyloid hypothesis offers a broad framework to explain AD pathogenesis, it is currently lacking in detail, and certain observations do not fit easily with the simplest version of the hypothesis." They also emphasize that soluble oligomers of $A\beta$ amyloid may be the toxic agents, whereas the emphasis until now has been on the effects of visible assemblies of insoluble amyloid fibrils. Others too have questioned the amyloid hypothesis and pointed to an imprecise relationship between amyloid deposition and neuronal loss, even suggesting that amyloid is in some way a protective mechanism of cells.

The finding of a reduced number and enlargement of synapses in affected cortex early in the disease by DeKosky and Scheff and others could be interpreted as either the first sign of neuronal death or the result of the neuronal loss. Amyloid deposition would then be a later, secondary phenomenon. The importance of neurofibrillary tangles has also been questioned, and the manner in which amyloid deposition relates to tangle formation is unclear. Unexplained also is prominent senile plaque formation in some cases and neurofibrillary tangles in others. One prevalent view is that the tangles are a secondary phenomenon. Nonetheless, the amyloid hypothesis is currently the strongest. In recent years, some of the subcellular mechanisms that are deranged by the presence of intracellular or extracellular amyloid have been elucidated. These are too complex and uncertain to list here, but they are among the most promising findings in this field of research.

It has been our view that vascular changes do not have an important role in the pathogenesis of Alzheimer disease, but several groups hold a different opinion. It was long ago established that Alzheimer disease is not caused by any of the usual types of arteriosclerosis. There are, however, small-vessel changes, accounting for the reduced cerebral blood flow reported in many cases of the disease. This small-vessel change is probably secondary to the cerebral atrophy, since a reduction in cerebral blood flow is found in mentally intact old individuals. Probably the deposition of amyloid in cerebral vessels is a secondary phenomenon as well. On the other hand, several studies have indicated that the presence of cerebral infarctions, small or large, may accelerate the deposition of amyloid and the development of neurofibrillary tangles in the brains of Alzheimer patients (see further on, under "Vascular Dementia"). Not surprisingly, cerebrovascular disease also exaggerates the rate of progression and degree of dementia. How this relates to the ill-defined entity called "arteriosclerotic," "multi-infarct," or "vascular" dementia has not been clear to the authors (see pages 373 and 707). A similar relationship between Alzheimer disease and previous head injuries is even more tentative but has led to speculation that several types of brain injury are conducive to the development of Alzheimer change and amyloid deposition, as if they were part of a reparative response.

No relationship to premorbid personality traits earlier in life has been established, but an intriguing finding from what has become known as the "nun study" suggests that poor linguistic ability early in life may correspond to the later development of Alzheimer disease (D. A. Snowden et al). In this study, the autobiographies of 93 nuns, written in their twenties, were rated for linguistic and ideational complexity. Of 14 sisters who died in late life, deterioration of cognitive function and neuropathologically proven Alzheimer disease occurred in 7 who had a low "idea density" in their

writings and in none of 7 whose writings were cognitively more complex. Obviously this type of correlation requires further study and is subject to several interpretations. Also, there has been a general notion, confirmed by a few studies such as the one by Vergheze et al, that an active mental life may reduce the severity of mental decline with aging; but a direct conclusion about Alzheimer disease cannot be made from the available information.

Neurotransmitter Abnormalities Considerable interest was created in the late 1970s by the finding of a marked reduction in choline acetyltransferase (ChAT) and acetylcholine in the hippocampus and neocortex of patients with Alzheimer disease. This loss of cholinergic synthetic capacity was attributed to the loss of cells in the basal forebrain nuclei (mainly the nucleus basalis of Meynert), from which the major portion of neocortical cholinergic terminals originate (Whitehouse et al). As is often true in medical science, the early enthusiasm for the cholinergic hypothesis has obtained less support from subsequent research. A 50 percent reduction in ChAT activity has been found in regions such as the caudate nucleus, which show neither plaques nor tangles (see review of Selkoe). The specificity of the nucleus basalis-cholinergic cortical changes was questioned for other reasons as well. The Alzheimer brain also shows a loss of monoaminergic neurons and a diminution of noradrenergic, GABA-ergic, and serotonergic functions in the affected neocortex. The concentration of amino acid transmitters, particularly of glutamate, is also reduced in cortical and subcortical areas (Sasaki et al). The Alzheimer cortex shows a decreased concentration of several neuropeptide transmitters—notably substance P, somatostatin, and cholecystokinin—but it has not been determined whether any of these biochemical abnormalities, including the cholinergic ones, are primary or are secondary to heterogeneous neuronal loss. Finally, the administration of cholinomimetics—whether they be acetylcholine precursors (e.g., choline or lecithin), degradation inhibitors (e.g., physostigmine), or muscarinic agonists that act directly on postsynaptic receptors—have had only a mild and unsustained therapeutic effect (see further on under "Treatment").

Chase and associates have demonstrated a 30 percent reduction in cerebral glucose metabolism in Alzheimer disease, greatest in the parietal lobes, but again the meaning of this, whether it is due to loss or to hypofunction of neurons, remains to be determined. It seems most likely to be secondary to tissue loss in these regions. The significance of aluminum in the genesis of neurofibrillary tangles, as was once proposed, has never been validated. Recently it has been suggested that the use of estrogen by postmenopausal women delays the onset of the disease and might reduce its frequency, but this has not been corroborated by subsequent studies.

Genetic Aspects of Alzheimer Disease (Table 39-1) Of great interest and potential importance was the aforementioned discovery, in patients with an inherited form of Alzheimer disease, of a defective gene that codes for an errant amyloid precursor protein (APP) and is localized to a region of chromosome 21, near the β -amyloid gene (St. George-Hyslop et al). This also provides an explanation for the Alzheimer changes that characterize the brains of practically all patients with the trisomy 21 defect (Down syndrome) who survive beyond their 20th year; they overproduce amyloid as a result of the triplication of the gene. But gene defects on chromosome 21, as already noted, are responsible for only a small proportion of familial cases and a minuscule percentage of disease overall. Other kindreds with familial Alzheimer disease have been linked to rare mutations of the presenilin genes on chromosome 14

Table 39-1

Genetic defects associated with Alzheimer disease

NOTATION	CHROMOSOME	GENE	GENETICS	AGE	CLINICAL FEATURES
APP	21	Amyloid precursor protein	AD	Early	Rare but clinically simulates sporadic Alzheimer disease
PS1	14	Presenilin 1	AD	Early	As above
PS2	1	Presenilin 2	AD	Early	As above
ApoE	19	Apolipoprotein E		Late	These variants modify susceptibility to typical Alzheimer disease
Trisomy 21	21	Amyloid precursor protein		Middle age	Alzheimer change is almost universal in Down syndrome

AD = autosomal dominant.

(presenilin 1, Sherrington et al), accounting in some series for up to 50 percent of familial cases, and on chromosome 1 (presenilin 2), which may account for many of the remaining ones (Levy-Lahad et al). These are summarized in Table 39-1. The age of onset of the disease in these familial forms, as in the Down cases, is earlier than that in sporadic forms. Notable is the common occurrence of asynchronous myoclonus, epilepsy, aphasia, and paratonia in the familial cases.

It has been clear for some time that an excess amyloid alone is an incomplete explanation for the disease. Apolipoprotein E (ApoE), a regulator of lipid metabolism that has an affinity for the β -amyloid protein in Alzheimer plaques, has been found to be another genetic marker that greatly modifies the risk of acquiring Alzheimer disease. Of the several isoforms of ApoE, the presence of E4 (and its corresponding gene allele e4 on chromosome 19) is associated with a tripling of the risk of developing sporadic Alzheimer disease (Roses, Strittmatter et al, and Polvikoski et al). This is the same allele that contributes to an elevated low-density lipoprotein fraction in the serum. Possession of two e4 alleles virtually assures the development of disease in those who survive to their eighties. The e4 allele also modifies the age of onset of some of the familial forms of the disease. In contrast, the e2 allele is underrepresented among Alzheimer patients. For these reasons it has been proposed that ApoE, by interacting with APP or tau protein in some way, modifies the formation of plaques. Indeed, possession of the e4 allele correlates with increased deposition of $A\beta$ in the brain (McNamara). Furthermore, as pointed out by Hardy, ApoE appears to act after the various genetic mutations have influenced the cell dysfunction that causes Alzheimer disease. These findings have led to interest in using the e4 genotype as a marker for the risk of Alzheimer disease, but it must be pointed out that these are statistical relationships that do not invariably connect the allele to the disease in a particular individual. In other words, the e4 allele does not act as a mendelian trait but as a susceptibility (risk) factor. It follows that many individuals without the allele also develop Alzheimer disease. Moreover, many individuals with the e4 allele live into their seventies and eighties without developing Alzheimer disease. Therefore the results of such testing must be interpreted with caution. All that can be stated with certainty is that, on average, the presence of the e4 allele accelerates the appearance of Alzheimer disease by about 5 years.

Studies of the molecular genetics of Alzheimer disease are yielding new information at such an astonishing rate that much of the foregoing text will soon be outdated. Useful basic reviews of this subject are those of Martin and of Selkoe, listed in the References.

Diagnostic Studies The most useful, but not definitive, ancillary tests in use are CT scanning and MRI (Fig. 39-3). In patients with advanced Alzheimer disease, the lateral and third ventricles are enlarged to about twice normal size and the cerebral sulci are widened. As stated previously, fine-section coronal MRI of the medial temporal lobes reveals a disproportionate atrophy of the hippocampi and a corresponding enlargement of the temporal horns of the lateral ventricles. Early in the disease, however, the changes do not exceed those found in many mentally intact old persons. For this reason, one cannot rely on imaging procedures alone for diagnosis. CT and MRI scans are most valuable in excluding brain tumor, subdural hematoma, cerebral infarction, and hydrocephalus. The EEG undergoes a diffuse slowing, but only late in the course of the illness. The CSF is also normal, though occasionally the total protein is slightly elevated. Using the constellation of clinical data, CT scanning, and MRI—along with the age of the patient and time course of the disease—the diagnosis of senile dementia of Alzheimer type is being made correctly in 85 to 90 percent of cases.

Of some value in our experience have been studies of cerebral blood flow (single-photon emission tomography, or SPECT) and metabolism (positron emission tomography, or PET), which show diminished activity in the medial temporal lobes, sometimes early in the disease. Nevertheless, in most cases, when such changes were evident, the diagnosis was already obvious on clinical grounds alone. Our recent experience has been that the pattern of Alzheimer change on these blood flow and metabolic studies is too often applied indiscriminately.

Neuropsychologic tests show deterioration in memory and verbal access skills. Testing is particularly useful when there is a serial decline in ability. The use of these examinations is described in Chap. 21. Certain aspects of attention and executive function in Alzheimer disease have recently been reviewed by Perry and Hodges.

There is no firm biologic marker of Alzheimer disease with the exception of an imprecise association with the disease-modifying e4 apolipoprotein allele, as mentioned earlier. The ratio of $A\beta$ to tau in the cerebrospinal fluid (curiously low in Alzheimer disease) has been proposed as a useful test, but is not yet well enough validated for routine use (Maddalena et al).

Differential Diagnosis (See also Table 21-3, page 374) Formerly, when virtually all forms of presenile and senile dementia were untreatable, there was little advantage to either the patient or the family in ascertaining the cause of the cerebral disease. Such patients were customarily left at home or committed to an institu-

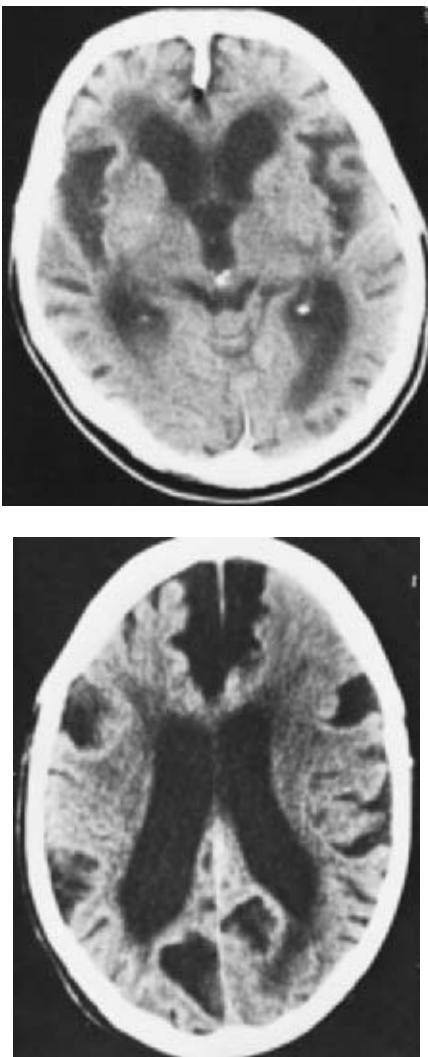

Figure 39-3. Top: Alzheimer disease. Axial CT section demonstrating severe generalized cerebral cortical atrophy and moderately severe ventricular enlargement. Bottom: Pick disease. Pronounced selective atrophy of the frontal and temporal lobes. (Reproduced by permission from Lee SH, Rao KCVG, Zimmerman RA: *Cranial MRI and CT*. New York, McGraw-Hill, 1992)

tion for the care of the psychiatrically or chronically ill. To the extent that the administration of anticholinergic and other drugs may, for a time, reduce the memory defect, there is value in arriving at the correct diagnosis. Now that a number of other dementing diseases are treatable, a great premium attaches to correct diagnosis. The physician is compelled to exercise care in their detection even though they may be relatively infrequent.

The treatable forms of dementia are those due to neurosyphilis (general paresis) and other chronic meningitides, normal-pressure hydrocephalus, chronic subdural hematoma, nutritional deficiencies (Wernicke-Korsakoff syndrome, Marchiafava-Bignami disease, pellagra, vitamin B₁₂ deficiency), chronic drug intoxication (e.g., alcohol, sedatives), certain endocrine-metabolic disorders (myxedema, Hashimoto thyroiditis encephalopathy, Cushing disease, chronic hepatic encephalopathy), some types of frontal and temporal lobe tumors, cerebral vasculitis, sarcoidosis, Whipple disease, and, above all, the pseudodementia of depression. The de-

mentia of AIDS and paraneoplastic limbic encephalitis may be partially amenable to treatment. Exclusion of these several diseases is most readily accomplished by sequential outpatient evaluations or by a brief admission to a hospital, where examinations of blood and CSF, EEG, CT, MRI, and neuropsychologic testing can be undertaken.

One of the problems in differential diagnosis, in the authors' experience, has been the distinction between a late-life depression and a dementia, especially when some degree of both are present. Observation over several weeks or more, and the patient's demeanor, makes the distinction obvious. Multi-infarct dementia is not difficult to separate from Alzheimer dementia, but patients with the latter illness may have had one or more clinically inapparent infarcts as discussed further on. The dementia of normal-pressure hydrocephalus may also be confused with Alzheimer dementia (page 535). The problem of distinguishing Alzheimer disease from a more "benign" form of memory decline associated with aging comes up frequently in practice, as discussed on page 370. The differential diagnosis of these several treatable conditions is discussed in Chaps. 21, 30, 34, and 49. From time to time, we have been confident on clinical grounds that a patient had Alzheimer disease, only to have revealed at autopsy that progressive supranuclear palsy, Lewy body disease, Pick disease another non-Alzheimer degeneration of the frontal lobes, or cortical-basal ganglionic degeneration was the cause, as noted below. All of these are discussed later in this chapter.

Treatment There is little evidence that any of the proposed forms of therapy for Alzheimer disease—cerebral vasodilators, stimulants, L-dopa, massive doses of vitamins B, C, and E, and many others—has any salutary effect. Trials of oral physostigmine, choline, and lecithin have yielded mostly negative or uninterpretable results, and the evidence favoring the currently popular cholinergic precursors and agonists and acetylcholinesterase inhibitors, such as tacrine and donepezil, is only modest. With regard to the latter group of drugs, most large trials have demonstrated a slight prolongation of the patient's ability to sustain an independent life, but such evidence generally requires that the medications be taken for 6 to 12 months. The salutary effects on memory are harder to document; nonetheless, despite some trials that have failed to demonstrate benefit (c.f., AD 2000 Collaborative Group), the balance of evidence may favor the use of these medications. Side effects may include nausea or diarrhea in a small number of patients. We have been unable to interpret the few reports from the families of our patients that the medication caused insomnia or increased confusion. It is worth mentioning that when the acetylcholine receptor antagonist succinylcholine is used prior to general anesthesia, its effects may be prolonged in patients taking the above drugs. The use of trazodone, haloperidol, thioridazine, risperidone, and related drugs may suppress some of the aberrant behavior and hallucinations when these are problems, making life more comfortable for both patient and family. Small doses of diazepines, such as lorazepam, are useful when sleep is severely disturbed.

The *N*-methyl-D-aspartate (NMDA) glutaminergic antagonists, specifically memantine (20 mg daily) have also been tried. In a study of memantine by Reisberg and colleagues of 252 patients (187 of whom completed the trial), there were better results on a few scales that reflect functional behavior compared to the use of placebo, but there was no change in three measures of cognitive performance. The side effects were minor and this drug has now been approved for use in late-stage Alzheimer disease. As a result,

memantine is now being applied more widely, particularly in later stages of the disease and in conjunction with cholinergic drugs.

A provocative series of animal experiments that demonstrated the possibility of removal of plaques by immunization against amyloid has led to human studies with a similar vaccination. One trial has been stopped because of the occurrence of an immune encephalitis induced by the treatment in a few patients, but in autopsy material there were indications that the treatment may have had the desired effect. Revised vaccines are being formulated for further testing of this novel approach.

Perhaps more important than the use of any drugs is the general management of the demented patient, which should proceed along the lines outlined in Chap. 21, keeping in mind that the physician's counsel is often the family's main resource for medical and social decisions.

Associated Pathologic States As indicated earlier, the histologic changes of Alzheimer disease have a number of interesting associations. The changes are far more common in the brains of patients with Parkinson disease than in the brains of age-matched controls (Hakim and Mathieson). These findings at least partly explain the high incidence of dementia in patients with Parkinson disease (see further on, in the sections regarding Parkinson disease and Lewy body dementia), yet not more than 20 to 30 percent of patients with Parkinson disease have plaques and tangles. Another association between the two diseases is apparent in the *Guamanian Parkinson-dementia complex*, which is also discussed below. In this entity, the symptoms of dementia and parkinsonism are related to neurofibrillary changes in the cerebral cortex and substantia nigra, respectively; senile plaques and Lewy bodies are unusual findings.

Alzheimer disease in relation to the Down syndrome, first noted and reported by Jervis, is now widely recognized. The characteristic plaques and neurofibrillary tangles appear in the third decade; they increase with age and are present in practically all patients with the Down syndrome after 40 years of age. The basis for excess amyloid production in Down syndrome was discussed earlier.

There are rare instances, such as those reported by Malamud and Lowenberg and by Loken and Cyvin, in which dementia begins in late childhood, with the finding at postmortem examination of the typical Alzheimer lesions in the cerebral cortex and basal ganglia. The clinical picture in these juvenile and early adult cases has been more varied than in the older ones. In some, paucity of speech, mutism, tremor, stooped posture, marked grasp and suck reflexes, and pyramidal and cerebellar signs leading to inability to stand or walk have appeared at various stages of the disease.

The finding of neurofibrillary changes (and to a lesser extent of plaques) in boxers ("punch-drunk" syndrome, or "dementia pugilistica") is another interesting ramification of the Alzheimer disease process (page 863). Hydrocephalus is present also, but there is insufficient information to determine whether this is due to a normal-pressure tension hydrocephalus from multiple subarachnoid hemorrhages or a hydrocephalus ex vacuo from cerebral atrophy.

Similarly, some cases of what has come to be called "primary progressive aphasia" (see page 908) have Alzheimer change and amyloid plaque deposition as the primary pathologic change. A close relationship between Pick, Alzheimer, and Parkinson diseases has been demonstrated in a large family with dysphasic dementia (Morris et al.). Other isolated combinations, wherein Alzheimer disease, hypothyroidism, hypopituitarism, or neurosyphilis were conjoined, were probably a matter of chance and prove nothing. From time to time other unusual associations come to light, such as de-

mentia with motor neuron disease or the cases of familial dementia with spastic paraparesis reported by Worster-Drought and by van Bogaert and their associates (see further on in this chapter). Here, neurofibrillary change is the most prominent feature while amyloid plaques are negligible in number or absent.

Lobar Atrophies (Pick Disease and Frontotemporal Dementia)

In 1892, Arnold Pick of Prague first described a special form of cerebral degeneration in which the atrophy is circumscribed (most often in the frontal and/or temporal lobes), with involvement of both gray and white matter—hence the term *lobar* rather than *cortical* sclerosis. In 1911, Alzheimer presented the first careful study of the microscopic changes. The most complete analyses of the pathologic changes until recently have been those of Spatz, van Mansvelt, Morris and coworkers, and Tissot and associates. The nosology of the lobar atrophies has become extremely confusing over the past decade. It has become clear that the pathologic change associated with neuronal loss in this category of disease may be any one of several types: lobar atrophy with Pick inclusion bodies, with neurofibrillary tangles, with other inclusions, or no characteristic changes. Furthermore, gliosis and mild spongiform changes in the superficial layers of cortex, and even typical Alzheimer plaque and tangle pathology, have all been associated with syndromes and gross pathologic atrophy of the frontal and/or temporal lobes. Confusion has arisen because these illnesses have been denominated either by the clinical syndrome that derives from a particular region of atrophy or by the pathologic change. Several terms have been applied to various forms of lobar atrophy, *frontotemporal dementia* being the most common (see below). Nonetheless, among these, fairly distinct clinicopathologic syndromes of Pick disease and of frontotemporal dementia are recognizable.

Since the recognition of Pick disease rests more on pathologic than on clinical criteria, this is described first. In contrast to Alzheimer disease, in which the atrophy is relatively mild and diffuse, the pathologic change in lobar atrophy is more circumscribed and sometimes asymmetrical. The atrophy may extend to the island of Reil and the amygdaloid-hippocampal structures. The parietal lobes are involved less frequently than the frontal and temporal lobes. The affected gyri become paper-thin, resembling the kernel of a dried walnut. The cut surface reveals not only a marked narrowing of the cortical ribbon but a grayish appearance and reduced volume of the underlying white matter. The corpus callosum and anterior commissure share in the atrophy. The overlying pia-arachnoid is thickened, and the ventricles are enlarged. The pre- and postcentral, superior temporal, and occipital convolutions are relatively unaffected and stand out in striking contrast to the wasted parts. Pick insisted that the disease essentially involves the association areas of Flechsig, but this is not always so. In some instances, atrophy of the caudate nuclei has been pronounced, almost to the degree seen in Huntington chorea. The thalamus, subthalamic nucleus, substantia nigra, and globus pallidus may also be affected, but only to a slight degree.

The salient histologic feature of Pick disease is a loss of neurons, most marked in the first three cortical layers. Surviving neurons are often swollen, and some contain argentophilic (Pick) bodies within the cytoplasm. Ultrastructurally, the Pick bodies are made up of straight fibrils, thus differing from the paired helical filaments that characterize Alzheimer disease. These bodies predominate in the medial parts of the temporal lobes, especially in the atrophic hippocampi. "Ballooning" of cortical neurons is found

mainly in the frontal cortex, and in such cases, according to Tissot and others, atrophy of the basal ganglia and substantia nigra is especially frequent and severe. There is a loss of myelinated fibers in the white matter beneath the atrophic cortex. A heavy astrocytic gliosis is seen in both the cortex and subcortical white matter. Most neuropathologists consider the loss of myelinated fibers in the white matter, basal ganglia, and thalamus to be consequent to neuronal loss in the cortex. Senile plaques and Alzheimer neurofibrillary changes are seen in the atrophic zones in some of the cases, as alluded to earlier, and there is granulovacuolar degeneration of neurons in the hippocampus, but not to the degree seen in Alzheimer disease.

It is the lobar atrophy and marked changes in the underlying white matter that provide the unifying elements of all the lobar atrophies. These changes are readily appreciated by CT scanning and MRI in advanced cases.

Clinical Features Whether the diagnosis of Pick disease can be made consistently on purely clinical grounds is doubtful. Our predictions as to the existence of the pathologic changes and their differentiation from those of Alzheimer disease and the more recently defined entity of "frontotemporal dementia" (described below) have been erratic, although they should improve with experience and proper use of CT and MRI (particularly coronal MR images). Sometimes the imaging features of unilateral or bilateral lobar tissue loss are so prominent as to almost oblige the diagnosis of lobar atrophy. In our experience, the gradual onset of mental confusion with respect to place and time, anomia, slowness of comprehension, inability to cope with unaccustomed problems, loss of tact, deterioration of work habits, neglect of personal hygiene and grooming, apathy, and alterations of personality and behavior have been prominent features. In addition to these personality changes, an inability to perform sequences of motor tasks, motor perseveration, apathy (emotional indifference), inattention, abulia, impairment of gait and upright stance, and prominent grasp and suck reflexes are attributable to predominant affection of the frontal lobes. Bulimia and alterations in sexual behavior occur to a distressing degree in some patients (Tissot et al).

The similarities to the clinical entity of frontotemporal dementia described below is apparent. In part for this reason, the notion of a "Pick complex" has been suggested, encompassing lobar atrophy with Pick bodies, frontotemporal dementia, and other entities in which tau depositions are prominent, such as corticobasal degeneration, primary progressive aphasia, and progressive supranuclear palsy. In keeping with the basic approach of the book, we still prefer to separate these entities when they are clinically distinct, only remarking that several pathologies may give rise to each of these states. The location of the neuronal degeneration is the main determinant of the clinical presentation.

Wilson distinguished two patterns of abnormal behavior: in one, the patient is talkative, lighthearted, cheerful or anxious, constantly on the move, occupied with trifles, and attentive to every passing incident; in the other, the patient is taciturn, inert, emotionally dull, and lacking in initiative and impulse. Probably these two patterns represent predominantly temporal and frontal types, respectively. According to Tissot and colleagues, the frontal, temporal, and parietal lobes are all affected in 75 percent of patients by the time the disease terminates.

The cause of Pick disease is unknown. While most cases are sporadic, Sjögren and associates concluded from a genetic survey of the cases in Stockholm that Pick disease may be transmitted as

a dominant trait with polygenic modification. Such a Dutch family with almost 100 percent penetrance over several generations has been reported by Schenk. Women seem to be affected more often than men. No chemical, vascular, traumatic, or other factor of possible causal importance has been identified.

The course of the illness is usually 2 to 5 years, occasionally longer, and nothing can be done therapeutically except to postpone the end by careful nursing.

Frontotemporal Dementia

(See also page 372)

This descriptive term has been used by neurologists and neuropathologists to refer to a dementia that is associated with degeneration of the frontal and temporal lobes. Many such instances have proved to be examples of Alzheimer disease and, in lesser numbers, Pick disease, as noted above. Also, for many years neuropathologists have been aware of instances of dementia that are identical clinically and in their gross pathology (severe gyral atrophy) to the Alzheimer and Pick types but do not show the characteristic histologic changes of either of these diseases. They do, however, exhibit tau-staining material in neurons of the affected regions. In some cases, this is attributable to mutations in the gene on chromosome 17 that encodes the tau protein. These mutations alter the proportions of different forms of this protein and lead both to tau accumulation and its hyperphosphorylation. Indeed, many cases of frontotemporal dementia are associated with tau gene mutations (Basun et al). However, it is important to note that abnormal aggregates of tau have been identified in practically all neurodegenerative atrophies and, of course, form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease, and they are abundant, although of slightly different structure, in progressive supranuclear palsy. From the observations of Brun and of Neary and their associates, pure tau-reactive cases actually outnumber Pick disease when the latter is strictly defined by the cortical white matter degeneration and Pick inclusions, but the distinctions between the two have not always been clear from writings on the subject.

Some of the clinical aspects of frontotemporal dementia are discussed in Chap. 21, but, broadly speaking, the patients under consideration present the personality and behavioral abnormalities that would be expected from frontal and anterior temporal lobe dysfunction, much as described earlier for Pick disease, including apathy, perseveration, poor judgment and abstraction, bizarre affect, and a general disengagement. Insight is almost always impaired, and some subjects become euphoric or display repetitive compulsive behaviors. An initial diagnosis of depression has been common on our services. Other psychiatric symptoms—such as sociopathic and disinhibited behavior with aspects of hyperorality and hyperphagia—may predominate. (All of Wilson's comments, noted above in relation to Pick disease, pertain here as well.) Alternatively, aphasic or word-finding syndrome corresponding to a lateral temporal lobe degeneration may be the initial presenting and predominant feature, sometimes for several years, before other manifestations of dementia become evident. A proportion of patients have parkinsonian features, but this should always raise the question of corticobasal-ganglionic degeneration (see further on). Motor neuron disease is also linked to frontotemporal dementia in a small number of cases. This is particularly the case in the Gaumian (now called *western Pacific*) variety and in the heredofamilial frontotemporal atrophy linked to a mutation on chromosome 17.

In recent writings on this subject, the term *frontotemporal dementia* has come to be used in a highly restricted sense, being arbitrarily assigned to cases that show only tau-staining material in neurons. Most of the cases are sporadic, but the inherited variety linked to chromosome 17, in which parkinsonism is prominent, supports its distinction as a separate entity; it is in these cases that the intraneuronal deposition of tau is most striking, in both the frontotemporal cortex and the substantia nigra.

Noteworthy also is the observation that a dementia identical to that of the tau-reactive cases has been observed in others without any tau staining of neurons. Also, some of the frontally predominant cases have shown only marked vacuolation (microcavitation) of the affected cortex; cases of the latter type have been described in patients with ALS (where tau staining has reportedly been found in the anterior horn cells). In such cases, amyloid plaques and neurofibrillary tangles are no more abundant than expected for the age of the patient.

In sum, the relationship between Pick disease and frontotemporal dementia is still uncertain, hence the appeal of the term *Pick complex*. The clinical and gross pathologic findings—a regional frontotemporal atrophy of the cerebrum, bilateral or unilateral—are nearly identical in the two disorders. The main distinction is the presence or absence of Pick bodies or tau-staining material in neurons of the affected regions and greater affection of the white matter in Pick disease. If indeed the Pick and tau inclusions are shown in the future to specify distinctive biologic types, they can be considered to represent separate diseases. A measure of the confusion among experts in the field is reflected in the monograph by Kertesz, in which votes were taken regarding various terminologies and opinion was considerably divided.

Primary Progressive Aphasia

(See also page 906)

Focal disturbances, particularly aphasia and apraxia, occur early and prominently in certain patients with Pick-like lobar atrophy, indicating a lesion in the left frontal and/or temporal lobes. Viewed from another perspective, a language disorder has been described in two-thirds of all patients with temporal lobe atrophy. At first, the patient speaks less and has word-finding difficulty (anomia), but language structure is intact (Mesulam); later, he may forget and misuse words and soon fails to understand much of what is heard or read. Speech becomes a “medley of disconnected words and phrases” and eventually is reduced to an incomprehensible jargon. Later, dysarthria and apraxia become apparent, and finally, the patient is mute, seemingly without impulse to speak, with a complete loss of the ability to form words (Snowden et al). In a less common form, there is early comprehension difficulty followed by verbal perseveration, but fluency is retained. The above descriptions conform also to what is now called *primary progressive aphasia*, and it is notable that, according to Mesulam, who has studied the condition extensively, 60 percent of these cases show no characteristic pathologic change, 20 percent have Pick bodies, and a similar proportion show the typical changes of Alzheimer disease in the affected cortical region. A familial tendency has not been found.

Lewy Body Dementia

Next to Alzheimer disease, diffuse Lewy body disease, or Lewy body dementia, has been the most frequent pathologic diagnosis established in most series of demented patients. Reports of this

condition have been increasing steadily since the original communication by Okazaki and others in 1961 (see review by Kosaka). The disease is marked by parkinsonian features, dementia, and a frequent tendency to episodic delirium, as described below. The syndrome may be clinically indistinguishable from Alzheimer disease, but it is defined by diffuse involvement of cortical neurons with Lewy body inclusions and by an absence or inconspicuous number of neurofibrillary tangles and senile plaques. To some extent increased recognition of this disorder is due to improved histologic techniques, particularly the ability to detect ubiquitin by immunostaining and, more recently, similar stains for synuclein, which enable one to visualize Lewy bodies in the cerebral cortex more clearly than had been possible in the past. Because the Lewy bodies in cortical neurons are not surrounded by a distinct halo, as they are in the substantia nigra in cases of Parkinson disease, they were not readily appreciated until the development of these antibody stains. The fact that aggregated α -synuclein is the main component of the Lewy body will undoubtedly prove important in understanding both Parkinson disease and Lewy body dementia.

Clinical Features Burkhardt and colleagues, in an analysis of 34 cases of diffuse Lewy body disease, found that the characteristic syndrome was one of progressive dementia in an elderly patient with the late onset of parkinsonian signs in some cases. For this reason, the disease also properly belongs in the category of dementias that are accompanied by other prominent neurologic features (page 897). Difficulty in diagnosis arises because the movement disorder may be either mild or prominent and may occur as an early or a late manifestation. In Lennox's summary of 75 cases published up to 1990, parkinsonism, and particularly a limb and axial rigidity, was a prominent feature in 90 percent once the illness was fully developed, and almost half had tremor of the Parkinson type.

The parkinsonian features may respond favorably to L-dopa, but only for a limited time and sometimes at the expense of delirium or hallucinations that would be uncharacteristic of early idiopathic Parkinson disease (Hely et al); in others, the response to L-dopa is not as consistent. Some patients also have orthostatic hypotension corresponding to cell loss and Lewy bodies in the intermediolateral cell column of the spinal cord or in the sympathetic ganglia, thereby simulating striatonigral degeneration or Shy-Drager syndrome (see further on).

Byrne and associates pointed out that episodic confusion, hallucinations, and paranoid delusions were a feature of the Lewy body dementia; such psychotic features are generally uncharacteristic of Alzheimer and lobar dementias. In Lennox's review, one-third of patients had these swings in behavior, but as the illness advanced, the amnesia, dyscalculia, visuospatial disorientation, aphasia, and apraxia did not differ from those of Alzheimer disease. In the cases reported by Fearnley and coworkers, there was a supranuclear gaze palsy simulating that of progressive supranuclear palsy.

In our experience with Lewy body disease, the parkinsonian symptoms have been more prominent than in progressive supranuclear palsy, and the most characteristic feature besides the movement disorder and a slowly advancing dementia has been a vacuous anxious state with intermittent psychotic or delirious behavior. Others have commented on an extreme sensitivity of such patients to neuroleptic drugs, including increased confusion and greatly worsening parkinsonism or the development of the neuroleptic malignant syndrome.

With regard to diagnostic testing, only the finding of reduced activity in the posterior parietal cortical regions on PET scans has been found as a relatively consistent but not invariable feature.

Other Degenerative Dementias

Diffuse Cerebral Atrophy of Non-Alzheimer Type There are other forms of progressive, diffuse brain atrophy leading to dementia that show none of the pathologic features of either Alzheimer or Pick disease or any of the other diseases sometimes associated with a dementing illness (i.e., frontotemporal, Parkinson or Lewy body disease, ALS, and progressive supranuclear palsy).

In Sweden, for example, Sjögren has found familial cases of this type, as have Schaumburg and Suzuki in this country, and we have seen several sporadic examples. The clinical picture in these cases has been indistinguishable or has varied only slightly from that of Alzheimer disease, and autopsy has disclosed widespread cerebral atrophy, most pronounced in the frontal lobes. Microscopically these cases are characterized by a diffuse neuronal loss, slight glial proliferation, and similarly slight secondary alteration of the white matter. Other instances of sporadic and familial presenile dementia have shown subcortical gliosis or nonspecific cellular changes (atrophy of nerve cells and nuclei, loss of Nissl substance). Some examples of the latter type have in the past been described under the rubric of "Kraepelin disease" and more recently as "dementia lacking distinctive histologic features" (Knopman et al.). Perhaps some of these cases will turn out to be a variant of the "tau" form of frontotemporal dementia, as discussed above. Notable is the presence of this same nondescript pathologic change in some cases of lobar atrophy, particularly primary progressive aphasia.

Argyrophilic Grain Disease This obscure entity has been connected with a late-life dementia in which behavioral disturbances precede memory difficulty. Whether the finding of argyrophilic grains in the mediotemporal lobe, different from tau-laden neurofibrillary tangles and from the glial inclusions (putatively a defining feature of multiple system atrophy), constitutes a specific entity is not clear to the authors. Probst and Tolnay remark that these argyrophilic grains are not found in nondemented individuals. It is not likely that the condition can be identified in life; if it is a genuine entity, it must be rare.

Thalamic Dementia A relatively pure degeneration of thalamic neurons is described from time to time in relation to a progressive dementia, but it must also be rare (Stern; Schulman). Reported cases have evolved rapidly (several months) and have been associated in some instances with choreoathetosis. Garcin and colleagues described five such instances of subacutely developing dementia, which they considered initially to be examples of Creutzfeldt-Jakob disease. In each of them the pathologic changes consisted primarily of neuronal loss and gliosis of the thalamus. A large kindred characterized by subacute dementia and myoclonus and inherited as an autosomal trait, has been reported by Little and coworkers. In members of this family, the clinical presentation was also very similar to that of Creutzfeldt-Jakob disease; however, the pathologic changes were confined to the thalamus, particularly to the mediadorsal and other anterior and medial thalamic nuclei. Transmission of the disease to primates was unsuccessful. We raise the question if some of these cases were unappreciated instances of cerebral deep venous thrombosis, late-onset Leigh disease (sub-

acute necrotizing encephalopathy), or even more unusual conditions such as fatal familial insomnia.

Neuroserpinopathy In recent years, there have been case reports of dominantly inherited, adult-onset dementia with a fulminant evolution suggestive of encephalopathy and the special feature of seizures. As distinctive as this combination of dementia and seizures has been the presence at autopsy of large eosinophilic, PAS-positive intraneuronal inclusions that contain aggregates of neuroserpin, thus the initial description under "familial encephalopathy with neuronal inclusion bodies." The serpins are a family of protease inhibitors that include neuroserpine, a protein expressed exclusively in neurons. The neuronal inclusions are densest in the deep layers of the cortex and in the substantia nigra. Missense mutations in the gene encoding neuroserpin have been identified as the cause. This newly described disease is reviewed by Lomas and Carrell.

Vascular Dementia Finally, a comment is required regarding the group of diseases popularly called "vascular dementia" and listed in many classifications as among the most common causes of chronic mental deterioration, second only to Alzheimer disease. One might remember that in past decades, much of senile dementia was incorrectly attributed to "cerebral atherosclerosis." Without doubt, as discussed in Chap. 34, multiple cerebral strokes may cause increasing deficits that cumulatively qualify as a dementia, but at least some of the focal lesions that contribute to the cognitive worsening in the clinical syndrome can be identified, and there is a corresponding stepwise decline. Admittedly, this type of vascular dementia may be more difficult to recognize when a number of the infarcts are of the relatively silent lacunar type. The mental capacities of such patients may then appear to fail in a gradual and continuous fashion. Memory is relatively spared in the early stages and, usually, a pseudobulbar state or severe deterioration in gait accompany the dementia. The subcortical white matter change of Binswanger disease causes similar diagnostic problems, as discussed on pages 373 and 707. Beyond these vascular diseases and the familial disease CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy, page 707), which is of uncertain cause, the authors have doubts about the entire category of vascular dementia and certainly of the frequency with which it is assumed to occur. Most cases turn out to be Alzheimer disease with one or more visible infarctions.

We are inclined toward the point of view expressed in Chap. 21 and summarized in the commentary by Jagust, specifically that while there may be an undefined but perhaps synergistic interaction between strokes and progressive mental decline in patients with Alzheimer disease, the relationship is unproven. Most often it is the degenerative condition of Alzheimer that explains the dementia.

Dementia Due to Metabolic Diseases (See Chap. 37) In the *diagnosis* of this large category of chronic dementias, one must consider several nondegenerative disorders in which dementia may predominate and focal neurologic abnormalities may be minimal. Several of the treatable ones were listed earlier in the discussion of Alzheimer disease above, and a larger group is reviewed in Chap. 21 and Table 21-3. Also to be considered, particularly among dementias with onset at an early age, are the inherited metabolic diseases discussed in Chap. 37, chief among which are the leukodystrophies—metachromatic, adrenal, globoid body (Krabbe disease)—and the poliodystrophies—neuronal ceroid lipofuscinoses

(Kufs disease), GM₂ gangliosidosis, and Wilson disease (see page 840). Each of these displays characteristic neurologic features that may present in the early stages with a decline in intellectual function and a general behavioral disorder.

DISEASES IN WHICH DEMENTIA IS A PROMINENT FEATURE WITH OTHER NEUROLOGIC ABNORMALITIES

Huntington Chorea

This disease—distinguished by the triad of dominant inheritance, choreoathetosis, and dementia—commemorates the name of George Huntington, a medical practitioner of Pomeroy, Ohio. In 1872, in a paper read before the Meigs and Mason Academy of Medicine and published later that year in the *Medical and Surgical Reporter* of Philadelphia, Huntington gave a succinct and graphic account of the disease, based on observations of patients that his father and grandfather had made in the course of their practice in East Hampton, Long Island. Reports of this disease had appeared previously (see DeJong, in the References, for historical background), but they lacked the accuracy and completeness of Huntington's description. Vessie, in 1932, was able to show that practically all the patients with this disease in the eastern United States could be traced to about six individuals who had emigrated in 1630 from the tiny East Anglian village of Bures, in Suffolk, England. One remarkable family was traced for 300 years through 12 generations, in each of which the disease had expressed itself.

To quote Huntington, the rule has been that "When either or both of the parents have shown manifestations of the disease . . . one or more of the offspring invariably suffer of the disease, if they live to adult life. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great-grandchildren of the original shakers may rest assured that they are free from disease." Davenport, in a review of 962 patients with Huntington chorea, found only 5 who had descended from unaffected parents. Possibly, in these latter patients, a parent had the trait, but in very mild form. Or, one or more of these patients may have represented a rare sporadic instance of Huntington chorea, i.e., may have been an individual in whom a spontaneous mutation had occurred.

In university hospital centers, this is one of the most frequently observed types of hereditary nervous system disease. Its overall frequency is estimated at 4 to 5 per million, and 30 to 70 per million among whites of northern European ancestry. The usual age of onset is in the fourth and fifth decades, but 3 to 5 percent begin before the 15th year and some even in childhood. In about 30 percent, symptoms become apparent after 50 years. The progression of the disease is slower in older patients. Once begun, the disease progresses relentlessly, until only a restricted existence in a nursing home or psychiatric hospital is possible and some other disease terminates life.

Exhaustive genealogic documentation has established the cause to be an autosomal dominant gene with complete penetrance (see below). Martin has made the observation that young patients usually inherit the disease from their fathers and older patients from their mothers. It has been observed beginning at almost the same age in identical twins.

Until recently, it had not been possible to foretell which of the children of a patient will be stricken with the disease. The most

important achievement in respect to the presymptomatic detection and biologic understanding of Huntington disease was the discovery by Gusella and colleagues of a marker linked to the Huntington gene, localized to the short arm of chromosome 4. Subsequently these investigators and others identified the gene abnormality as an excessively long repeat of trinucleotides (CAG) within the Huntington gene, the length (number) of which determines not only the presence of the disease but also the age of onset, longer repeat lengths being associated with an earlier appearance of clinical signs. This discovery has made possible the development of a test for the detection of the defective gene in asymptomatic individuals. Since there is no treatment for the disease, testing raises certain ethical considerations that must be resolved before its widespread utilization.

Clinical Features *The mental disorder* assumes several subtle forms long before the more obvious deterioration of cognitive functions becomes evident. In approximately half the cases, slight and often annoying alterations of character are the first to appear. Patients begin to find fault with everything, to complain constantly, and to nag other members of the family; they may be suspicious, irritable, impulsive, eccentric, untidy, or excessively religious, or they may exhibit a false sense of superiority. Poor self-control may be reflected in outbursts of temper, fits of despondency, alcoholism, or sexual promiscuity. Disturbances of mood, particularly depression, are common (almost half of the patients in some series) and may constitute the most prominent symptoms early in the disease. Invariably, sooner or later, the intellect begins to fail. The patient becomes less communicative and more socially withdrawn. These emotional disturbances and changes in personality may reach such proportions as to constitute a virtual psychosis (with persecutory delusions or hallucinations).

Diminished work performance, inability to manage household responsibilities, and disturbances of sleep may prompt medical consultation. There is difficulty in maintaining attention, in concentration, and in assimilating new material. Mental flexibility lessens. There is loss of fine manual skills (see further on). The performance parts of the Wechsler Adult Intelligence Scale show greater loss than the verbal parts. Memory is relatively spared. This gradual dilapidation of intellectual function has been characterized as a "subcortical dementia" (page 372), i.e., elements of aphasia, agnosia, and apraxia are observed only rarely and memory loss is not profound. Often the process is so slow, particularly in cases of late onset, that some degree of intellectual capacity seems to be retained for many years.

The *abnormality of movement* is at first slight and most evident in the hands and face; often the patient is merely considered to be fidgety, restless, or "nervous." Slowness of movement of the fingers and hands, a reduced rate of finger tapping, and difficulty in performing a sequence of hand movements are early motor signs. Gradually these abnormalities become more pronounced until the entire musculature is implicated with chorea. The frequency of blinking is increased (the opposite of parkinsonism), and voluntary protrusion of the tongue is constantly interrupted by unwanted darting movements. In the advanced stage of the disease, the patient is seldom still for more than a few seconds. The choreic movements are slower than the brusque jerks and postural lapses of Sydenham chorea, and they involve many more muscles. They tend to recur in stereotyped patterns yet are not as stereotyped as tics. In more advanced cases, they acquire an athetoid or dystonic quality. Muscle tone is usually decreased until late in the illness, when there

may also be some degree of rigidity, tremor, and bradykinesia, elements suggestive of Parkinson disease (the Westphal or "rigid" variant, which is more common with a childhood onset). Tendon reflexes are exaggerated in one-third of patients, but only a few have Babinski signs. Voluntary movements are initiated and executed more slowly than normal, but there is no weakness and no ataxia, although speech, which becomes dysarthric and explosive due to incoordination between tongue and diaphragm, may convey the impression of a cerebellar disorder. There is poor control of the tongue and diaphragm. In late-onset cases there may be an almost constant rapid movement of the tongue and mouth, simulating the tardive dyskinesia that follows the use of neuroleptic drugs. Denny-Brown pointed out that when the Huntington patient is suspended, the upper limbs assume a flexed posture and the legs an extended one, a posture that he considered to be expressive of the striatal syndrome. The disorder of movement that characterizes Huntington chorea has been described more fully in Chap. 4. Oculomotor function is subtly affected in most patients (Leigh et al; Lasker et al). Particularly characteristic are impaired initiation and slowness of both pursuit and volitional saccadic movements and an inability to make a volitional saccade without movement of the head. Excessive distractibility may be noticed during attempted ocular fixation. The patient feels compelled to glance at extraneous stimuli even when specifically instructed to ignore them. Upward gaze is often impaired.

As Wilson stated, the relation of the choreic to the mental symptoms "abides by no general rule." Most often the mental symptoms precede the chorea, but they may accompany or follow it, sometimes by many years. In our own material, with several exceptions of late onset with rigidity rather than chorea, once the movement disorder was fully established, there was nearly always some degree, perhaps slight, of cognitive abnormality. Exceptional cases have been reported in which the movement disorder existed for 10 to 30 years without mental changes in patients with the gene abnormality of Huntington disease (Britton et al). After 10 to 15 years, most patients deteriorate to a vegetative state, unable to stand or walk and eating little; in this late stage, a mild amyotrophy may appear. Noteworthy is the high suicide rate in huntingtonians, as pointed out by Huntington himself (see also Schoenfeld et al). There is a higher than normal incidence of head trauma; therefore chronic subdural hematoma is another common finding at autopsy.

The first signs of the disease may appear in childhood, before puberty (even under the age of 4), and several series of such early-onset cases have been described (Farrer and Conneally; van Dijk et al). Mental deterioration at this early age is more often accompanied by cerebellar ataxia, behavior problems, seizures, bradykinesia, rigidity, and dystonia than by chorea (Byers et al). However, this rigid form of the disease (Westphal variant, as it is known) also occurs occasionally in adults, as mentioned above. Functional decline is much faster in children than it is in adults (Young et al).

At the gene locus in Huntington disease there are normally 11 to 34 (median 19) consecutive repetitions of the CAG triplet, each of which codes for glutamine. Individuals with 35 to 39 triplets may eventually manifest the disease, but it tends to be late in onset and mild in degree or limited to the below-mentioned senile chorea, and those with more than 42 almost invariably acquire the signs of disease if they live long enough.

Earlier onset in successive generations (*anticipation*) is well described in the early writings on the subject and is now known to be attributable to increasing lengths of the CAG repeat sequence. The dementia is generally more severe in cases of early onset (15

to 40 years) than in those of later onset (55 to 60 years). In adult patients with early onset, the emotional disturbance tends to be more prominent initially and precedes the chorea and intellectual loss by years; with older age of onset, choreiform features are more often the initial components; in the middle years, dementia and chorea have their onset at nearly the same age. At the other extreme of age, the first features may become evident in the eighties, with orofacial or other dyskinesias that are mistakenly attributed to an exposure to neuroleptic drugs.

Pathology and Pathogenesis Gross atrophy of the head of the caudate nucleus and putamen bilaterally is the characteristic abnormality, usually accompanied by a moderate degree of gyral atrophy in the frontal and temporal regions. The caudatal atrophy alters the configuration of the frontal horns of the lateral ventricles in that the inferolateral borders do not show the usual bulge formed by the head of the caudate nucleus. In addition, the ventricles are diffusely enlarged (Fig. 39-4); in CT scans, the bicaudate-cranial ratio is increased in the majority of patients, and this finding corroborates the clinical diagnosis in the moderately advanced case.

The early articles of Alzheimer and Dunlap and the more recent one of Vonsattel and DiFiglia contain the most authoritative descriptions of the microscopic changes. The latter authors have graded the disease into early, moderately advanced, and far advanced stages. In five early but genetically verified cases, no striatal lesion was found, which suggests that the first clinical manifestations are based on a biochemical disorder without visible structural change, at least by light microscopy. This view is supported by the observation that Huntington patients studied with PET show a characteristic decrease in glucose metabolism in the caudate nuclei, which appears early in the disease and precedes the loss of tissue (Hayden et al). The striatal degeneration begins in the medial part of the caudate nucleus and spreads, tending to spare the nucleus accumbens. Of the six cell types in the striatum (a differentiation based on size, dendritic arborizations, spines, and axon trajectories), the smaller neurons are affected before the larger ones. Loss of dendrites of the small spiny neurons has been an early finding, while the large cells are relatively preserved and exhibit no special alterations. The lost cells are replaced by fibrous astrocytes. The anterior parts of the putamen and caudate are more affected than the posterior parts. In our own cases we have not been impressed with changes in the globus pallidus, subthalamic nucleus, red nucleus, or cerebellum, but others have observed slight changes in these parts and in the pars reticulata of the substantia nigra. In the cerebral cortex, there is said to be slight neuronal loss in layers 3, 5, and 6, with replacement gliosis. Cases are reported with typical striatal lesions but normal cortices, in which only chorea had been present during late life. In our early to moderately advanced cases, even quantitative analyses of the cortex have not disclosed a significant loss of neurons. Several neuropathologists have observed marked cell loss and gliosis in the subthalamic nuclei in children or young adults with chorea and behavior disorders.

The biochemical defects in Huntington chorea are only beginning to be understood. Impaired glucose metabolism in the caudate nucleus, preceding visible atrophy, has already been noted in some studies. Since at least a partial explanation for L-dopa-induced involuntary movements is an excess of dopamine (in contrast to Parkinson disease, in which there is a decrease in dopamine), it has been postulated that the abnormal movements of Huntington chorea represent a heightened sensitivity of striatal dopamine receptors. There are disturbances in the metabolism of other putative

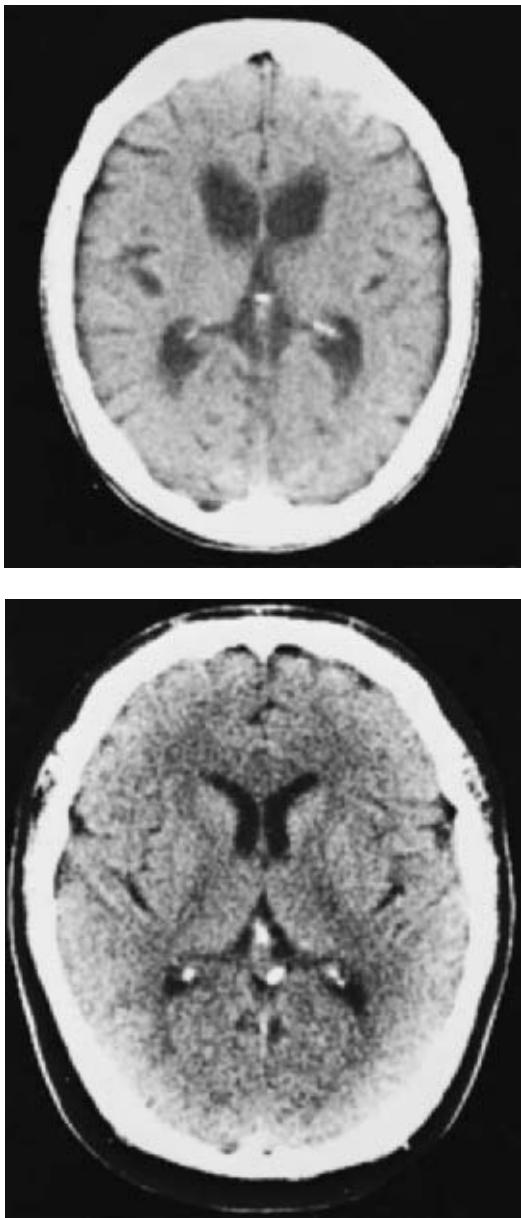

Figure 39-4. The upper CT scan is from a 54-year-old mildly demented woman with a 10-year history of Huntington chorea. The bulge in the inferolateral border of the lateral ventricle, normally created by the head of the caudate nucleus (lower scan from a patient of the same age for comparison), has been obliterated. There is also a diffuse enlargement of the lateral ventricles.

neurotransmitters (norepinephrine, glutamic acid decarboxylase, choline acetyltransferase, GABA, acetylcholine, and somatostatin), but the significance of these biochemical disturbances is unknown.

Viewed from the molecular perspective, the pathogenesis of this disease is a direct but still poorly understood consequence of the aforementioned expansion of the polyglutamine region of *huntingtin* (the protein product of the Huntington gene). It has been shown that the expansion predisposes the mutant huntingtin protein to aggregate in the nuclei of neurons. Moreover, the protein accumulates preferentially in cells of the striatum and parts of the cortex affected in Huntington disease. Evidence, particularly that given by Wetz (cited in the review by Bates), suggests that these aggre-

gates may be toxic to neurons, either directly or in their protofibrillary form (a situation similar to that suggested for the toxicity of synuclein in Parkinson disease). The situation is, however, likely to be more complex, since the bulk of huntingtin deposition is found in cortical neurons, whereas the neuronal loss is predominantly striatal. One theory, based on experimental data, supports the concept that the polyglutamine expansion renders certain cell types unduly sensitive to glutamate-mediated excitotoxicity; another notion is that it creates an insufficiency of trophic influences directed to the caudate from the cortex; yet another theory relates the polyglutamine expansion to the acetylation of histones, which leads to cell death. This finding has led to trials of inhibitors of histone deacetylases and other therapies that modify gene expression in transgenic mouse models of Huntington disease. Other theories implicate mitochondrial dysfunction. As importantly, since polyglutamine expansions are implicated in several neurodegenerative diseases (reviewed below), treatments that block their effect on cellular function may be broadly effective in several degenerative diseases.

Diagnostic Problems Once the disease has been observed in its fully developed form, its recognition requires no great clinical acumen. The main difficulty arises with patients who lack a family history but who display the progressive chorea, emotional disturbance, and dementia with onset in adult life. This difficulty has been largely overcome since the mutation causing Huntington disease was identified. It is now possible to confirm or exclude the diagnosis by analysis of DNA from a blood sample. The presence of greater than 39 to 42 CAG repeats at the Huntington locus essentially confirms its presence; lesser numbers leave room for equivocation. Sometimes it is learned later that the family history was incomplete or falsified or that an illness in a parent had been misinterpreted.

Chorea that begins in late life, with only mild or questionable intellectual impairment and without a family history of similar disease, is another source of difficulty; referring to it as “senile chorea” does not solve the problem. Indeed, senile chorea may have more than one cause. We have seen it appear with infections, drug therapy, and thyrotoxicosis, only to disappear after a few weeks. A few times we have been confronted with the problem of an older patient who displays orolingual dyskinesias that are most characteristic of exposure to neuroleptic drugs but in whom there was no such history of exposures; testing disclosed Huntington disease.

Chorea in early adult life always raises the question of a late form of Sydenham chorea, of lupus erythematosus with antiphospholipid antibodies, or of cocaine use, but neither familial occurrence nor mental deterioration is part of these processes. A “benign inherited chorea,” transmitted as an autosomal dominant trait without prolongation of a triplet sequence, has been traced to chromosome 14q. It is differentiated from Huntington disease by onset before age 5, progressing little and having no associated mental deterioration (Breedveld et al). Other progressive neurologic disorders inherited as autosomal dominant traits and beginning in adolescence or adult life (e.g., polymyoclonus with or without ataxia, acanthocytosis with progressive chorea, and dentatorubropallidoluysian degeneration) can closely mimic Huntington disease, as described further on; sometimes only the genetic and pathologic findings settle the matter.

There are several other rare degenerative disorders with chorea, some of which have already been mentioned. A midlife progressive chorea without dementia (after more than 25 years follow-

up) that does not display the Huntington genotype has been reported. In at least one family in which this clinical picture is dominantly inherited, the fundamental defect is a mutation in the gene encoding the light chain (L chain) of ferritin (Curtis). Affected individuals have axonal changes in the pallidum with swollen, ubiquitin- and tau-positive aggregates; serum ferritin levels may be depressed. The implication of this mutation is that perturbations of iron metabolism may be toxic to neurons, a feature that also characterizes Hallervorden-Spatz disease (page 832).

Dentatorubropallidolysian atrophy (DRPLA), often misdiagnosed clinically as Huntington chorea, was described in four European families by Warner and associates and is discussed further on in the section on cerebellar degenerations. The extrapyramidal manifestations include chorea, myoclonus, and rigidity. Adult-onset chorea and dementia has been described with *propionic aciduria*; propionic acid is elevated in the plasma, urine, and CSF. This disorder must be added to other metabolic diseases described in Chap. 37 as causes of chorea and dyskinesia—such as glutaric aciduria, keratin sulfaturia, calcification of basal ganglia, phenylketonuria, and Hallervorden-Spatz disease (Hagberg et al).

Other problems in differential diagnosis include bilateral thalamic degeneration with dementia and chorea, referred to earlier; paroxysmal choreoathetosis (page 68); Wilson disease (page 830); acquired hepatocerebral degeneration (page 975); and, most often and especially, tardive dyskinesia (page 94). Many drugs in addition to the toxic effects of L-dopa and antipsychotic medications occasionally cause chorea (amphetamines, cocaine, tricyclic antidepressants, lithium, isoniazid).

Treatment The dopamine antagonist haloperidol, in daily doses of 2 to 10 mg, is probably the most effective agent in suppressing the movement disorder. Because of the danger of superimposing tardive dyskinesia on the chronic disorder, the chorea should be treated only if it is functionally disabling, using the smallest possible dosages. Haloperidol may also help alleviate abnormalities of behavior or emotional lability, but it does not alter the progress of the disease. The authors have not been impressed with the therapeutic effectiveness of other currently available drugs. Levodopa and other dopamine agonists make the chorea worse and, in the rigid form of the disease, evoke chorea. Drugs that deplete dopamine or block dopamine receptors—such as reserpine, clozapine, and tetrabenazine—suppress the chorea to some degree, but their side effects (drowsiness, akathisia, and tardive dyskinesia) outweigh their desired effects. The juvenile (rigid) form of the disease is probably best treated with antiparkinsonian drugs. Preliminary studies of the transplantation of fetal ganglionic tissue into the striatum achieved mixed results. The psychologic and social consequences of the disease require supportive therapy, and genetic counseling is essential. Huntington disease pursues a steadily progressive course and death occurs as mentioned, on average 15 to 20 years after onset, sometimes much earlier or later.

Acanthocytosis with Chorea

A few reports of a slowly progressive, familial chorea and dementia in association with an abnormality of erythrocytes have appeared in English, American, and Japanese journals. The disease has the following characteristics: (1) onset in adolescence or early adult life of generalized involuntary movements (described as chorea but including dystonia and tics), usually beginning as an orofacial dyskinesia and spreading to other parts of the body and to other neural

systems; (2) mild to moderate mental deterioration with behavioral disturbance in some but not all cases; (3) decreased or absent tendon reflexes and evidence of chronic axonal neuropathy and denervation atrophy of muscles; (4) atrophy and gliosis of the caudate nuclei and putamen but no neuronal loss in the cerebral cortex or other parts of the brain; (5) the defining element, acanthocytosis (thorny or spiky appearance of erythrocytes); and (6) an autosomal recessive inheritance pattern. The acanthocytosis, according to Sakai and coworkers, is due to an abnormal composition of covalently (tightly) bound fatty acids in erythrocyte membrane proteins (palmitic and docosahexanoic acids increased and stearic acid decreased). Although the inheritance is usually autosomal recessive, at least one family with the dominantly transmitted trait has been described. The acanthocytosis may be overlooked when it is mild but can be detected by scanning electron microscopy. In the series of 19 cases reported by Hardie and colleagues, the manifestations included dystonia, tics, vocalizations, rigidity, and lip and tongue biting; more than half had cognitive impairment or psychiatric features. The average age of onset was 32 years; 7 of the 19 cases were sporadic. The disease has been linked in almost all families to chromosome 9q, where there is a mutation in the gene encoding a large (3100–amino acid) protein designated *chorein* that is thought to be involved in cellular protein sorting and trafficking (Rampoldi). Some of the families with dominantly inherited neuroacanthocytosis have mutations in the *chorein* gene.

McLeod's disease, another choreiform disorder with acanthocytosis and the gradual development of chorea in middle to late life, is characterized by degeneration of the caudate and putamen and a myopathy (elevated serum CPK). These individuals have fewer facial tics and orofacial features than those with neuroacanthocytosis. McLeod's syndrome arises from mutations in a gene on the X chromosome that encodes the KX protein, which binds to surface Kell antigens on red cells. In addition to the primary KX gene mutations, these individuals show diminished Kell antigen expression on the red-cell surface.

Corticostriatospinal Degenerations

Included in this category are a somewhat heterogeneous group of degenerative diseases in which the symptoms of parkinsonism and corticospinal degeneration present in various combinations. Some of the diseases that make up this group have not been sharply delineated and are difficult to separate from one another (see also page 928).

Variants of this category of disease continue to appear. The authors have observed several patients in whom extreme rigidity, corticospinal signs, but no dementia have developed over a period of several years. In the later stages of the disease, the patient, while alert, is totally helpless—unable to speak, swallow, or move the limbs. Only eye movements are retained, and even these are hampered by supranuclear gaze palsies in advanced cases. Intellectual functioning appears to be better preserved than movement but is difficult to assess. Other bodily functions are intact. The course is slowly progressive and ends fatally in 5 to 10 years. There is no family history of similar disease, and there are no clues as to causation. Gilbert and colleagues have described similar cases with signs of Parkinson disease, motor neuron disease, and dementia; in their cases, there were no senile plaques or Lewy bodies. The concurrence of typical motor neuron disease and Parkinson disease may be coincidental, but Qureshi and colleagues described 13 patients in whom both clinical phenomena began within a short time

and they considered them to be related. In the variant described by Tandan and colleagues, an autosomal dominant syndrome of Charcot-Marie-Tooth polyneuropathy was combined with ptosis, parkinsonism, and dementia, again without Lewy bodies or senile plaques. Other variants have been described by Schmitt and co-workers and by Mata and colleagues. Hudson has reviewed 42 sporadic cases in which ALS-parkinsonism-dementia were combined (see References).

Under the title "Spastic Pseudosclerosis," Jakob, in 1921, described a chronic disease of middle to late adult life, characterized by abnormalities of behavior and intellect; weakness, ataxia, and spasticity of the limbs (chiefly the legs); extrapyramidal symptoms such as rigidity, slowness of movement, tremors, athetotic postures, and hesitant, dysarthric speech; and normal spinal fluid. The pathologic changes were diffuse and consisted mainly of an outfall of neurons in the frontal, temporal, and central motor gyri, corpus striatum, ventromedial thalamus, and bulbar motor nuclei. In one of Jakob's cases, there were also prominent changes in the anterior horn cells and corticospinal tracts in the spinal cord like those of ALS. The latter finding gave rise to Wilson's concept of the disease as a *corticostriatospinal degeneration*. A degenerative and probably familial disorder that had been described earlier by Creutzfeldt was considered by Spielmeyer to be sufficiently similar to the one of Jakob to warrant the designation *Creutzfeldt-Jakob disease*.

As discussed in Chap. 33, the disorder described by Creutzfeldt and Jakob has been a source of endless controversy because of its indeterminate character. On the one hand, it has been confused with the subacutely evolving myoclonic dementia, or subacute spongiform encephalopathy, which is now known to be an infection due to an unconventional transmissible prion agent. The authors believe that the latter disease, which is described on page 653, bears at best only a superficial resemblance to the one described by Creutzfeldt and Jakob and that the two disorders should be clearly separated. Unfortunately, the use of the eponym for the prion-related disease is so entrenched in medical usage that any attempt to delete it stands little chance of success. On the other hand, sporadic and familial cases that are not transmissible and lack a prominent spongiform change merge with a rather heterogeneous but overlapping group of degenerative disorders, all rare, including progressive dementia and spastic paraparesis, progressive frontotemporal dementia and ALS, the Parkinson-dementia-ALS complex of Guam, and the corticopallidospinal degeneration of Davison.

One is tempted to conclude that the spastic pseudosclerosis of Jakob may not constitute a disease type, and certainly everyone agrees that the term *pseudosclerosis* (also used for the Westphal-Strümpell form of hepatolenticular degeneration) is meaningless.

The *Guamanian Parkinson-dementia-ALS* complex deserves separate comment because it has been well defined in a large number of carefully studied cases with almost uniform clinical and pathologic features. The disease occurs in the indigenous Chamorro peoples of Guam and the Mariana islands, predominantly in men between ages 50 and 60. Progressive parkinsonism and dementia are combined with upper or lower motor neuron disease (ALS is also common among the Chamorro), leading to death in 5 years. The pathologic changes, described by Hirano and others, consist of severe cortical atrophy with neurofibrillary tangles but, notably, no detectable amyloid plaques, even with sensitive neurochemical staining. As in Parkinson disease, the substantia nigra and to a lesser extent other pigmented nuclei are depopulated of nerve cells but contain no Lewy bodies. Cases with amyotrophy show the typ-

ical loss of anterior horn cells. The cause of the Guamanian multisystem degeneration is not known, although several studies have incriminated one or more adverse environmental influences, including putative neurotoxins in the food supply.

Familial Dementia with Spastic Paraparesis

From time to time the authors have encountered families in which several members developed a spastic paraparesis and a gradual failure of intellectual function during the middle adult years. The patient's mental horizon narrowed gradually, and the capacity for high-level thinking diminished; in addition, the examination showed appropriately exaggerated tendon reflexes, clonus, and Babinski signs. In one such family the illness had occurred in two generations; in another, three brothers in a single generation were afflicted. Skre described two recessive types of hereditary spastic paraparesia in Norway, one with onset in childhood, the other in adult life. In contrast to the dominant form (see further on), the recessive types displayed evidence of more widespread involvement of the nervous system, including dementia, cerebellar ataxia, and epilepsy. Also, Cross and McKusick have observed a recessive type of paraparesia accompanied by dementia beginning in adolescence. They named it the *Mast syndrome*, after the afflicted family.

Worster-Drought and others have reported the pathologic findings in two cases of this type. In addition to senile plaques and neurofibrillary changes, there was demyelination of the subcortical white matter and corpus callosum and a "patchy but gross swelling of the arterioles," which gave the staining reactions for amyloid ("Scholz's perivascular plaques"). Van Bogaert and associates published an account of similar cases that showed the characteristic pathologic features of Alzheimer disease.

Adult forms of metachromatic leukodystrophy and adrenoleukodystrophy may present with a similar clinical picture (Chap. 37). Quite rare instances of the same syndrome with adult onset have turned out to be due to phenylketonuria or other aminoacidopathies (see Chap. 37). Another interesting association of familial spastic paraparesia is with progressive cerebellar ataxia. Fully one-third of the cases that we have seen with such a spastic weakness were also ataxic and would fall into the category of spinocerebellar degenerations. Yet another variant of this group of diseases has been described by Farmer and colleagues; the inheritance in their cases was autosomal dominant, and the main clinical features were deafness and dizziness, ataxia, chorea, seizures, and dementia, evolving in that order. Postmortem examinations of two patients disclosed calcification in the globus pallidus, neuronal loss in the dentate nuclei, and destruction of myelinated fibers in the centrum semiovale.

Adult Polyglucosan Body Disease

Under this title, Robitaille and colleagues have described a distinct type of progressive neurologic disease in adults characterized clinically by spasticity, chorea, dementia, and a predominantly sensory polyneuropathy. Structures that closely resembled Lafora bodies and corpora amylacea were found in large numbers in both central and peripheral neural processes (mainly in axons) and also in astrocytes. These basophilic PAS-positive structures (up to 40 μm in size) were composed of glucose polymers (polyglucosans) and were readily demonstrated in sural nerve biopsies. Some were also found in the heart and liver.

More recently, Rifaï and associates have reviewed the findings in 25 cases of this disease—one observed personally and 24 reported previously. The dementia appears to be relatively mild, consisting of impairment of retentive memory, dysnomia, dyscalculia, and sometimes expressive dysphasia and deficits of “visual integration”; this was overshadowed by the rigidity and spasticity of the limbs and the peripheral nerve disorder. Nerve conduction velocities were diminished and the leg muscles were denervated. Moderate degrees of generalized cerebral atrophy, multifocal areas of white matter rarefaction, and increased iron deposition in the putamina was disclosed by MRI. The finding of polyglycosan axon inclusion in biopsied nerve confirms the diagnosis. The disease has sometimes been misdiagnosed as adrenoleukodystrophy. Its status is unclear to the authors, and there is no treatment.

DISEASES CHARACTERIZED BY ABNORMALITIES OF POSTURE AND MOVEMENT

Parkinson Disease (Paralysis Agitans)

This common disease, known since ancient times, was first cogently described by James Parkinson in 1817. In his words, it is characterized by “involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace, the senses and intellect being uninjured.” Strangely, his essay contains no reference to rigidity or to slowness of movement, and it stresses unduly the reduction in muscular power. The same criticism can be leveled against the term *paralysis agitans*, which appeared for the first time in 1841 in Marshall Hall’s textbook *Diseases and Derangements of the Nervous System*.

The natural history of the disease is of interest. As a rule, it begins between 40 and 70 years of age, with the peak age of onset in the sixth decade. It is infrequent before 30 years of age, and most series contain a somewhat larger proportion of men. Trauma, emotional upset, overwork, exposure to cold, “rigid personality,” and so on, are among many factors that have been suggested over the years as predisposing to the disease, but there is no convincing evidence to support any such claims. A possible relationship to repeated cerebral trauma and to the “punch-drunk” syndrome (dementia pugilistica, page 863) has been particularly problematic and is unresolved despite several celebrated cases (Lees). Idiopathic Parkinson disease is observed in all countries, all ethnic groups, and all socioeconomic classes, although the incidence in African Americans is only one-quarter that in whites. In Asians, the incidence is one-third to one-half that in whites. The disease is frequent in North America, where there are approximately 1 million patients, constituting about 1 percent of the population over the age of 65 years. The incidence in all European countries where vital statistics are kept is similar.

Genetic Aspects Considering its frequency, coincidence in a family on the basis of chance occurrence might be as high as 5 percent. A lack of concordance of Parkinson disease in twins was at first thought to negate the role of genetic factors, but a study of dopamine metabolism utilizing PET scanning has shown that 75 percent of asymptomatic twins of Parkinson patients had evidence of striatal dysfunction and only a small portion of dizygotic twins showed these changes (Piccini et al). These data suggest a more substantial role for an inherited trait in cases of ostensibly sporadic disease

(see below regarding the Parkin mutations). Also, Krüger and colleagues have reported a 13-fold increased susceptibility to the disease in patients who harbor a combination of certain α -synuclein and apolipoprotein E genotypes, but this awaits confirmation.

While familial cases are decidedly rare (Table 39-2), Golbe and colleagues advanced the understanding of the genetic underpinning of the disease by describing two large kindreds (probably related and originating from a small town in southern Italy) in which 41 patients in four generations were affected. The illness in their cases was characteristic of Parkinson disease both clinically and pathologically, the only unusual features being a somewhat earlier onset (mean age 46 years), a relatively rapid course (10 years from onset to death), and a low incidence of tremor (only 8 of the 41 patients). The dominantly inherited parkinsonism described by Dwork and others also differed clinically (onset in the third decade, prominence of dystonia) and pathologically (absence of Lewy bodies) from classic Parkinson disease. It was in the latter kindred and in three Greek families that Polymeropoulos et al identified a locus on chromosome 4q that contained a mutation in the gene encoding the protein α -synuclein, a main component of the Lewy body. Other families in which there have been mendelian patterns of inheritance have gene defects at other sites. These genetic data have been reviewed by Dunnett and Björklund. It is now clear that while such mutations are uncommon in the usual late-onset sporadic form of Parkinson disease, they are predominant in earlier-onset cases (see below). The main mutations are summarized in Table 39-2.

More recently, there has been emphasis on mutations on 1 of 12 exons in the so-called *Park2 gene*, which codes for the protein parkin on chromosome 6q (see Table 39-2). The commonest types are point mutations or deletions in exon 7, but abnormalities of the other exons evince similar syndromes. Homozygous mutations generally give rise to early-onset disease, but certain hemizygous changes (in exon 7) are also associated with a later onset. The resultant syndromes have been termed *parkin disease* to distinguish them from the idiopathic variety. It has been estimated by Kahn and colleagues that 50 percent of families that display an early onset of Parkinson disease and 18 percent of sporadic cases with early onset (before age 40) harbor mutations in this gene. Perhaps of greater clinical interest is finding that up to 2 percent of late-onset cases are due to parkin mutations. Sequencing of this gene is now available in commercial laboratories for the purposes of detecting mutations.

From a clinical perspective, the presentation of the late-onset cases with parkin mutations has been quite variable. Collectively they can often be identified by two outstanding features: an extreme sensitivity to L-dopa, maintaining an almost complete suppression of symptoms over decades with only small doses of medication; also, they have a low threshold for dyskinesias. We can corroborate from experience with our own patients an excellent response of tremor, postural changes, and bradykinesia to anticholinergic drugs. Moreover, most of these patients may enjoy a remarkable restorative benefit from sleep, which creates an apparent diurnal pattern of symptoms. Several series, particularly the ones of Lohmann and of Kahn and colleagues, indicate that there may be a wide variety of additional features: hyperreflexia (which we can also attest to); cervical, foot, or other focal dystonias, sometimes induced only by exercise; and, less often, autonomic dysfunction, peripheral neuropathy, and psychiatric symptoms. The sensitivity to medication and sleep benefit have long been known as the distinguishing components of juvenile-onset parkinsonism, which proves also to be derived from a different parkin mutation.

Table 39-2
Genetic defects associated with Parkinson's disease

NOTATION	CHROMOSOME	GENE	GENETICS	AGE OF ONSET	LEWY BODIES	SPECIAL FEATURES
Park1	4q	α -synuclein	AD	30–40 years	+	Two main mutations: A53T, A30P; promote oligomerization of α -synuclein
Park2	6q25	<i>parkin</i>	AR	20–40 years	—	Accounts for 50% of early-onset inherited PD; 20% of “sporadic” early onset cases.
Park5	4p	<i>UCH-L1</i>	AD	50's	+	Gene is E3 ubiquitin protein ligase; activity is decreased by parkin mutations. PET: widespread reductions in dopamine uptake (unlike sporadic PD).
Park6	1p36	<i>PINK1</i>	AR	varies	?	Mitochondrial gene.
Park7	1p36	<i>DJ-1</i>	AR	30's	?	Slow progression; gene plays role in cellular response to oxidative stress.
Park 8	12 cent	<i>dardarin</i>	AD	late	+/-	Gene is novel kinase.
NR4A2	2q22	<i>NURR1</i>	AD		?	Gene is implicated in the formation and identity of dopaminergic neurons.

Clinical Features A tetrad of hypo- and bradykinesia, resting tremor, postural instability, and rigidity are the core features of Parkinson disease. These are evident as expressionless face, poverty and slowness of voluntary movement, “resting” tremor, stooped posture, axial instability, rigidity, and festinating gait. These manifestations of basal ganglionic disease have been fully described in Chap. 4, and only certain diagnostic problems and nuances of the clinical picture need be considered here. The early symptoms may be difficult to appreciate and are often overlooked by family members because they evolve slowly and tend to be attributed to the natural changes of aging. The voice becomes soft and monotonous. For a long time the patient may not be conscious of the inroads of the disease. At first the only complaints may be of aching of the back, neck, shoulders, or hips and of vague weakness. A slight stiffness and slowness of movement or a reduction in the natural swing of one arm during walking are ignored, until one day it occurs to the physician or to a member of the family that the patient has the cast of Parkinson disease. Infrequency of blinking, as pointed out originally by Pierre Marie, is often a helpful early sign. The usual blink rate (12 to 20 per minute) is reduced in the parkinsonian patient to 5 to 10 per minute, and with it there is a slight widening of the palpebral fissures, creating a stare (Stellwag sign). A reduction in movements of the small facial muscles imparts the characteristic expressionless “masked” appearance (hypomimia). When seated, the patient makes fewer small shifts and adjustments of position than the normal person (hypokinesia), and the fingers straighten and assume a flexed and adducted posture at the metacarpophalangeal joints.

The characteristic tremor, which usually involves a hand, is often listed as the initial sign; but in at least half the cases, observant family members will already have remarked on the patient's relative immobility and reduction or slowness of movement. More-

over, in 20 to 25 percent of cases the tremor is mild and intermittent or evident in only one finger or one hand. The tremor of the fully developed case takes several forms, as was remarked in Chap. 6. The four-per-second “pill-rolling” tremor of the thumb and fingers, while most characteristic, is seen in only a proportion of patients and is typically present when the hand is motionless, i.e., not used in voluntary movement (hence the term *resting tremor*). Complete relaxation, however, greatly reduces or abolishes the tremor, and a volitional movement usually dampens it momentarily. The rhythmic beat coincides with an alternating burst of activity in agonist and antagonist muscles in the electromyogram (EMG); hence the apt description *alternating tremor* is also applied. The arm, jaw, tongue, eyelids, and foot are less often involved. Even the least degree of tremor is felt during passive movement of a rigid part (cogwheel phenomenon, or Negro's sign). The tremor shows surprising fluctuations in severity and is aggravated by walking and excitement, but the frequency of the tremor remains constant (Hunker and Abbs). *It bears repetition that one side of the body is typically involved before the other*, and the classic tremor then remains asymmetrical as the illness advances.

Lance and associates have called attention to a second common type of tremor in Parkinson disease—a fine, seven- to eight-per-second, slightly irregular action tremor of the outstretched fingers and hands. This tremor, unlike the slower one, persists throughout voluntary movement, is not evident with the limb in a resting position, and is more easily suppressed by relaxation. Electromyographically, it lacks the alternating bursts of action potentials seen in the more typical tremor and resembles, if not equates with, essential tremor (page 81, Table 6-1)). It is subject to different medications than those used for the alternating tremor. The Parkinson patient may have either type of tremor or both.

We have been less impressed with rigidity and hypertonus as

important early findings. These features tend to appear in the more advanced stages of the disease. Once rigidity develops, it is constantly present; it can be felt by the palpating finger and seen as a salience of muscle groups even when the patient relaxes. When the examiner passively moves the limb, a mild resistance appears from the start (without the short free interval that characterizes spasticity), and it continues evenly throughout the movement in both flexor and extensor groups, being interrupted only by the cogwheel phenomenon. Both the rigidity and its cogwheel feature can be elicited or enhanced by having the patient engage the opposite limb in a motor task requiring some degree of concentration, such as tracing circles in the air or touching each finger to the thumb. In the muscles of the trunk, postural hypertonus predominates in the flexor groups and confers on the patient the characteristic flexed posture. Other particulars of the parkinsonian disorders of muscle tone, stance, and gait are discussed further in Chaps. 4 and 7.

Regarding the quality of volitional and postural movements, a few additional points should be made. The patient is slow and ineffective in attempts to deliver a quick hard blow; he cannot complete a quick (ballistic) movement. On the EMG, the normal single burst of agonist-antagonist-agonist sequence of energizing activity is replaced by several brief bursts (Hallett and Khoshbin). Alternating movements, at first successful, if repeated become progressively impeded and finally are blocked completely or adopt the rhythm of the patient's alternating tremor. Also, the patient has difficulty in executing two motor acts simultaneously. Originally the impaired facility of movement was attributed to rigidity, but the observation that appropriately placed surgical lesions in the brain can abolish rigidity without affecting the disorder of movement refutes this interpretation. Thus the difficulty is not one of rigidity but one of *bradykinesia* (slowness in both the initiation and execution of movement in contrast to the reduced frequency and amplitude of movement, *hypokinesia*), the extreme degree of bradykinesia being akinesia, in which the patient is motionless. The bradykinetic deficits underlie the characteristic poverty of movement, reflected also by infrequency of swallowing, slowness of chewing, a limited capacity to make postural adjustments of the body and limbs in response to displacement of these parts, a lack of small "movements of cooperation" (as in arising from a chair without first adjusting the feet), absence of arm swing in walking, etc. Despite a perception of muscle weakness, the patient is able to generate normal or near-normal power, especially in the large muscles; however, in the small ones, strength is slightly diminished.

As the disorder of movement worsens, all customary activities show the effects. Handwriting becomes small (micrographia), tremulous, and cramped, as first noted by Charcot. The voice softens and the speech seems hurried and monotonous and mumbling; the voice becomes less audible and finally the patient only whispers. Caekebeke and coworkers refer to the speech disorder as a "hypokinetic dysarthria"; they attribute it to respiratory, phonatory, and articulatory dysfunction. There is a failure to fully close the mouth. The consumption of a meal takes an inordinately long time. Each morsel of food must be swallowed before the next bite is taken.

Walking becomes reduced to a shuffle; the patient frequently loses balance, and in walking forward or backward may seem to be "chasing" the body's center of gravity with a series of short steps in order to avoid falling (festination). Defense and righting reactions are faulty. Falls do occur, but surprisingly infrequently given the degree of postural instability. Gait is typically improved by sensory guidance, as by holding the patient at the elbow. Obstacles such as door thresholds have the opposite effect, at times

causing the patient to "freeze" in place. Getting in and out of a car or elevator or walking into a room or in a hall are then particularly difficult. Difficulty in turning over in bed is a characteristic feature as the illness advances, but the patient rarely volunteers this information; several of our patients have fallen out of bed at a frequency that suggests a connection to their reduced mobility. Shaving or applying lipstick becomes difficult, as the facial muscles become more immobile and rigid.

Persistent extension or clawing of the toes, jaw clenching, and other fragments of dystonia, often painful, may enter the picture but are not usually early findings. (These are particularly resistant to treatment.)

As noted above, these various motor impediments and tremors characteristically begin in one limb (more often the left) and spread to one side and later to both sides, until the patient is quite helpless. Yet in the excitement of some unusual circumstance (as escaping from a fire, for example), the patient with all but the most advanced disease is capable of brief but remarkably effective movement (*kinesthesia paradoxica*).

Regarding other elicitable neurologic signs, there is an inability to inhibit blinking in response to a tap over the bridge of the nose or glabella (Myerson sign), but grasp and suck reflexes are not present and buccal and jaw jerks are rarely enhanced. Commonly there is an impairment of upward gaze and convergence; if prominent or noted early in the disease, this sign suggests more the possibility of progressive supranuclear palsy. The bradykinesia may extend to eye movements, in that there is a delay in the initiation of gaze to one side, slowing of conjugate movements (decreased maximal saccadic velocity), hypometric saccades, and breakdown of pursuit movements into small saccades. There are no sensory changes, but a variety of paresthetic complaints are common. Drooling is troublesome; an excess flow of saliva has been assumed, but actually the problem is one of failure to swallow with normal frequency. Seborrhea and excessive sweating are probably secondary as well, the former due to failure to cleanse the face sufficiently, the latter to the effects of the constant motor activity.

Postural instability can be elicited by tugging at the patient's shoulders from behind and noting the lack of a small step backward to maintain balance. The tendon reflexes vary, as they do in normal individuals, from being barely elicitable to brisk. Even when parkinsonian symptoms are confined to one side of the body, the reflexes are usually equal on the two sides, and the plantar responses are flexor. Exceptionally, the reflexes on the affected side are slightly brisker, which raises the question of corticospinal involvement; but the plantar reflex remains flexor. In these respects, the clinical picture differs from that of corticobasal ganglionic degeneration, in which rigidity, hyperactive tendon reflexes, and Babinski signs are combined with apraxia (see further on). There is a tendency to orthostatic hypotension and sometimes syncope; this has been attributed by Rajput and Rozdilsky to cell loss in the sympathetic ganglia. However, syncope is never as prominent as in the Shy-Drager type of striatonigral degeneration (page 925). It is worth mentioning that two of our younger Parkinson patients with recurrent syncope proved to have cardiac arrhythmias, which were cured by the insertion of a pacemaker, hence other causes of fainting are still to be considered.

At times, Parkinson disease is complicated by a dementia, a feature that had been commented upon by Charcot. The reported frequency of this combination varies considerably, based on the selection of patients and type of testing. An estimate of 10 to 15 percent (Mayeux et al) is the generally accepted figure and matches

our experience. The incidence increases with advancing age, approaching 65 percent in Parkinson patients above 80 years of age, but it may be disabling even in patients in their late fifties. In some instances of Parkinson disease with dementia, MRI reveals lesions in the cerebral white matter (in T1-weighted images). They are not seen in parkinsonians without dementia. The pathologic basis of the dementia is discussed below.

The overall course of the disease is quite variable. In the majority of patients, the mean period of time from inception of the disease to a chairbound state is 7.5 years, but again, with a wide range (Hoehn and Yahr; Martilla and Rinne). On the other hand, as many as one-third of cases are relatively mild and such patients may remain stable for 10 years or more.

Much can still be gained from perusal of the study by Hoehn and Yahr, published in 1967, before the widespread use of L-dopa. Table 39-3 is reproduced from that paper.

Diagnosis Early in the course of Parkinson disease, when only a slight asymmetry of stride or an ineptitude of one hand is present and tremor has yet to appear and impart the unmistakable stamp of the disease, a number of small signs already mentioned may be helpful in diagnosis. These include a reduced blink rate, the Myerson glabellar sign, a lack of arm swing, digital impedance in a succession of movements (a tendency for rapid alternating movements to be slowed, to assume a tremor rhythm, or to be blocked altogether), and perceptible rigidity of one arm when the opposite limb is occupied in a motor task such as tracing circles in the air. Lack of a Babinski sign or of increased tendon reflexes in the affected limbs eliminates a corticospinal lesion as the cause of slowed movements, and lack of a grasp reflex helps to exclude a premotor cerebral disorder.

The two main difficulties in diagnosis are to distinguish typical Parkinson disease from the many parkinsonian syndromes caused by other degenerative diseases and by medications or toxins and to distinguish the Parkinson tremor from other types. It is worth noting that Parkinson disease is far more common than any of the syndromes that resemble it. Bradykinesia and rigidity of the limbs and axial musculature are symptoms shared with other forms of parkinsonism, but only in Parkinson disease does one see an early sign of "resting" alternating tremor that is more prominent in one arm.

The typical signs of Parkinson disease, when present in their entirety, impart an unmistakable clinical picture. When not all the signs are evident, there is no alternative but to re-examine the patient at several-month intervals until it is clear that Parkinson dis-

ease is present or until the signature of another degenerative process becomes evident (e.g., vertical gaze impairment in progressive supranuclear palsy; dysautonomia with fainting, bladder, or vocal cord signs in striatonigral degeneration; early and rapidly evolving dementia or psychosis in Lewy body disease, or apraxia in corticobasal ganglionic degeneration). If the patient's symptoms warrant, a beneficial response to levodopa or a dopamine agonist also gives a reasonably secure although not entirely conclusive indication of the presence of Parkinson disease (see further on). The other parkinsonian syndromes are for the most part unchanged by the drug. Conversely, although some experts disagree, we have adhered to the notion that complete resistance of the symptoms to L-dopa early in the illness makes the diagnosis unlikely.

The epidemic of encephalitis lethargica (von Economo encephalitis) that spread over western Europe and the United States after the First World War left great numbers of parkinsonian cases in its wake. No definite instance of this form of encephalitis had been recorded before the period 1914–1918, and virtually none has been seen since 1930; hence postencephalitic parkinsonism is no longer a diagnostic consideration. Rarely, a Parkinson-like syndrome has been described following other forms of encephalitis, particularly with Japanese B virus, West Nile virus, and eastern equine encephalitis. In the few cases caused by these viruses that we have observed, there has been symmetrical rigidity, hypokinesia, and little or no tremor.

In England and Europe, an "arteriopathic" or "arteriosclerotic" form of Parkinson disease was at one time much diagnosed, but we have never been convinced of its reality. Pseudobulbar palsy from a series of lacunar infarcts or from Binswanger disease (page 707) can cause a clinical picture that simulates certain aspects of Parkinson disease, but unilateral and bilateral corticospinal tract signs, hyperactive facial reflexes, spasmodic crying and laughing, and other characteristic features distinguish spastic bulbar palsy from Parkinson disease. Of course, the parkinsonian patient in advancing years is not impervious to cerebrovascular disease, and the two conditions then overlap.

Normal-pressure hydrocephalus can undoubtedly create a syndrome resembling Parkinson disease, particularly in regard to gait and postural instability and at times to bradykinesia; but rigid postures, slowness of alternating movements, hypokinetic ballistic movements, and resting tremor are not part of the clinical picture. Sometimes a lumbar puncture gives surprising benefit, then indicating hydrocephalus as the cause of the motor slowing.

Essential tremor is distinguished by its fine, quick quality, its tendency to become manifest during volitional movement and to disappear when the limb is in a position of repose, and the lack of associated slowness of movement, flexed postures, etc. The head and voice are more often involved in essential tremor than in Parkinson disease. Some of the slower, alternating forms of essential tremor are difficult to distinguish from parkinsonian tremor; one can only wait to see whether it is the first manifestation of Parkinson disease. An asymmetrical or unilateral tremor favors Parkinson disease. Also as noted, a faster oscillation is often mixed with the slow alternating Parkinson tremor, but the fast-frequency tremor is seldom an opening feature of the disease.

Progressive supranuclear palsy (see further on) is characterized by rigidity and dystonic postures of the neck and shoulders, a staring and immobile countenance, and a tendency to topple when walking—all of which are vaguely suggestive of Parkinson disease. Early falls are particularly suggestive of this disease, and are not typical of Parkinson disease until its late stages; there are, how-

Table 39-3

Initial symptoms in patients with Parkinson disease (Adapted from Hoehn and Yahr's study of 183 idiopathic cases)

Tremor	70%
Gait disturbance	11%
Stiffness	10%
Slowness	10%
Muscle aches	8%
Loss of dexterity	7%
Handwriting disturbance	5%
Depression, nervousness, other psychiatric disturbance	4%
Speech disturbance	3%

ever, exceptions. Inability to produce vertical saccades and, later, paralysis of upward and downward gaze and eventually of lateral gaze with retention of reflex eye movements establish the diagnosis in most cases. Strict adherence to the diagnostic criteria for Parkinson disease also permits its differentiation from corticostriatal-spinal, striatonigral, and corticobasal ganglionic degeneration as well as Machado-Joseph disease—all of which are discussed in other parts of this chapter.

The rapid onset of parkinsonism should suggest exposure to neuroleptic medications or a variant of Creutzfeldt-Jakob disease.

Paucity of movement, unchanging attitudes and postural sets, and a slightly stiff and unbalanced gait may be observed in patients with an anergic or hypokinetic ("retarded") type of depression. Since as many as 25 to 30 percent of parkinsonian patients are depressed, the separation of these two conditions is at times difficult. The authors have seen patients who were called parkinsonian by competent neurologists but whose movements became normal when antidepressant medication or electroconvulsive therapy was given. Several such patients have nonetheless insisted that L-dopa helps them in some nondescript way.

The rapid onset of the Parkinson syndrome, especially in conjunction with other medical diseases, should always raise the suspicion of drug effects; phenothiazines, haloperidol, and the neuroleptics pimozide and metoclopramide, used at times as antiemetics, all cause a slight masking of the face, stiffness of the trunk and limbs, lack of arm swing, fine tremor of the hands, and mumbling speech. They may also evoke an inner restlessness, a "muscular impatience," an inability to sit still, and a compulsion to move about much like that which occurs at times in the parkinsonian patient (akathisia; page 97). Spasms of the neck, face, and jaw muscles (open mouth, protruded tongue, retrocollis or torticollis, grimacing) may also be provoked by such drugs. Even the newer antipsychotic medications, favored specifically because of a putative lack of extrapyramidal effects, may be at fault. A mild, localized rigidity of an arm due to local tetanus was studied by R. D. Adams in a patient who had been referred as a case of acute parkinsonism.

All in all, if one adheres to the strict definition of Parkinson disease—bradykinesia, "resting" tremor, postural changes and instability, cogwheel rigidity, and response to L-dopa—errors in diagnosis are few. Yet in a series of 100 cases, studied clinically and pathologically by Hughes and associates, the diagnosis was inaccurate in 25 percent. The reasons are that about this number of Parkinson patients fail to display the characteristic tremor and about 10 percent are said to not respond to L-dopa. These authors noted that early dementia and autonomic disorder and the presence of ataxia and corticospinal signs were reliable guides to an alternate diagnosis.

Pathology and Pathogenesis The most constant and pertinent finding in both idiopathic and postencephalitic Parkinson disease is a loss of pigmented cells in the substantia nigra and other pigmented nuclei (locus ceruleus, dorsal motor nucleus of the vagus). The substantia nigra is visibly pale to the naked eye; microscopically, the pigmented nuclei show a marked depletion of cells and replacement gliosis, and some of the remaining cells have reduced quantities of melanin, findings that enable one to state with confidence that the patient must have suffered from Parkinson disease. Also, many of the remaining cells of the pigmented nuclei contain eosinophilic cytoplasmic inclusions, surrounded by a faint halo, called Lewy bodies (Fig. 39-5). These are seen in practically all

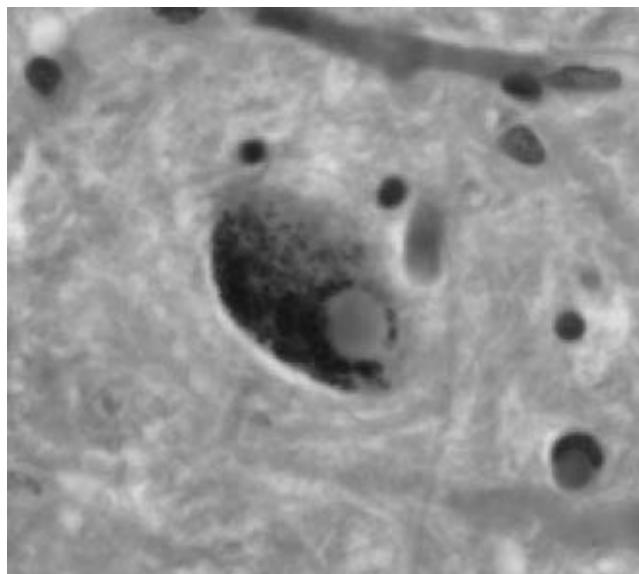

Figure 39-5. Photomicrograph of a round Lewy body inclusion in the cytoplasm of a nigral neuron. (Taken from H and E.) (Courtesy of M. Frosch, M.D., PhD.)

cases of idiopathic Parkinson disease. They were generally absent in postencephalitic cases, but neurofibrillary tangles were the usual nigral cell abnormalities. Both of these cellular abnormalities appear occasionally in the substantia nigra of aged, nonparkinsonian individuals. Possibly the individuals with Lewy bodies would have developed Parkinson disease if had they lived a few more years.

Noteworthy is the finding by McGeer et al that nigral cells normally diminish with age, from a maximal complement of about 425,000 to 200,000 at age 80. Tyrosine-hydroxylase, the rate-limiting enzyme for the synthesis of dopamine, diminishes correspondingly. However, these authors and others have found that in patients with Parkinson disease, the number of pigmented neurons was reduced to 30 percent or less of that in age-matched controls. Using more refined counting techniques, Pakkenberg and coworkers estimated the average total number of pigmented neurons to be 550,000 and to be reduced in absolute numbers by 66 percent in Parkinson patients. (The number of nonpigmented neurons was reduced in Parkinson cases by only 24 percent.) Thus, aging contributes importantly to nigral cell loss, but the cell depletion is so much more marked in Parkinson disease that some factor other than aging must also be operative.

Other depletions of cells are widespread as mentioned, but they have not been quantitatively evaluated and their significance is less clear. There is neuronal loss in the mesencephalic reticular formation, near the substantia nigra. These cells project to the thalamus and limbic lobes. In the sympathetic ganglia, there is slight neuronal loss and Lewy bodies are seen. This is also true of the pigmented nuclei of the lower brainstem as well as of neuronal populations in the putamen, caudatum, pallidum, and substantia innominata. On the other hand, dopaminergic neurons that project to cortical and limbic structures, to caudate nucleus and nucleus accumbens, and to periaqueductal gray matter and spinal cord are affected little or not at all. The lack of a consistent lesion in either the striatum or the pallidum is noteworthy in view of the reciprocal connections between the striatum and the substantia nigra and the depletion of striatal dopamine, based on the loss of nigral projections, that characterizes the disease.

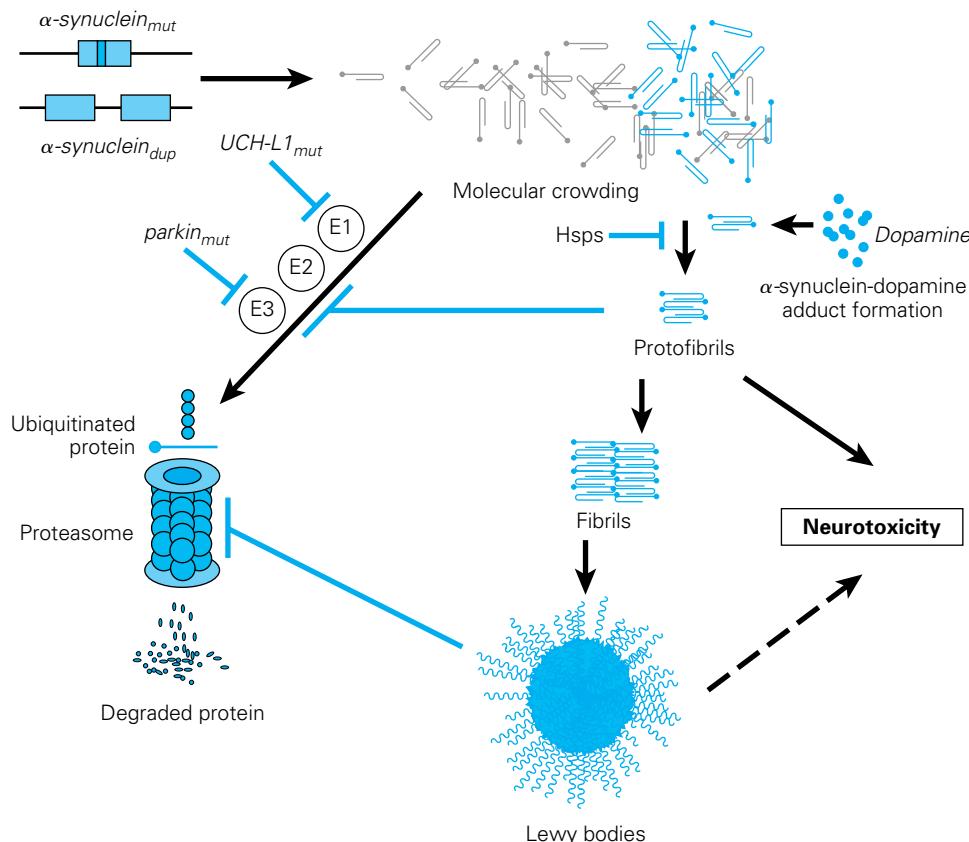

Figure 39-6. Schematic diagram of proposed mechanisms of α -synuclein toxicity in Parkinson disease. In this model, α -synuclein levels are elevated by (a) duplication of one copy of the α -synuclein gene; (b) point mutations in the α -synuclein gene that generate excessive accumulations of synuclein; or (c) mutations in parkin and UCH-L1 genes that reduce normal removal of synuclein by the proteasomes. The excess of synuclein polymerizes to form protofibrils, a process that is enhanced by defects in heat shock proteins (Hsps) or by the action of dopamine, which binds to synuclein. In turn, this leads to formation of Lewy bodies. This model attributes the neurotoxicity to either the protofibrils or the Lewy bodies. (Adapted by permission from Eriksen JL, Dawson TM, Dickson DW, Petrucelli L: Caught in the act: α -Synuclein is the culprit in Parkinson's disease. *Neuron* 40:453–456, 2003.)

The statistical data relating Parkinson and Alzheimer diseases are difficult to assess because of different methods of examination from one reported series to another (Quinn et al). Nevertheless, the overlap of the two diseases is more than fortuitous, as indicated in an earlier part of this chapter. In our own pathologic material, the majority of the demented Parkinson patients showed some Alzheimer-type changes, but there were several in whom few plaques or neurofibrillary changes could be found or in whom the cortical neuronal loss was accompanied by a widespread distribution of Lewy bodies marking the process as a Lewy body dementia (see earlier discussion).

Of interest has been the observation, both in humans and in monkeys, that a neurotoxin (known as MPTP) produces irreversible signs of parkinsonism and selective destruction of cells in the substantia nigra (this is discussed further on). The toxin, an analogue of meperidine, which was self-administered by addicts, binds with high affinity to monoamine oxidase, an extraneuronal enzyme that transforms it to a toxic metabolite, pyridinium MPP. The latter is bound by the melanin in the dopaminergic nigral neurons in sufficient concentration to destroy the cells. The precise mechanism by which MPTP produces the Parkinson syndrome is unsettled. One hypothesis is that the inner segment of the globus pallidus

is rendered hyperactive because of reduction of the influence of gamma-aminobutyric acid (GABA) of the subthalamic nucleus. The hypothesis of some other environmental toxin as a cause of Parkinson disease has been greatly stimulated by the MPTP findings (see Uhl et al; also the review by Snyder and D'Amato). Indeed, Parkinson disease is slightly more frequent in industrialized countries and agrarian regions where toxins are commonly used, but its universal occurrence would argue against this hypothesis. Despite extensive study, to date no chemical toxin or heavy metal, has been incriminated in the causation of Parkinson disease. Some theories hold that a toxin might be implicated only on a genetic background predisposing to the disease. The MPTP disease serves best as a model for the neurophysiologic and neurochemical changes of Parkinson disease, but in many other respects it does not reflect the naturally occurring disorder (e.g., the absence of Lewy bodies).

The most provocative recent discoveries have involved the nuclear and synaptic protein α -synuclein, the main component of Lewy bodies in both the sporadic and inherited forms of Parkinson

disease as well as in Lewy body disease, as mentioned earlier. Synuclein normally exists in a soluble unfolded form, but in high concentrations it forms aggregates of filaments, which are the main constituent of the Lewy body. Immunostaining techniques also disclose less specific proteins, such as ubiquitin and tau, within the Lewy bodies. Furthermore, as noted earlier, in unrelated families with a rare autosomal dominant form of Parkinson disease, three different mutations on chromosome 4 code for an aberrant form of synuclein that decreases its stability and promotes its aggregation (Polymeropoulos et al). A family has also been described in which the primary genetic cause is an extra nonmutant copy of the α -synuclein gene (Singleton). Additionally, some cases of familial parkinsonism are found in families with mutations of genes that control the removal of α -synuclein from the cell via a proteasomal pathway. Together, these findings indicate that instability and the misfolding of α -synuclein may be the primary protein defect in these forms of Parkinson disease. In this view, somewhat analogous to the amyloid hypothesis for Alzheimer disease, the propensity to misfolding is increased by elevated levels of α -synuclein, and misfolded proteins form toxic protofibrils and then Lewy bodies. This process is accelerated by defects in heat shock proteins that chaperone α -synuclein into and out of the cell (Fig. 39-2). Curiously, Lewy bodies are not found in patients with most of the parkin-

mutations. It must be emphasized, just as it was in Alzheimer disease, that no genetic error relating to synuclein has been found in patients with sporadic Parkinson disease.

Parkin is a ubiquitin protein ligase that participates in the removal of unnecessary proteins from cells through the proteosomal system (Fig. 39-6). Attachment of parkin and ubiquitin to cytosolic proteins is understood to be an obligatory step in the disposal of proteins by proteasomes. Mutations in the parkin gene lead either to an inadequacy or misfolding of synuclein, resulting in its accumulation, or to the disruption of disposal of proteins in dopamine-producing cells. The importance of the ubiquitination pathway in this disease is further highlighted by the report that parkinsonian features are present in a family with mutations in ubiquitin carboxy-terminal hydrolase L1 (UCHL-1) (Table 39-2). These relationships and the processing of synuclein in the cell are illustrated in Fig. 39-6. It must be emphasized that some of the notions illustrated are speculative or, more specifically, are derived largely from the molecular study of familial Parkinson disease and therefore may not apply to the sporadic disease. They do, however, accurately describe the pathways involved in the handling of synuclein and are therefore likely to be implicated in idiopathic Parkinson disease.

Several other gene defects are of interest in familial parkinsonism. One is a dominantly inherited mutation in the gene *Nurr1*, whose normal function is to specify the identity of dopaminergic neurons. Another is in recessively inherited parkinsonism due to defects in the gene *DJ-1*, a protein that is essential for the normal neuronal response to oxidative stress. Also, a disease-causing mutation in the gene termed "PINK," corresponding to *Park6*, codes for a mitochondrial kinase, therefore implicating this cellular structure in some forms of Parkinson disease (Valente et al). Presum-

ably, dopaminergic neurons are compromised in some manner by these defects.

It is hoped that the genetic mutations that give rise to Parkinson disease will expose the molecular pathophysiology of the disease. As discussed earlier, several sites are implicated in the familial forms of Parkinson disease, most related to the gene that codes for synuclein, the main component of the Lewy body. This conceptually links familial Parkinson disease with Alzheimer disease and possibly with ALS, all potential sequelae of toxic protein aggregation. As in the aforementioned diseases, new findings suggest that soluble forms of the protein may be the toxic agent, rather than the aggregated protein within cells, or that there is an interaction between the mutated proteins and other proteins such as ubiquitin, another major component of the Lewy body. The binding of ubiquitin is a step in the degradation of intracellular proteins, and mutant parkin proteins appear to have lost this ability. In any case, the current evidence favors a role for the regulation of synuclein in the viability of dopaminergic neurons in the inherited forms of disease, and probably in the sporadic ones as well (Fig. 39-6).

Treatment Although there is no current treatment that halts or reverses the neuronal degeneration underlying Parkinson disease, methods are now available that afford considerable relief from symptoms. Treatment can be medical or surgical, although reliance is placed mainly on drugs, particularly on L-dopa (Table 39-4). The following sections are necessarily detailed in order to give the clinician a full comprehension of the use and side effects and interactions of these drugs.

L-Dopa and L-Dopa-Modifying Drugs At present, L-dihydroxyphenylalanine (L-dopa) is unquestionably the most effective agent

Table 39-4
Drugs commonly used in the treatment of Parkinson disease

MEDICATION	STARTING DOSE	TARGET DOSE	MAIN BENEFIT	SIDE EFFECTS
Carbidopa-L-dopa (Sinemet)	25/100 tid	Up to 50/250 q 3 h	Reduction of tremor and bradykinesia; less effect on postural difficulties	Nausea, dyskinésias, orthostatic hypotension, hallucinations, confusion
Controlled release carbidopa-L-dopa	25/100 tid	Up to 50/200 q 4 h		
Dopamine agonists				
Ropinirole	0.25 mg tid	9 to 24 mg/day	Moderate effects on all aspects; reduced motor fluctuations of L-dopa	Orthostatic hypotension, excessive and abrupt sleepiness, confusion, hallucinations
Pramipexole	0.125 mg tid	0.75 to 3 mg/day		
Glutamate agonist				
Amantadine (Symmetrel)	100 mg/day	100 mg bid-tid	Smoothing of motor fluctuations	Leg swelling, congestive heart failure, prostatic outlet obstruction, confusion, hallucinations, insomnia
Anticholinergics				
Benztropine (Cogentin)	0.5 mg per day	Up to 4 mg per day	Tremor reduction, less effect on other features	Atropinic effects: dry mouth, urinary outlet obstruction, confusion and psychosis
Trihexyphenidyl (Artane)	0.5 mg bid	Up to 2 mg tid	As above	As above
COMT inhibitors				
Entacapone	200 mg with L-dopa			Urine discoloration, diarrhea, increased dyskinésias

for the treatment of Parkinson disease, and the therapeutic results, even in those with far advanced disease, are much better than have been obtained with other drugs. As mentioned earlier, some degree of response is so nearly universal that many neurologists view responsiveness to L-dopa as a diagnostic criterion. The theoretical basis for the use of this compound rests on the observation that striatal dopamine is depleted in patients with Parkinson disease but that the remaining diseased nigral cells are still capable of producing some dopamine by taking up its precursor, L-dopa. The number of neurons in the striatum is not diminished, and they remain receptive to ingested dopamine acting through the residual nigral neurons. Over time, however, the number of remaining nigral neurons becomes inadequate and the receptivity to dopamine of the striatal target neurons becomes excessive, possibly as a result of denervation hypersensitivity; this results in both a reduced response to L-dopa and to paradoxical and excessive movements (dyskinesias) with each dose.

Most patients tolerate the drug initially and experience few serious adverse effects and will show dramatic improvement, especially in hypokinesia and tremor after several days or sooner. The side effects and limitations of L-dopa become considerable as the drug therapy continues and the disease progresses. These are discussed below.

By combining L-dopa with a decarboxylase inhibitor (carbidopa or benserizide), which is unable to penetrate the central nervous system (CNS), decarboxylation of L-dopa to dopamine is greatly diminished in peripheral tissues. This permits a greater proportion of L-dopa to reach nigral neurons and, at the same time, reduces the peripheral side effects of L-dopa and dopamine (nausea, hypotension, etc.). Combinations of carbidopa-levodopa are available in a 1:10 or 1:4 ratio and the benserizide-levodopa combination in a 1:4 ratio. The initial dose of levodopa-carbidopa is typically one-half to one of a 25/100-mg tablet given two or three times daily and increased slowly until optimum improvement is achieved, usually up to four tablets administered five or more times daily as the disease advances, or a similar dose of the 25/250-mg combination.

A newer class of catechol-O-methyltransferase (COMT) inhibitors, typified by entacapone, extends the plasma half-life and the duration of L-dopa effect by preventing its breakdown (as opposed to increasing its bioavailability, as in the case of carbidopa). A combination of L-dopa, carbidopa, and a COMT inhibitor has recently become available in one pill.

Long-acting preparations of levodopa-carbidopa (Sinemet-CR) may reduce dyskinesias in some patients (Hutton and Morris) in the advanced stages of disease, but our experience with these drugs given earlier in the course of disease has been less positive. In transferring a patient from conventional L-dopa/carbidopa preparations to the long-acting formulation, the frequency of administration can be roughly halved while the total amount of L-dopa initially remains unchanged. The absorption of the long-acting drug, however, is approximately 70 percent, often necessitating a slight increase in total dose. To facilitate the treatment of morning rigidity and tremor, the long-acting tablet can be broken in half to speed absorption or a small dose of conventional medication can be given at the same time.

Dopamine Agonists These drugs have a direct dopaminergic effect on striatal neurons, thereby partially bypassing the depleted nigral neurons. They have found a place both as the initial treatment in the early phases of disease, replacing L-dopa in this role, and in modifying the effects of L-dopa later in the illness. In both cases,

they are favored because they are associated with fewer dyskinetic motor complications and also because of a putative neuroprotective effect that is alleged to slow the progress of disease (see below). *Bromocriptine*, *pergolide*, and *lisuride* are synthetic ergot derivatives whose action in Parkinson disease is explained by their direct stimulating effect on dopamine (D_2) receptors located on striate neurons. The nonergot dopamine agonists *ropinirole* and *pramipexole* have a similar type and duration of effectiveness. However, it should be pointed out that dopamine agonists are consistently less potent than L-dopa in managing the main features of Parkinson disease and, in higher doses, they produce similar side effects (see further on).

Representative of studies using dopamine agonists, Rascol and colleagues reported that the use of ropinirole during the first 5 years of illness controlled the symptoms satisfactorily and, in addition, reduced the incidence of dyskinesias compared to treatment with L-dopa. Why dyskinesias are less frequent with ropinirole than with L-dopa is not known. Some specialists attribute this simply to their lower potency. All these drugs should be introduced cautiously. For example, the initial dose of pramipexole is 0.125 mg three times daily, following which the dosage is doubled weekly to a total of 3 to 4.5 mg per day if the medication is used without L-dopa. Bromocriptine therapy begins at 7.5 to 10 mg daily in three to four divided doses, and the dosage is increased very slowly to an optimal level of 40 to 60 mg daily. With all of these drugs it is possible to gradually reduce levodopa-carbidopa by about 50 percent. (A dose of 5 to 10 mg of bromocriptine is approximately equivalent to 25/100 mg carbidopa/levodopa.) Their duration of action is slightly longer than that of L-dopa and they cause less nausea, but otherwise the action and side effects of the two drugs are much the same, as noted. These medications are also undoubtedly useful in smoothing the effects of L-dopa. The addition of small doses of one of these agents to a stable regimen of L-dopa in order to reduce dyskinesias requires careful titration over several weeks and a reduction of the total L-dopa dose (see further on).

Our experience is in general agreement with that of Marsden, who found that of 263 patients given dopamine agonists as the sole treatment, all but 82 had abandoned medication after 6 months because of lack of effect or adverse reactions. Nevertheless, the fact that a large enough proportion of patients continue to benefit for up to 3 to 5 years indicates that the initial use of dopamine agonists has merit.

Even small doses of these drugs, when first introduced, may induce a prolonged episode of hypotension or orthostatic hypotension, but most patients are quite tolerant of them. They may also produce abrupt and unpredictable sleepiness, and patients should be warned of this possibility in relation to driving. More data are required to judge the efficacy of the current trend of initiating therapy with a dopamine agonist rather than with L-dopa.

Anticholinergic Agents and Other Alternatives to L-Dopa and Dopamine Agonists Because of the side effects of levodopa and of dopaminergic agents, some neurologists avoid all types of pharmacotherapy if the patient is in the early phase of the disease and the parkinsonian symptoms are not troublesome. When the predominant manifestation is tremor, very satisfactory results can be obtained in some patients for up to several years with anticholinergic agents alone. The anticholinergic drugs have little effect on the postural, hypokinetic, and other manifestations of disease. Koller's study, which quantified the effect of anticholinergic medication on tremor and compared it to L-dopa, concluded that there was variability in response between patients but that L-dopa was

on average more effective. Nonetheless, anticholinergic agents have long been in use for the treatment of tremor in younger patients and we still use them occasionally, either in conjunction with L-dopa or in patients who cannot tolerate the latter drug. The optimum dosage level is the point at which the greatest relief from tremor is achieved within the limits of tolerable side effects, mainly dry mouth. In older patients, one must be alert to changes in cognitive function, hallucinations, and prostatic obstruction.

Several synthetic preparations of anticholinergic drugs are available, the most widely used ones being trihexyphenidyl (Artane, beginning with 1 to 2 mg per day and increased up to 6 to 8 mg over several weeks) and benztrapine mesylate (Cogentin, 1 to 4 mg per day in divided doses). When tremor is the most prominent symptom, we have also had success with the related agent ethopropazine (50 to 200 mg daily in divided doses; Parsitol, Parsitan). The effects on tremor are cumulative and may not be evident for several days. In order to obtain maximum benefit from the use of these drugs, they should be given in gradually increasing dosage to the point where toxic effects appear: dryness of the mouth (which can be beneficial when drooling of saliva is a problem), blurring of vision from pupillary mydriasis, constipation, and urinary retention (especially with prostatism). Tremor abates in several days and most of our patients have become tolerant to the dry mouth after several weeks. Pyridostigmine, propantheline, or glycopyrrolate can be given to reduce the dryness.

With higher dose ranges, mental slowing, confusional states, hallucinations, and impairment of memory in elderly patients—specifically if there is already some degree of forgetfulness—are side effects that limit usefulness. Occasionally, further benefit may accrue from the addition of another antihistaminic drug, such as diphenhydramine or phenindamine.

The antiviral agent amantadine (Symmetrel, 100 mg twice daily) has mild or moderate benefit for tremor, hypokinesia, and postural symptoms. In some patients it reduces L-dopa-induced dyskinésias (see further on). Its mechanism of action is not known but is thought to be through antagonism of *N*-methyl-D-aspartate (NMDA). It should be noted that amantadine commonly causes leg swelling, may worsen congestive heart failure, and can have an adverse effect on glaucoma as well as exaggerating the cognitive changes associated with anticholinergic medications.

Carbidopa/levodopa or an agonist preparation is introduced only when the symptoms begin to interfere with work and social life or falling becomes a threat, and then these drugs are used at the lowest possible dose.

Slowing the Progression of Disease (“Neuroprotective” Effects of Medication) Another approach, now controversial, had been to initiate the treatment of patients with newly diagnosed Parkinson disease with the monoamine oxidase inhibitor selegiline, 5 mg twice daily, and to continue its use until symptoms become disabling, at which point L-dopa or a dopamine agonist is introduced. Selegiline inhibits the intracerebral metabolic degradation of dopamine, and clinical trials conducted by the Parkinson Study Group have suggested that it slows progression of the disease in its early stages. Subsequent observations, however, have not fully corroborated this claim. We use it sparingly, but some authoritative clinicians find it useful.

Following this same line of reasoning, several studies, most still disputed or unconfirmed, have suggested that ropinirole, pramipexole, and even L-dopa have “neuroprotective” effects in Parkinson disease. Also, the proposal that the progression of symptoms, as measured by a variety of scales, is slowed has not been

fully corroborated. Technical problems in interpreting these results are discussed at length in the reviews by Wooten and by Clarke and Guttman. The uncertainties here have to do with clinical grading systems, functional imaging techniques, and points of comparison to treatment with L-dopa. Nevertheless, in the last few years these observations have led to the promotion of dopamine agonists as the initial therapy.

The notion that the administration of L-dopa early in the disease might reduce the period over which it remains effective has been largely dispelled, but some neurologists continue to adhere to it. Cedarbaum et al, who reviewed the course of the illness in 307 patients over a 7-year period, found no evidence that the early initiation of L-dopa treatment predisposed to the development of fluctuations in motor response or to dyskinesia and dementia. In discussing this with patients, we point out the findings of the “Ell-dopa” trial by the Parkinson Study Group; in 361 individuals with Parkinson disease of less than 2 years duration who were treated with L-dopa for 40 weeks and then had the medication withdrawn, functional and other measures were better than in those who received no medication. That is, L-dopa may have itself been neuroprotective. Also, the large multicenter study reported by Diamond et al indicated that patients who were given L-dopa early in the disease actually survived longer and with less disability than those who began the medication late in the course. These results emphasize the difficulty of assessing the protective effect of various drugs.

Finally, attempts to slow the disease by vitamin antioxidants such as vitamin E have met with mixed but generally negative results. A possible exception has been the trial of coenzyme Q₁₀ by Shults and colleagues. Massive doses of this agent, 1200 mg per day, were found to offer some marginal advantages on the progression over 6 to 18 months as measured by certain standard scores of overall daily function but not on most neurologic scales. Further study of this approach is advised. For the moment, unless it presents a financial burden, the use of this agent seems reasonable but not obligatory.

Side Effects of L-Dopa Treatment As already mentioned, the side effects of L-dopa are at times significant to the degree that its continuation cannot be tolerated. Some patients are at first troubled by nausea, although this can be mitigated by taking the medication with meals. A few have mild orthostatic hypotensive episodes. Nausea usually disappears after several weeks of continued use or can be allayed by the specific dopaminergic chemoreceptor antagonist domperidone.

However, the most troublesome effects of L-dopa as the disease advances, usually after several years of treatment, are an end-of-dose reduction in efficacy (and the more precipitous “on-off” phenomenon) and the induction of involuntary “dyskinetic” movements—restlessness, head wagging, grimacing, lingual-labial dyskinesia, and especially choreoathetosis and dystonia of the limbs, neck, and trunk. A decline in efficacy after the usual 2 to 4 h may be treated by more frequent dosing or the addition of a COMT inhibitor.

The on-off phenomenon is a rapid and sometimes unpredictable change in the patient, in a matter of minutes or from one hour to the next, from a state of relative freedom from symptoms to one of complete or nearly complete immobility. Both dyskinésias and severe “off” periods eventually appear in about 75 percent of patients within 5 years. Above a certain daily dose level of L-dopa, which varies from patient to patient, very few patients escape these effects, forcing an increased frequency of administration and usually a reduction in dosage.

If involuntary movements are induced by relatively small doses of L-dopa, the problem may be suppressed to some extent by the addition of direct-acting dopaminergic agents or by the concurrent administration of amantadine. The use of lower doses of long-acting preparations of L-dopa may also be helpful in reducing dyskinesias, and the atypical antipsychotic medications have been said to be useful.

The onset of psychiatric symptoms coincident with the use of L-dopa may also present problems and is to be expected eventually in 15 to 25 percent of patients, particularly in the elderly. Depression, although frequent, is only occasionally a serious problem, even to the point of suicide. Delusional thinking may also occur in these circumstances. This combination of movement and psychiatric disorders is difficult to treat, and one is faced with instituting an antidepressant regimen or perhaps using one of the newer class of antipsychotic medications that have the least extrapyramidal side effects (see below and Chap. 50). While the selective serotonin reuptake inhibitors have been useful in cases of apathetic depression, they may cause slight worsening of parkinsonian symptoms. In our hands, trazodone has been most helpful in treating depression and insomnia, the latter also being a major problem in some patients. Excitement and aggressiveness appear in a few. A return of libido may lead to sexual assertiveness.

Confusion and outright *psychosis* (hallucinations and delusions) are seen in advanced cases of Parkinson disease when high doses of L-dopa are required and the disease has been present for many years. This may first be treated by attempting to reduce the dose of the drug. If this is not tolerated, the atypical neuroleptics olanzapine, clozapine, risperidone, or quetiapine in low doses are recommended by Friedman and Lannon. The side effects of these drugs include sleepiness, orthostatic hypotension, and sialorrhea. As noted above, clozapine has been said to provide an additional benefit of suppressing dyskinesias in advanced Parkinson disease (Bennett et al), but it requires surveillance of the white blood cell count because of the idiosyncratic occurrence of agranulocytosis in up to 2 percent of patients. Although useful in the treatment of frankly psychotic patients, these drugs tend to be far less effective once dementia has supervened. The anticonvulsant valproate is also said to be useful in this circumstance, but in our hands it has not been as effective as clozapine and related drugs. Despite their lesser tendency to produce rigidity, olanzapine and probably the other similar agents in high doses may slightly worsen motor disability.

An important note of warning: anticholinergic agents or L-dopa should not be discontinued abruptly in advanced Parkinson disease. If this is done, the patient may become totally immobilized by a sudden and severe increase of tremor and rigidity; rarely, a neuroleptic syndrome, sometimes fatal, has been induced by such withdrawal. Reducing the medication dose over a week or so is usually adequate.

With progressive loss of nigral cells, there is an increasing inability to store L-dopa and periods of drug effectiveness become shorter. In some instances, the patient becomes so sensitive to L-dopa that as slight an excess as 50 to 100 mg will precipitate choreoathetosis; if the dose is lowered by the same amount, the patient may develop disabling rigidity. With the end-of-dose loss of effectiveness and on-off phenomenon, which with time become increasingly frequent and unpredictable, the patient may experience pain, respiratory distress, akathisia, depression, anxiety, and even hallucinations. Some patients function quite well in the morning and much less well in the afternoon, or vice versa. In such cases, and for end-of-dose and on-off phenomena, one must titrate the

dose of L-dopa and utilize more frequent doses during the 24-h day; combining it with a dopamine agonist or a long-acting preparation may be helpful. Sometimes temporarily withdrawing L-dopa and at the same time substituting other medications may reduce the on-off phenomenon.

Based on the notion that alimentary-derived amino acids antagonize the clinical effects of L-dopa, the use of a low-protein diet has been advocated as a means of controlling the motor fluctuations described above (Pincus and Barry). Symptoms can sometimes be reduced by the simple expedient of eliminating dietary protein from breakfast and lunch. Moreover, this dietary regimen may permit the patient to reduce slightly the total daily dose of L-dopa. Such dietary manipulation is worth trying in appropriate patients; it is not harmful, and most of our patients with advance disease who have persisted with this diet have reported improvement in their symptoms or an enhanced effect of L-dopa.

Surgical Measures Until recently, success with L-dopa had practically replaced the use of the ablative surgical therapy pioneered by Cooper. This involved the stereotactic placement of lesions in either the globus pallidus, ventrolateral thalamus, or subthalamic nucleus, contralateral to the side of the body chiefly affected. The best results were obtained in relatively young patients, in whom unilateral tremor or rigidity rather than akinesia were predominant. The symptoms that responded least well to operation (and indeed to treatment with L-dopa) in Cooper's patients were postural imbalance and instability, paroxysmal akinesia, bladder and bowel disturbances, dystonia, and speech difficulties.

In the last two decades, through the work of Laitinen and others, this mode of therapy has been revived and advanced by the newer technique of implanted electrical stimulators. Both the ablative approach and the implantation of electrodes involve the placement, under precise stereotactic control, of a lesion or a wire in the posterior and ventral (medial) part of the subthalamic nucleus or the globus pallidus. Improvement of parkinsonian symptoms is reliably effected, particularly on the side opposite the procedure. Also, there is in most patients an enhanced responsiveness to L-dopa and a reduction of drug-induced dyskinesias. In patients who have been studied for more than a few years after the unilateral ablative procedure, the beneficial effects on dyskinesias contralateral to the operation are sustained to some extent, but not in the ipsilateral limbs. The improvement in "off-state" bradykinesia is lost after 2 or so years and any betterment in axial rigidity and imbalance abates in many patients within a year of operation, as reported by Gregory and by Lang et al. In a randomized trial comparing pallidotomy to continued medical treatment of patients with dyskinesias, bradykinesia, or severe fluctuations in response to L-dopa, de Bie and colleagues demonstrated a clear improvement in motor function after surgery, while the group treated with medication continued to worsen. These improvements are in part due to the ability to reduce the dose of L-dopa. Most groups have abandoned the pallidum as a surgical target in favor of the subthalamic nucleus.

The technique of high-frequency electrical stimulation has given probably better results than surgical ablation. It is now used almost exclusively. In particular, stimulation of the subthalamic nucleus has produced improvement in all features of the disease but least of all in gait and balance (Limousin et al). A study by The Deep-Brain Stimulation for Parkinson's Disease Group has demonstrated at least short-term benefit in motor fluctuations after the bilateral implantation of stimulating electrodes in both subthalamic nuclei, but the durability of this effect is not known. The patients

chosen were those who had failed to derive benefit from medications. The benefit with bilateral stimulation of the globus pallidus was somewhat less. Several groups have pointed out that cognitive function is not improved and may even decline.

The ideal patient for deep-brain stimulation is currently considered to be an individual who, to maintain mobility, requires a dose of L-dopa that produces unacceptable dyskinesias and who is constantly cycling between on and off periods. Dystonia, when present as part of the native disease or as a result of medication, may also benefit by this treatment. However, some patients appear to do very well with the introduction of brain stimulation early in the course of illness.

Presumably, the high-frequency electrical impulses cause a disruption of local neuronal activity that is the functional equivalent to an ablative lesion, but the effects may be more complex by way of stimulating neurotransmitter release.

The observed improvement in the L-dopa-induced dyskinesias has recently led to the earlier more liberal use of subthalamic stimulators. But as with ablative surgery, the durability of the benefit is uncertain. Readjustment of the frequency of the stimulus and breakage of the wire are minor problems. Hemorrhage into the basal ganglia and local infection near the stimulator has occurred in a small number of patients so treated.

The cerebral implantation of embryonic adrenal medullary tissue from 8- to 10-week-old human fetuses has provided a modest but undeniable improvement in motor function (Spencer et al, Freed et al), and some patients also appear to have benefited from the striatal implantation of human fetal and porcine nigral cells and autologous adrenal cells. The study by Freed and colleagues found a small improvement on a global scale that measures functional, psychologic, and neurologic aspects only in younger patients. These procedures are hampered by many difficulties, mainly in obtaining tissue and the failure of grafts to survive but also the problem of uncontrollable dyskinesias in some patients. Much of the enthusiasm for these procedures has temporarily subsided. Investigation into their possible usefulness continues.

Other Ancillary Treatments Finally, in the management of the patient with Parkinson disease, one must not neglect the maintenance of optimum general health and neuromuscular efficiency by a planned program of exercise, activity, and rest; expert physical therapy and exercises such as those performed in yoga may be of help in achieving these ends. Sleep may be aided by the soporific antidepressants. Postural imbalance and falls can be greatly mitigated by the use of a cane or walking frame. A number of excellent exercise programs have been devised specifically for patients with Parkinson disease, and measures such as massage and yoga have their advocates. Our position has been that any activity that keeps the patient active and committed is of great value. Speech exercises help the motivated patient. Hypotensive episodes respond to 0.5 mg of fludrocortisone (Florinef) each morning. Focal dystonias of the foot are partially treatable with local injections of botulinum toxin. In addition, the patient often needs a great deal of emotional support in dealing with the stress of the illness, in comprehending its nature, and in carrying on courageously in spite of it.

Striatonigral Degeneration, Shy-Drager Syndrome, and Multiple System Atrophy

Closely related to Parkinson disease but with a different pathologic basis is a state designated by Adams and colleagues as *striatonigral*

degeneration. The pathologic changes were found by chance in four middle-aged patients, none with a family history of similar disease, in three of whom a parkinsonian syndrome had been described clinically. In one of the three, who had been examined carefully, the typical rigidity, stiffness, and akinesia had begun on one side of the body, then spread to the other, and progressed over a 5-year period, but with little or none of the characteristic tremor of idiopathic Parkinson disease. A flexed posture of the trunk and limbs, slowness of all movements, poor balance, mumbling speech, and a tendency to faint when standing were other elements in the clinical picture. Mental function was intact, and there were no reflex changes, no suck and grasp reflexes, and no cerebellar signs or involuntary movements. The other two patients had been seen by competent neurologists who had made a diagnosis of Parkinson disease. Some of the symptoms had been partially relieved by anticholinergic drugs. There was an early-onset cerebellar ataxia in the fourth patient, later obscured by a Parkinson syndrome.

In each case the postmortem examination disclosed extensive loss of neurons in the zona compacta of the substantia nigra, but notably there were no Lewy bodies or neurofibrillary tangles in the remaining cells. Even more striking were the degenerative changes in the putamina and to a lesser extent in the caudate nuclei. These structures were greatly reduced in size and had lost most of their neurons—more of the small than the large ones and more on the side opposite the first clinical symptoms. The findings were suggestive of the striatal lesions of Huntington chorea except that the cell loss was greater in the putamen than in the caudatum. Secondary pallidal atrophy (mainly a loss of striatopallidal fibers) was present. In the fourth patient there was, in addition, an advanced olivopontocerebellar degeneration.

Following the original report, in 1964, many patients were recognized in whom the changes of striatonigral and olivopontocerebellar degeneration were combined and in some of whom the symptoms and signs of cerebellar ataxia actually preceded the parkinsonian manifestations. Equally frequent was a predominantly extrapyramidal syndrome accompanied by autonomic insufficiency, as described below.

Shy-Drager Syndrome Nearly half of the patients with striatonigral degeneration are handicapped by *orthostatic hypotension*, which proves at autopsy to be associated with loss of intermedio-lateral horn cells and of pigmented nuclei of the brainstem. This combined parkinsonian and autonomic disorder, still referred to as the Shy-Drager syndrome, has been mentioned in the chapters on fainting and the autonomic nervous system (pages 326 and 463). In addition to orthostatic hypotension, symptoms of failure of autonomic control include impotence, loss of sweating, dry mouth, miosis, and urinary retention or incontinence. Vocal cord palsy is an important and sometimes initial manifestation of the autonomic disorder. It causes dysphonia or stridor and airway obstruction requiring tracheostomy (see page 463). A dusky discoloration of the hands that has been ascribed to poor control of cutaneous blood flow has been emphasized by Klein and colleagues, but we have not seen it in our patients. It should be noted that orthostatic hypotension is also observed in up to 15 percent of patients with idiopathic Parkinson disease, sometimes exaggerated by medications, but the degree of drop in blood pressure is far greater and more consistent in patients with this form of multiple system atrophy.

Multiple System Atrophy Because of the recognition that the clinical and pathologic features of sporadic striatonigral degeneration, with or without autonomic failure, and in some instances

those of olivopontocerebellar atrophy often coexist, each component expressing itself variably in any individual, Graham and Oppenheimer in 1969 proposed the term *multiple system atrophy* (MSA), which has gained wide acceptance. Several large series of cases of this complex syndrome have now been published, providing a perspective on the frequency and nature of its components. Aside perhaps from a unifying feature of glial and neuronal inclusions described below, the syndromes in which parkinsonism and cerebellar ataxia are prominent are quite different from each other on clinical grounds, for which reason we prefer to apply the term *MSA* only to cases displaying both features. Others have categorized them as MSA-P and MSA-C, depending on whether they display predominantly parkinsonism or cerebellar ataxia. In this nosology, cases in which autonomic failure as described above predominate might be denominated as MSA-A.

In the Brain Tissue Bank of the Parkinson Disease Society of Great Britain, MSA accounted for 13 percent of patients who had been identified during life as having idiopathic Parkinson disease. All of the patients with MSA had one or more symptoms of autonomic failure (postural hypotension, urinary urgency or retention, urinary or fecal incontinence, impotence) and dysphonia or stridor. Babinski signs were present in half the patients and cerebellar ataxia in one-third. Tremor was rare. Males were affected more often than females. In a comparable series of 100 patients (67 men and 33 women) studied by Wenning and coworkers, the disease began with a striatonigral-parkinsonian syndrome in 46 percent; often it was asymmetrical to begin with. Mild tremor was detected in 29 percent, but in only a few was it of the "resting" Parkinson type. In another 41 percent the illness began with autonomic manifestations; orthostatic hypotension occurred eventually in almost all patients, but it was disabling in only a few. Cerebellar features dominated the initial stages of the disease in only 5 percent, but ataxia was eventually obvious in half the group. This presentation will be elaborated further in the section on the degenerative cerebellar ataxias. The extrapyramidal illness, on the whole, was more severe than Parkinson disease, since more than 40 percent of patients were confined to a wheelchair or otherwise severely disabled within 5 years. These observations generally match the findings in a group of 188 patients described by Quinn and colleagues. In that series, pyramidal signs were present in 60 percent and autonomic features in 77 percent, a feature we have found helpful in diagnosis and one that certainly marks the illness as affecting multiple systems.

Colosimo and colleagues, who reviewed the clinical findings in 16 pathologically verified cases of MSA, found that several signs—namely, the relative symmetry of the signs and rapid course, the lack of response to L-dopa and absence or minimal amount of tremor, and the presence of autonomic disorders—reliably distinguished this syndrome from Parkinson disease. These observations are in keeping with our own, and we would add that abnormalities of eye movement are not prominent in MSA. Additional odd features, especially dystonia, are remarked upon in other series; anterocollis or dystonia of the lower facial muscles, for example, are striking in a few cases. It is noteworthy that levodopa has had little or no effect or has made these patients worse early in the disease, but we have seen exceptions. This is probably attributable to the loss of striatal dopamine receptors.

The diagnosis of MSA has been aided to some extent by imaging techniques. Both MRI and CT scans frequently show atrophy of the cerebellum and pons in those with cerebellar features. The putamina are hypodense on T2-weighted MRI and may show an

increased deposition of iron. Studies with PET have disclosed an impairment of glucose metabolism in the striatum and to a lesser extent in the frontal cortex—a reflection, no doubt, of the loss of functioning neuronal elements in these parts. Finally, it should be repeated that, despite the frequent concurrence of striatonigral degeneration, olivopontocerebellar degeneration, and the Shy-Drager syndrome, *each of these disorders occurs in pure or almost isolated form*; we therefore prefer to retain their original designations. This distinction was reflected in the findings of Gilman et al, who followed a series of 51 patients with olivopontocerebellar atrophy for up to 10 years; only 17 of their patients acquired a parkinsonian syndrome or autonomic failure.

Pathology In recent years, attention has been drawn to the presence of abnormal staining material in the cytoplasm of astroglia and oligodendrocytes and in some neurons as well. These cytoplasmic aggregates have been referred to as glial cytoplasmic inclusions (Papp et al). Although they bear little resemblance morphologically to other discrete inclusions that have come to be accepted as characteristic of certain degenerative CNS diseases (e.g., Lewy bodies) they nonetheless contain α -synuclein (which is the main component of Lewy bodies). It is not clear to us whether these glial cytoplasmic accumulations represent a histopathologic hallmark of sporadic cases of MSA (Chin and Goldman; Lantos), since their presence is not specific; they have been identified in practically every degenerative disease that has been subjected to sensitive silver impregnation stains (Gallyas silver technique). By the same token, α -synuclein-positive inclusions have been detected in several neurodegenerative syndromes. Appropriate control studies to determine whether the glial inclusions are found in nondegenerative lesions in brain (at the edge of an infarct, for example) are needed. Also lacking is information about the frequency of these cytoplasmic inclusions in relation to the aging brain. The fundamental question remains unanswered: Do the cytoplasmic glial aggregates play a central role in the genesis of this and the other degenerative diseases, or are they simply some form of detritus that accumulates in glia as a reaction to or a by-product of the basic abnormality—namely, the wasting and loss of neurons?

Progressive Supranuclear Palsy (PSP)

In 1963 Richardson, Steele, and Olszewski crystallized medical thought about a clinicopathologic entity—progressive supranuclear palsy, or PSP—to which there had been only ambiguous reference in the past. The condition is not rare or unusual. By 1972, when Steele reviewed the subject, 73 cases (22 with postmortem examinations) had been described in the medical literature, and several examples are to be found in every large neurologic center; the present authors encounter approximately five new cases yearly, most of them not previously diagnosed. Rare familial clusters have been described in which the pattern of inheritance is compatible with autosomal dominant transmission (Brown et al; de Yébenes et al). No toxic, encephalitic, racial, or geographic factor has been incriminated.

Clinical Features Characteristically the disease has its onset in the sixth decade (range 45 to 75 years), with some combination of difficulty in balance, abrupt falls, visual and ocular disturbances, slurred speech, dysphagia, and vague changes in personality, sometimes with an apprehensiveness and fretfulness suggestive of an agitated depression. The most common early complaint is unsteadiness of gait and unexplained falling. At first, the neurologic and

ophthalmologic examinations may be unrevealing, and it may take a year or longer for the characteristic syndrome—comprising supranuclear ophthalmoplegia, pseudobulbar palsy, and axial dystonia—to develop fully.

Difficulty in voluntary vertical movement of the eyes, often downward but sometimes only upward, and later impairment of voluntary saccades are characteristic in more than half of the cases. A related but more subtle sign has been the finding of hypometric saccades in response to an optokinetic drum or striped cloth moving vertically in one direction (usually best seen with stripes moving downward). Later, both the ocular pursuit and refixation movements diminish and eventually all voluntary eye movements are lost, first the vertical ones and then the horizontal ones as well. However, if the eyes are fixated on a target and the head is turned, full movements can be obtained, proving the supranuclear, non-paralytic character of the gaze disorder. Other prominent oculomotor signs are sudden jerks of the eyes during fixation, cogwheel pursuit movements, and hypometric saccades of long duration (Troost and Daroff). Bell's phenomenon (reflexive upturning of eyes on forced closure of the eyelids) and the ability to converge are also lost eventually, and the pupils then become small. The upper eyelids may be retracted, and the wide-eyed, unblinking stare, imparting an expression of perpetual surprise, is characteristic. Blepharospasm and involuntary eye closure are prominent in some cases. In the late stages, the eyes may be fixed centrally, and all oculocephalic and vestibular reflexes may be lost as well. It should be emphasized, however, that *a proportion of patients do not demonstrate these eye signs for a year or more* after the onset of the illness. We have also followed several patients who had no disorder of eye movement during life but in whom the typical pathologic changes of PSP were found unexpectedly. In one such patient there was a subcortical type of dementia; in another, focal limb dystonia and parkinsonism. Furthermore, in a few cases, several other degenerative conditions manifest a supranuclear vertical gaze disorder, although never to the extent seen in PSP; these include mainly corticobasal-ganglionic degeneration, Lewy body disease, and Parkinson disease.

The *gait disturbance* and *repeated falling* have proved difficult to analyze. Walking becomes more and more awkward and tentative; the patient has a tendency to totter and fall repeatedly but has no ataxia of the limbs, Romberg sign, or orthostatic tremor. Some patients tend to lean and fall backward (retropulsion). One of our patients, a large man, fell repeatedly, wrecking household furniture as he went down, yet careful examination provided no clue as to the basic defect in this “toppling phenomenon.”

Along with the oculomotor and balance disorders, there is a gradual stiffening and extension of the neck (in one of our patients it was sharply flexed), but this is not an invariable finding. The face acquires a staring, “worried” expression with a furrowed brow and rigid demeanor, made more striking by the paucity of eye movements. A number of our patients have displayed mild dystonic postures of a hand or foot, especially as the illness advanced but occasionally early on. The limbs may be slightly stiff, and there are Babinski signs in a few cases.

The stiffness, slowness of movement, difficulty in turning and sitting down, and hypomimia may suggest a diagnosis of Parkinson disease. However, the facial expression of the PSP patient is more a matter of tonic grimace than of lack of movement, and the lack of tremor, the erect rather than stooped posture, and prominence of oculomotor abnormalities also serve to distinguish the two disorders. The signs of pseudobulbar palsy are eventually prominent,

and this feature, along with the eye movements, distinguishes the process most conspicuously from other degenerative conditions. The face becomes less expressive (“masked”), speech is slurred, the mouth tends to be held open, and swallowing is difficult. Forced laughing and crying, said to be infrequent, have been present in about half of our cases. Many patients complain of sleep disturbances. The total sleep time and rapid-eye-movement (REM) sleep are reduced, and spontaneous awakenings during the night are more frequent and longer than in normal individuals of the same age.

Other features—such as focal limb dystonia, palilalia, myoclonus, chorea, orofacial dyskinesias, and disturbances of vestibular function—are observed in some cases. Finally the patient becomes anarthric, immobile, and quite helpless. Complaints of urinary frequency and urgency have been very frequent in advanced cases under our care. Dementia of some degree is probably present in many cases but is mild in most. Some patients do eventually become forgetful and appear apathetic and slow in thinking; many others are irritable or at times euphoric.

By MRI, one can, in advanced cases, visualize the atrophy of the dorsal mesencephalon (superior colliculi, red nuclei), giving rise to a “mouse ears” configuration, but these changes may be difficult to detect. The CSF remains normal.

Although most cases of PSP are sporadic, the disease can be familial. Rojo and coworkers have described 12 pathologically confirmed pedigrees. The mode of inheritance is thought to be autosomal dominant with incomplete penetrance. The authors made note of the variable phenotypical expression of the disease even within a single pedigree.

Postmortem examinations have disclosed a bilateral loss of neurons and gliosis in the periaqueductal gray matter, superior colliculus, subthalamic nucleus of Luys, red nucleus, pallidum, dentate nucleus, and pretectal and vestibular nuclei, and to some extent in the oculomotor nucleus. The expected loss of the myelinated fiber bundles arising from these nuclear structures has been observed. A remarkable finding has been the neurofibrillary degeneration of many of the residual neurons. The neurofibrillary tangles are thick and often composed of single strands, either twisted or in parallel arrangement. The neurons of the cerebral cortex have been involved in some cases (shown by staining of tau protein), but these changes apparently do not correlate with dementia. The cerebellar cortex is usually spared.

The cause and nature of this disease are quite obscure. Conceivably, some cases originally considered to be instances of post-encephalitic parkinsonism were examples of PSP. Studies with PET have demonstrated a decrease in blood flow—most marked in the frontal lobes—and a lesser extent of oxygen utilization in central structures (Leenders et al). Striatal dopamine formation and storage have been significantly decreased compared with control values. Much current interest has been directed to the neurofibrillary tangles and tau deposition in PSP and a potential link to the tau pathology displayed in frontotemporal dementia and in corticobasal-ganglionic degeneration (see below). As summarized by Golbe, certain tau gene haplotypes on chromosome 17p (the same site implicated in familial frontotemporal dementia) are more often associated with PSP than in unaffected individuals, but other factors, environmental or genetic, must also be involved. It is intriguing that the tau-gene haplotype of frontotemporal dementia is not found in PSP.

PSP should be suspected whenever an older adult inexplicably develops a state of imbalance, frequent falls with preserved consciousness, and variable extrapyramidal symptoms, particularly

dystonia of the neck, ocular palsies, or a picture resembling pseudobulbar palsy. If the classic abnormalities of eye movements are present, the diagnosis is not difficult. When only a parkinsonian syndrome without tremor is present, the main diagnostic consideration is striatonigral degeneration or the corticobasal-ganglionic syndrome, described below.

Treatment L-Dopa has been of slight but unsustained benefit in some of our patients, and combinations of L-dopa and anticholinergic drugs have been entirely ineffective in others. A marked response to these drugs should, of course, suggest the diagnosis of Parkinson disease. Recently, the drug zolpidem, a GABA-ergic agonist of benzodiazepine receptors, has been reported to ameliorate the akinesia and rigidity of PSP (Daniele et al); however, these observations require corroboration. Benztrapine or trihexyphenidyl have been somewhat helpful in reducing dystonia but botulinum injections may be a better alternative if there is focal affection. Treatment of the sleep difficulties and urinary incontinence are of great assistance to the patient and family. A feeding tube becomes necessary in advanced cases.

Corticobasal-Ganglionic Syndromes

Over the years, the authors have observed several elderly patients, both men and women, in whom the essential abnormality was a progressive asymmetrical extrapyramidal rigidity combined with signs of corticospinal disease. Sometimes a mild postural action tremor (beginning unilaterally and suggestive in some respects of Parkinson disease) was added. The parkinsonism is generally unresponsive to L-dopa. These cases have come to be known on our neurology service by the names *corticobasal-ganglionic* or *cortical-basal degeneration*. The clinical relation of such cases to corticostriatospinal degeneration, described earlier, is indeterminate, and more interesting, based on the finding of tau inclusions, is a possible biologic relationship to frontotemporal dementia, Pick disease, and to progressive supranuclear palsy, as noted below.

The patients, though able to exert considerable muscle power, cannot effectively direct their voluntary actions. Attempts to move a limb to accomplish some purposeful act might result in a totally inappropriate movement, always with great enhancement of rigidity in the limb and in other affected parts, or the limb may drift off and assume an odd posture, such as a persistent elevation of the arm without the patient's awareness—a kind of involuntary catalepsy. The disorder of limb function has some of the attributes of a limb-kinetic or an ideomotor apraxia (see Chap. 3), but the hand postures, involuntary movements, and changes in tone are at times more reminiscent of what has been described as "the alien hand." Some patients exhibit an anosognosia. Babinski signs, impaired eyelid or ocular motion (up-gaze paresis or abnormal saccadic movements), or lingual dyskinesias, frontal release signs, and dysarthria occur in some affected individuals. Another distinct group had dementia as an early feature, as described by Grimes and colleagues.

With progression of the disease, the limbs—first on one side of the body and then on both—and the cranial muscles become involved; apraxia and variable combinations of rigidity, bradykinesia, hemiparesis, sensory ataxia, and postural and action tremor and sometimes myoclonic jerking finally render the patient helpless—unable to sit, stand, speak, or take care of basic needs. Apraxia of gaze, eyelid opening and closure, and stimulus-sensitive myoclonus appear in some cases. Mental deterioration occurs late and only in some cases. Occasionally, there is some involvement

of lower motor neurons with resulting amyotrophy. Two of our patients had myoclonus as an early feature, one displaying it only on one side of the face, the other in an arm. The condition progresses for 5 years or more before some medical complication overtakes the patient.

Wenning and colleagues have described a series of 14 such patients in whom the diagnosis was confirmed at postmortem examination. The most common early symptom was an asymmetrical clumsiness of the limbs, in half of the patients with rigidity and in one-fifth with tremor; these features are now considered to be the most characteristic early features of the process. As the illness progressed, almost all the patients developed an asymmetrical or unilateral akinetic-rigid syndrome, which may be considered the essential motor disorder of this disease; various forms of gait disorder; and dysarthria. Stimulus-induced or spontaneous myoclonus and pyramidal signs, mentioned in other reports and frequent in our cases, were not prominent, and fewer than half the patients exhibited an alien-hand phenomenon; limitations of vertical gaze and frontal lobe release signs eventually became apparent in half of the patients.

Postmortem examination of several of our colleagues' patients, reported by Rebeiz and colleagues, has disclosed a combination of findings that stamps the disease process as unique. Cortical atrophy (mainly in the frontal motor-premotor and anterior parietal lobes) was associated with degeneration of the substantia nigra and, in one instance, of the dentatorubrothalamic fibers. The loss of nerve cells was fairly marked, but there was no gross lobar atrophy, as occurs in Pick disease. The neuronal degeneration was more on one side of the brain than the other. There was moderate gliosis in the cortex and underlying white matter. Many of the residual nerve cells were swollen and chromatolyzed with eccentric nuclei, a state that was called *achromasia* by Rebeiz and colleagues; it resembled the central chromatolysis of axonal reaction. More recently, in over half the cases, the affected neurons and adjacent glia have been shown to be filled with a particular configuration of tau protein, thereby linking the disease to frontotemporal dementia and Pick disease, as already mentioned. The remaining cases have shown tau deposition that is more similar to that of progressive supranuclear palsy, or Alzheimer pathology, or non-specific cell loss with replacement gliosis.

Both CT and MRI have demonstrated asymmetrical cerebral and pontine atrophy, and PET studies have revealed thalamoparietal metabolic asymmetries—a greater reduction of glucose metabolism on the side of the most extensive lesion (Riley et al).

In subsequent observations of such cases, other investigators have searched unsuccessfully for clues as to the cause and pathogenesis of this disease. There is no family history. No organ other than the CNS is affected. The progression is relentless. None of the drugs in common use for spasticity, rigidity, and tremor has been helpful. We know of no attempt to transfer the disease to primates.

Marinescu has described a somewhat different disease resembling more a severe form of Alzheimer disease, but with signs of both pyramidal and extrapyramidal disease (rigidity, tremor, nystagmus, incoordination, confusion, disorientation, and loss of memory). There was amyloidosis of blood vessels (so-called Scholz's perivascular plaques) in the cerebral white matter as well as in the liver and kidney. The disease bears some resemblance to, and may indeed be identical to, the corticostriatospinal degeneration ("spastic pseudosclerosis") of Jakob, discussed on page 913. The relation of this disease to the corticopallidospinal and the pallidopy-

ramidal syndromes first described by Davison (1932, 1954) is also uncertain. The features of eight such cases of a “pallidopyramidal” syndrome have more recently been summarized by Tranchant and associates.

Dystonic Disorders

Dystonia Musculorum Deformans (Torsion Dystonia) Dystonia as a symptom has been discussed in Chaps. 4 and 6. Here we are concerned with a disease or diseases of which dystonia is the major manifestation. Schwalbe’s account, in 1908, of three siblings of a Jewish family who were afflicted with progressive involuntary movements of trunk and limbs probably represents the first description of a disease in which severe and progressive dystonia was the sole manifestation. In 1911, Oppenheim contributed other cases and coined the term *dystonia musculorum deformans* in the mistaken belief that the disorder was primarily one of muscle and always associated with deformity. Flatau and Sterling, in the same year, first suggested that the disease might have a hereditary basis and gave it the more accurate name *torsion dystonia of childhood*. At first the condition was thought to be a manifestation of hysteria, and only later was it recognized as a neurologic entity with a predilection for Russian and Polish Jews. Soon thereafter, a second hereditary form of torsion dystonia, affecting non-Jews, was observed. The epidemiologic study of Eldridge, who analyzed all reported primary cases up to 1970, revealed two patterns of inheritance, one autosomal recessive, the other dominant. The recessive form begins in early childhood, is progressive over a few years, and is restricted to Jewish patients with normal and often even superior intelligence. The dominant form begins later, usually in late childhood and adolescence, progresses more slowly, and is not limited to any ethnic group.

As indicated in Chap. 6, most instances of idiopathic (primary) dystonias that come to our attention, particularly the segmental or restricted types, do not conform to the classic hereditary disorders as defined above, although some may represent limited variants. In general, these more restricted types have a later onset and a relatively milder, more slowly progressive course, with a tendency to involve the axial or the distal musculature alone. Only the paravertebral, cervical, or cranial muscles may be involved (focal dystonia including torticollis and writer’s cramp), with little change from year to year. The clinical classification of the predominantly adult-onset dystonias is made more complex by the fact that both the restricted and generalized forms may be sporadic or familial. Bressman and colleagues, for example, have described a restricted (cervicocranial) adult-onset form of dystonia in four generations of a non-Jewish family. The symptomatology included cervical dystonia, facial grimacing, dysarthria, and dysphonia. In one of our familial cases, a dystonia of the foot appeared during adolescence and later disappeared; we have also observed this time-limited occurrence to happen occasionally in spasmodic torticollis, which is a common form of restricted or segmental dystonia, described further on.

In a survey of idiopathic torsion dystonia of local and generalized type in the United Kingdom by Fletcher and associates, the investigators concluded that approximately 85 percent of these cases were due to an autosomal dominant gene of low penetrance and that a small proportion represented new mutations. The risk of the disease in a first-degree relative of a familial case is about 25 percent.

Molecular genetic studies, though still incomplete, hold the

promise of clarifying the classification of the heritable dystonias (see Korf). More than 10 types of dystonia have been distinguished by genetic mapping. The most important of these is an abnormal gene (DYT1), which codes for the protein torsin A, that has been mapped to the long arm of chromosome 9q in both Jewish and non-Jewish families. The most common DYT1 mutation, deletion of a single glutamate from the torsin A peptide, is found in most cases of dystonia musculorum deformans, as discussed in Chap. 4. This disease is inherited in an autosomal dominant pattern. Although the penetrance of the clinical trait in these families is low, PET scanning demonstrates hypermetabolism in the cerebellum, lenticular nuclei, and supplementary motor cortex in all carriers of the mutated gene.

The function of torsin A is not fully defined. It is present in neurons throughout the brain and has ATP binding and nuclear localization. It may function as a chaperone protein that shuttles other proteins in and out of cells. A current speculation, shared with other degenerative disease, is that the absence of torsin A renders neurons unduly sensitive to oxidative stress (Walker and Shashidharan).

German Mennonite families with restricted adult-onset dystonia (torticollis and spasmodic dysphonia) have an unrelated mutation at 18p; a rare X-chromosome mutation that causes dystonia has also been described. Another rare form of dystonia with myoclonus is caused by mutations in the gene encoding ϵ -sarcoglycan, a transmembrane protein. A unique, dopa-sensitive dystonia, described below, arises from a dominantly transmitted defect on chromosome 14q in the protein GTP cyclohydrolase (see below, under “Hereditary Dystonia-Parkinsonism”).

Although DYT1 mutations account for the majority of inherited cases of generalized dystonia, they are implicated in a relatively small proportion of the more restricted dystonias (see further on). Perhaps it is more notable that some cases of apparently sporadic and regionally restricted dystonias are indeed associated with the mutation or variants of it. However, the relationship of these inherited childhood and adolescent varieties of generalized dystonia to the more common sporadic and restricted dystonias has not been settled. It is true that some individuals in families affected with generalized dystonia will demonstrate only localized forms (e.g., writer’s cramp or torticollis). The general rule stated above still holds—namely, that the inherited variety (dystonia musculorum deformans) related to chromosome 9q manifests early in life and begins in one limb, then spreads to most muscles of the body, while in the common dystonias (mostly sporadic but some of which may be heritable) the disease remains confined to the craniocervical or another region and does not generalize or progress.

Clinical Features The first manifestations of the generalized disease may be rather subtle. Intermittently, and usually after activity (late in the day), the patient (usually a child between 6 and 14 years of age, less often an adolescent) begins to invert one foot, to extend one leg and foot in an unnatural way, or to hunch one shoulder, raising the question of a nervous tic. As time passes, however, the motor peculiarity becomes more persistent and interferes increasingly with the patient’s activities. Soon the muscles of the spine and shoulder or pelvic girdles become implicated in involuntary, spasmodic twisting movements. The cardinal feature of these severe dystonic muscle contractions is the simultaneous contraction of both agonists and antagonists at a joint. These cocontraction spasms are intermittent at first; in free intervals, muscular tone and volitional movements are normal. Indeed, in some instances the

muscles are hypotonic. Gradually the spasms become more frequent; finally they are continuous, and the body may become grotesquely contorted. Lateral and rotatory scoliosis are regular secondary deformities. For a time, recumbency relieves the spasms, but later on position has no influence. The hands are seldom involved, though at times they may be fisted. Cranial muscles do not escape, and in a few instances a slurring, staccato-type speech has even been the initial manifestation. Uncontrollable blepharospasm was the initial disorder in one of our patients; in two others, severe dysarthria and dysphagia were the first signs of the disease, caused by dystonia of the tongue, pharyngeal, and laryngeal muscles. Other manifestations of the movement disorder include torticollis, tortipelvis, dromedary gait, propulsive gait, action tremor, myoclonic jerks during voluntary movement, and mild choreoathetosis of the limbs. Excitement worsens the condition and sleep abolishes it. As the years pass the postural distortion may become fixed to the point where it does not disappear even in sleep. Tendon reflexes are at all times normal; corticospinal signs are absent; there is no ataxia, sensory abnormality, convulsive disorder, or dementia.

Pathology No agreement has been reached concerning the pathologic substrate of the disease. In several cases the ferrocalcinosis of Hallervorden-Spatz disease, the lesions of Wilson disease or of kernicterus, the état marbré of neonatal hypoxia, or the CT lucencies of familial striatal necrosis have been observed in the basal ganglia. Obviously in these instances the dystonia was symptomatic of another disease. However, in the hereditary forms, which are the subject of this section, one cannot be certain of any specific lesions that would account for the clinical manifestations. The brain is grossly normal, and the ventricular size is not increased. According to Zeman, who reviewed all the reported autopsy studies up to 1970, there are no significant changes in the striatum, pallidum, or elsewhere. This does not mean that there are no lesions, only that the techniques being used (qualitative analysis of random sections by light microscopy) are inadequate for their demonstration or the problem is subcellular. The recent report by McNaught and colleagues of perinuclear inclusions in periaqueductal neurons by the use of special immunostaining methods is provocative. It is worth remarking that in more contemporary studies, abnormalities of torsin A protein has not been detected in autopsy tissue from individuals with either dystonia muscularum deformans or other forms of dystonia. Newer methods of identification of striatal cell types and quantification of protein levels have probably not been adequately evaluated. Dopamine β -hydroxylase is elevated in the plasma of patients with the autosomal dominant form of the disease and the plasma norepinephrine levels are also raised, but the meaning of these findings is not clear; PET scan changes have already been mentioned.

Treatment Early in the course of the illness, several drugs—including L-dopa, bromocriptine, carbamazepine, diazepam, and tetrabenazine—seem to be helpful, but only in a few patients, and the benefit is not lasting. Intrathecal baclofen has been somewhat more successful in children. The rare hereditary form of dystonia-parkinsonism (described below) responds well to small doses of L-dopa and dopamine agonists and is exceptional in this respect. Burke and coworkers advocate the use of very high doses (up to 30 mg daily or more) of trihexyphenidyl (Artane). Apparently dystonic children can tolerate these high doses if the medication is raised gradually, by 5-mg increments weekly. In adults, high-dose anticholinergic treatment is less successful but worthy of a trial. Clonazepam is beneficial in some patients with segmental myoclonus.

The most impressive results have been obtained by the use of stereotactic techniques to make lesions that are centered in the ventrolateral nuclei of the thalamus or in the pallidum–ansa lenticularis region. Some frightfully deformed children, unable to sit or stand, have been restored to near normalcy for a time. Approximately 70 percent of the patients in Cooper's series were moderately to markedly improved by unilateral or bilateral operations, and, based on a 20-year follow-up study, the improvement was usually sustained. More recent studies have reported a somewhat less favorable but nonetheless clear-cut improvement (see Tasker et al; Andrew et al). The main risk of operation has been a corticospinal tract lesion, produced inadvertently by damaging the internal capsule. Bilateral lesions have sometimes been disastrous, causing pseudobulbar palsy. Newer techniques employing stimulators and implanted electrodes may give better results.

Hereditary Dystonia-Parkinsonism (Segawa Syndrome, Juvenile Dopa-Responsive Dystonia) This process is discussed here because its main characteristic is a dystonia that is responsive to L-dopa, but most cases also have features of parkinsonism; it is therefore included in the differential diagnosis of that syndrome in young patients. Following the description of this disease by Segawa and colleagues in 1976, several others drew attention to a unique form of hereditary dystonia (Allen and Knopp; Deonna; Nygaard and Duvoisin). The pattern of inheritance is probably autosomal dominant and there is no ethnic predilection. Nygaard and colleagues have found a linkage to the gene on chromosome 14q for the protein GTP cyclohydrolase 1. This gene is implicated in the synthesis of tetrahydrobiopterin, which is a cofactor for tyrosine hydroxylase. It is likely that mutation impairs the generation of dopamine, a prediction that accords with responsiveness of the parkinsonian and dystonic features to L-dopa. In one autopsied case (an accidental death), there was a reduction in the amount of tyrosine hydroxylase in the striatum and depigmentation but no cell loss in the substantia nigra (Rajput et al). The affected enzyme was reduced in the striatum, as was the level of dopamine.

The dystonic manifestations usually become evident in childhood, usually between 4 and 8 years of age; females outnumber males in a ratio of 3 to 2. Often the legs are first affected by intermittent stiffening, with frequent falls and peculiar posturing, sometimes the feet assuming an equinovarus position. The arms become involved as well as the truncal muscles; retrocollis or torticollis may appear. Within 4 to 5 years, all parts of the body including the bulbar muscles are involved. Sometimes, as mentioned, parkinsonian features (rigidity, bradykinesia, postural instability) can be detected early in the course of the illness, but characteristically they are added to the clinical picture several years later. In our own patients and in several of those of Deonna, there was in some instances a rigidity of the limbs as well as slowness of movement and a tremor at rest, all aspects more parkinsonian than dystonic. In still others, the clinical picture has been one of cerebral spastic diplegia.

A remarkable feature is the disappearance or marked subsidence of the symptoms after a period of sleep and worsening as the day progresses. This diurnal variation has been a notable feature in some but not all cases and is shared with many of the inherited forms of Parkinson disease discussed earlier. Fluctuations of symptoms with exercise and menses and in the first month of pregnancy have been observed in some cases.

The unique feature of this *juvenile dystonia-parkinsonism syndrome*, as it has also been called, is the dramatic response of both

the dystonic and parkinsonian symptoms to treatment with L-dopa. As little as 10 mg/kg per day may eliminate the movement disorder and permit normal functioning. In this condition, unlike Parkinson disease, the medication can be continued indefinitely without the development of tolerance or wearing-off effects. Segawa disease accounts for some cases that had in the past been reported as juvenile Parkinson disease.

Torticollis and Other Restricted Dyskinesias and Dystonias (See Chap. 6) With advancing age, a large variety of degenerative movement disorders come to light. Supposedly there is loss of neurons in certain parts of the basal ganglia, but this has not been verified by appropriate pathologic studies. In the common restricted dystonias, localized groups of adjacent muscles manifest arrhythmic cocontracting spasms (agonist and antagonist muscles are activated simultaneously). The patient's inability to suppress the dystonia and the recognition that it is for the most part beyond voluntary control distinguishes it from typical tics, habit spasms, and mannerisms described in Chap. 6. If the muscle contraction is frequent and prolonged, it is accompanied by an aching pain that may mistakenly be blamed for the spasm, and the involved muscles may gradually undergo hypertrophy. Worsening under conditions of excitement and stress and improvement during quiet and relaxation are typical of this group of disorders and contributed in the past to the mistaken notion that the spasms had a psychogenic origin.

The most frequent and familiar type is *torticollis* as described in Chap. 6, wherein an adult, more often a woman, becomes aware of a turning of the head to one side while walking. Usually this condition worsens gradually to a point where it may be more or less continuous, but in some patients it remains mild or intermittent for years on end. When followed over the years, the condition is observed to remain limited to the same muscles (mainly the scalene, sternocleidomastoid, and upper trapezius). Rarely the torticollis is combined with dystonia of the shoulder, arm and trunk; tremor; facial spasms; or dystonic writer's cramp.

Other restricted dyskinesias involve the neck in combination with facial muscles, the orbicularis oculi (*blepharospasm* and *blepharoclonus*), the throat and respiratory muscles ("spastic dysphonia," *orofacial dyskinesia*, and *respiratory and phonatory spasms*), the hand in writer's cramp (*graphospasm*) or musician's dystonia, and proximal leg and pelvic-girdle muscles, where dyskinesia is elicited by walking. All these conditions and their treatment are discussed fully in Chap. 6.

Other Forms of Hereditary Dystonia Several familial movement-induced (kinesogenic) dystonic syndromes and a type that is not kinesogenic and arises suddenly in adolescence, at times with parkinsonian features, have been described (see page 184). There are other degenerative diseases that combine hereditary dystonia with neural deafness and intellectual impairment (Scribanu and Kennedy) and with amyotrophy in a paraplegic distribution (Gilmann and Romanul).

Two other important diseases that fall into the category of hereditary dystonia have been described in Chap. 37. These are Hallervorden-Spatz disease and calcification of the basal ganglia—and, of course, Wilson disease may have dystonia as a central feature. Also, many extrapyramidal diseases, including idiopathic Parkinson disease and progressive supranuclear palsy, may include fragmentary dystonias of the hand, foot, face, or periorbital muscles.

SYNDROME OF PROGRESSIVE ATAXIA

This topic was introduced in Chap. 5, and some of the congenital and acute acquired varieties are mentioned on pages 818, 826, and 976. Here we consider only the *chronic, progressive forms of cerebellar disease*. While many of these are familial and are more or less confined to this part of the nervous system, a number of other systems may be involved to a varying degree. Many of these diseases are so chronic that one would expect a close correspondence between their symptomatology and anatomic pathology, yet attempts to determine these relationships have generally been disappointing. The classic examples of chronic progressive cerebellar disease are subsumed under the "system atrophies," but no one classification designed to bring precise order to this category of diseases has proved entirely satisfactory. Wilson wrote that "the group of degenerative conditions strung together by the common feature of ataxia is one for which no very suitable classification has yet been devised"—a statement that is as appropriate today as when it was written about 70 years ago. Even recent insights provided by the tools of molecular genetics have not provided a satisfactory basis for classification, mainly because the same gene abnormality may be expressed by a number of different phenotypic syndromes.

Nevertheless, largely through the clinical and pathologic studies of Greenfield and subsequent reviews by Harding and others, a semblance of order has been achieved. The clinical classification proposed by Harding represents a scholarly effort to meet this goal. Setting aside those of congenital type and those caused by an underlying metabolic disorder, she grouped the ataxias by age of onset, pattern of heredity, and associated features. A modification of the classifications of Greenfield and of Harding, which is included in the introductory listing of the degenerative diseases (page 897) is used here. It divides the progressive cerebellar ataxias into three groups—(1) the spinocerebellar ataxias, with unmistakable involvement of the spinal cord (Romberg sign, sensory loss, diminished tendon reflexes, Babinski signs); (2) the pure cerebellar ataxias, with no other associated neurologic disorders; and (3) the complicated cerebellar ataxias, with a variety of retinal, optic nerve, oculomotor, auditory, pyramidal, extrapyramidal, peripheral nerve, and cerebrocortical accompaniments. Inherited ataxias of early onset (before the age of 20 years) are usually of autosomal recessive type; those of later onset may be autosomal recessive but are more likely autosomal dominant. Table 39-5 provides a listing of several types of ataxia that have a genetic basis. At the same time, it should be emphasized that many patients in our clinics have no family history of a similar ataxia.

In the approach to a patient with a heritable ataxia, we find such a classification—based on well-established clinical and pathologic features and patterns of mendelian inheritance—to be the most useful. Without doubt, the advances in molecular genetics of recent years have greatly altered our understanding of the inherited ataxias and has already disclosed a large number of unexpected relationships between specific genetic defects and other neural and nonneural disorders. These data are incorporated at appropriate points in the following discussion and are summarized in Table 39-5 and at the end of this section.

Early-Onset Spinocerebellar Ataxias (Predominantly Spinal)

Friedreich Ataxia This is the prototype of all forms of progressive spinocerebellar ataxia and accounts for about half of all cases

Table 39-5
Genetic defects associated with hereditary spinocerebellar ataxia (SCA)

	NOTATION	CHROMOSOME	GENE	GENETICS	AGE OF ONSET	CLINICAL AND MISCELLANEOUS FEATURES IN ADDITION TO ATAXIA
Progressive						
Dentatorubropallidoluysian atrophy	SCA1	12p13 6p23	Atrophin Ataxin-1	AD ^a AD ^a	Childhood Variable	Chorea, dystonia, seizures, dementia 10–25% of dominant ataxias. Spasticity, polyneuropathy, ophthalmoplegia, dementia
SCA2		12q24	Ataxin-2	AD ^a	Teens	Neuropathy, ophthalmoplegia, extrapyramidal features
SCA3 (Machado-Joseph)		14q32	Ataxin-3	AD ^a	Teens	25% of dominant ataxias, spasticity, neuropathy, extrapyramidal features
SCA6		19p13	alpha1A calcium channel	AD ^a	Adult	20% of dominant ataxias; dysarthria, nystagmus, posterior column signs
SCA7		3p14	Ataxin-7	AD ^a	Late teens Infantile	Retinal degeneration, hearing loss, ophthalmoplegia, spasticity Fulminant, with large CAG expansion
SCA8		13q21	CTG repeat (noncoding) ATTCT repeat (ataxin-10)	AD	Adult	Sensory neuropathy, spasticity; there is rapid infantile variant
SCA10		22q13	Protein phosphatase 2A	AD	Teens-adult	Seizures, personality change
SCA12		5q31	Protein kinase C gamma	AD ^a	Variable	Neuropathy, extrapyramidal features, dementia, facial myokymia
SCA14		19q13	TATA box binding protein	AD	Teens-adult	Myoclonus, tremor
SCA17		6q27	Fibroblast growth factor 14	AD ^a	Variable	Cognitive decline, seizures, extrapyramidal features
SCA with tremor		13q34	Frataxin	AD	Childhood	Tremor, cognitive defects, facial dyskinesia
Friedreich's ataxia		9q13	Vitamin E transport protein	AR	Teens	Spinocerebellar ataxia, neuropathy, cardiomyopathy, arrhythmia
Friedreich's ataxia variant		8q13		AR	Childhood	Spinocerebellar ataxia, neuropathy, cardiomyopathy, arrhythmia
Episodic						
Episodic ataxia with myokymia		12p13	KCNA	AD	Teens	Limb stiffness, dizziness, visual blurring
Paroxysmal episodic ataxia		19p13	alpha1A calcium channel	AD	Teens	Nystagmus, vertigo, weakness
Episodic ataxia		2q22	CACNB4β4	AD	Teens	Seizures, myoclonus, nystagmus

^a CAG expansion.

of hereditary ataxia in most large series (86 of 171 cases in Sjögren's series); its incidence among Europeans and North Americans is 1.5 per 100,000 cases per year. Friedreich, of Heidelberg, began in 1861 to report on a form of familial progressive ataxia that he had observed among nearby villagers. It was already known through the writings of Duchenne in Paris that locomotor ataxia was the prominent feature of spinal cord syphilis, i.e., tabes dorsalis, but it was Friedreich who demonstrated that a nonsyphilitic hereditary type also existed. This concept was greeted with some skepticism, but soon Duchenne himself affirmed the existence of the new disease and other case reports appeared in England, France, and the United States. In 1882, in a thesis on this subject by Brousse of Montpellier, Friedreich's name was attached to the new entity.

As further cases appeared, it was noted that in about half the onset was before the tenth year and sometimes as early as the second or third year; Mollaret could find no examples with onset after the age of 25 years. The disease is always steadily progressive; within 5 years of onset, walking is no longer possible in many cases. Genetic linkage studies of 22 families with three or more affected siblings have led to the assignment of the gene mutation to chromosome 9q13-2 (Chamberlain et al). Subsequently, a form of Friedreich ataxia of later onset (between 20 and 30 years) and slower progression has been recorded (DeMichele et al); in this form, the gene abnormality, like that of the classic Friedreich ataxia, is in the centromeric region of chromosome 9. In the vast majority of cases the chromosome 9 mutation is an expansion of a GAA trinucleotide repeat within a gene that codes for the protein *frataxin*. (It is of interest that this mutation is within an intron). In a very small proportion of cases, the mutation is a missense mutation rather than an expansion. In either case, the consequence of the mutation is a reduction in levels of frataxin and loss of its function. This is consonant with the recessive pattern of inheritance. Cases in which the mutation allows the presence of some residual protein have a milder course. A current hypothesis is that frataxin is a mitochondrial matrix protein whose function is to prevent intramitochondrial iron overloading.

Clinical Features Ataxia of gait is nearly always the initial symptom. Occasionally the ataxia begins rather abruptly after a febrile illness, and one leg may become clumsy before the other. This "hemiplegic" pattern is exceptional; usually both legs are affected simultaneously. Difficulty in standing steadily and in running are early symptoms; however, Wilson had commented on fatigability, leg pains, and postexertional cramps—symptoms that we have seldom elicited. The hands usually become clumsy months or years after the gait disorder, and dysarthric speech appears after the arms are involved (this is rarely an early symptom).

In some patients, pes cavus and kyphoscoliosis precede the neurologic symptoms; in others, they follow by several years. The characteristic foot deformity takes the form of a high plantar arch with retraction of the toes at the metatarsophalangeal joints and flexion at the interphalangeal joints (hammertoes).

A notable feature is cardiomyopathy, which is demonstrable in more than half the patients. The myocardial fibers are hypertrophic and may contain iron-reactive granules (see Koeppen). Many of the patients die as a result of cardiac arrhythmia or congestive heart failure. For this reason, it is essential that affected individuals have a cardiologic assessment including regular electrocardiography and echocardiography. The cardiomyopathy of Friedreich disease can develop insidiously but with fulminant consequences, for which reason cardiologists caring for these patients should be knowledgeable about the neurologic disease. Kyphosco-

liosis and restricted respiratory function are also important contributory causes of death. Harding observed that about 10 percent of these patients have diabetes mellitus and a similar proportion have impaired glucose tolerance.

In the fully developed state, the abnormality of gait is of mixed sensory and cerebellar type, aptly called *tabetocerebellar* by Charcot. According to Mollaret, the author of an authoritative monograph on the disease, the cerebellar component predominates, but in our relatively small series we have been impressed almost as much with the sensory (tabetic) aspect. The patient stands with feet wide apart, constantly shifting position to maintain balance. Friedreich referred to the constant teetering and swaying on standing as *static ataxia*. In walking, as with all sensory ataxias, the movements of the legs tend to be brusque, the feet resounding unevenly and irregularly as they strike the floor, and closure of the eyes causes the patient to fall (Romberg sign). This reflects the spinal component (posterior columns). Attempts to correct the imbalance may result in abrupt, wild movements. Often there is a rhythmic tremor of the head. The arms are grossly ataxic, and both action and intention tremors are manifest. Speech is slow, slurred, explosive, and finally almost incomprehensible. Breathing, speaking, swallowing, and laughing may be so incoordinate that the patient nearly chokes while speaking. Holmes remarked on an ataxia of respiration that causes "curious short inspiratory whoops." Facial, buccal, and arm muscles may display tremulous and sometimes choreiform movements. Mentation has been preserved in all our patients. However, emotional lability has been sufficiently prominent to provoke comment by others. Horizontal nystagmus may be present with the eyes in the primary position and is increased on lateral gaze. Rotatory and vertical nystagmus are rare. Deafness has been recorded, along with vertigo and, more rarely, with inexcitability of the labyrinth and blindness with optic atrophy. Ocular movements usually remain full, and pupillary reflexes are normal. The facial muscles may seem slightly weak, and deglutition may become impaired. Amyotrophy occurs late in the illness and is usually slight, but it may be extreme in patients with an associated neuropathy (see below). The tendon reflexes are abolished in nearly every case; rarely, they may be obtainable when the patient is examined early in the illness (see below). Plantar reflexes are extensor, and flexor spasms may occur even with complete absence of tendon reflexes, indicating that the areflexia is sensory in origin. The abdominal reflexes are usually retained until late in the illness. Loss of vibratory and position sense is invariable from the beginning; later, there may be some diminution of tactile, pain, and temperature sensation as well. Sphincter control is usually preserved.

In one important variant of Friedreich ataxia the tendon reflexes are preserved or even hyperactive and the limbs may be spastic. Some of these cases are associated with hypogonadism. It is the finding of the aberrant *frataxin* gene on chromosome 9 that links these cases to Friedreich ataxia. Harding found 20 such cases among her 200 familial ataxias at the National Hospital, London. Nevertheless, the distinction between classic Friedreich ataxia and ataxia with retained tendon reflexes is an important one clinically, insofar as kyphoscoliosis and heart disease do not occur in the latter group and the prognosis is better. In other cases, some familial, a spastic paraparesis and optic atrophy are combined with ataxia (Behr). We would also include here cases of the type described by Hogan and Bauman, in which a progressive cerebellar ataxia was associated with spasticity and other corticospinal tract signs of the legs. Cerebellar atrophy has not been a prominent feature of these cases, and we would adopt the position that they are forms of spi-

nocerebellar degeneration that are transitional between Friedreich ataxia and some of the other heredoataxias with cerebellar atrophy. In the few autopsied cases, the main abnormality has been in the spinal cord and the spinocerebellar (cerebellopetal) tracts, but some in addition show corticospinal tract degeneration.

Other abortive and atypical forms are numerous. Peroneal muscular atrophy is sometimes associated with Friedreich ataxia, as is true of the areflexic dystasia (sensory neuropathy) of Roussy and Levy. These disorders are discussed with the hereditary neuropathies on page 1157. Hereditary forms of optic atrophy, retinitis pigmentosa, deafness, and myoclonus are occasionally combined with Friedreich ataxia as well, but we agree with Skre that they probably represent genetically independent entities. Two of our Friedreich patients had occasional seizures.

Laboratory tests of diagnostic value are the measurement of sensory nerve conduction velocities and amplitudes, electrocardiography (demonstrating signs of ventricular hypertrophy and in some, heart block), and chest and spine films (to show heart size and kyphoscoliosis). The CT scans and MRI seldom reveal a significant degree of cerebellar atrophy; the spinal cord is small. There is no consistent abnormality of blood or CSF. Visual evoked potentials are abnormal only in patients with associated optic atrophy. **Pathology** The spinal cord is thin. The posterior columns and the corticospinal and spinocerebellar tracts are all depleted of medullated fibers, and there is a fibrous gliosis that does not replace the bulk of the lost fibers. The nerve cells in Clarke's column and the large neurons of the dorsal root ganglia, especially lumbosacral ones, are reduced in number—but perhaps not to a degree that would fully explain the posterior column degeneration. The posterior roots are thin. Betz cells are also diminished in some cases, but the corticospinal tracts are relatively intact down to the medullary-cervical junction. Beyond this point, they are degenerated, but to a lesser degree than the posterior columns. The nuclei of cranial nerves VIII, X, and XII all exhibit a reduction of cells. Slight to moderate neuronal loss is seen also in the dentate nuclei, and the middle and superior cerebellar peduncles are reduced in size. Some depletion of Purkinje cells in the superior vermis and neurons in corresponding parts of the inferior olfactory nuclei can be seen.

Many of the myocardial muscle fibers degenerate and are replaced by fibrous connective tissue. No consistent biochemical abnormalities have been demonstrated.

By way of exploring the anatomic basis of the clinical findings, pes cavus is not different from that seen in other diseases with mild hypertonus of the long extensors and flexors of the feet and in the early-onset hereditary polyneuropathies. These also cause amyotrophy of intrinsic foot muscles when the bones of the feet are still malleable. The kyphoscoliosis is probably due to imbalance of the paravertebral muscles. The tabetic aspects of the disease are explained by the degeneration of large cells in the dorsal root ganglia and the large sensory fibers in nerves, dorsal roots, and the columns of Goll and Burdach. The loss of large neurons in the sensory ganglia also causes abolition of tendon reflexes. The cerebellar ataxia is attributable to a degeneration of the spinocerebellar tracts, the superior vermis, and the dentatorubral pathways in various combinations. Corticospinal lesions account for the weakness and Babinski signs and contribute to the pes cavus as well.

Diagnosis Friedreich disease and its variants must be distinguished from familial cerebellar cortical atrophy, described next, and from familial spastic paraparesis with ataxia, as well as from peroneal muscular atrophy and the Levy-Roussy syndrome, which

are discussed with the hereditary neuropathies in Chap. 46. It is advisable to assay serum vitamin E levels, since a rare but treatable inherited deficiency of a vitamin E transport protein causes a spinocerebellar syndrome with areflexia in children, resembling Friedreich's disease, as detailed in Chap. 41. This vitamin deficiency syndrome is difficult to distinguish from Friedreich ataxia, but the absence of dysarthria and of skeletal or cardiac abnormalities may be helpful. Exceptionally, a cardiac disturbance has been seen. A form of chronic inflammatory demyelinating polyneuropathy has long since overtaken tabes dorsalis as the most frequent type of areflexic ataxia. It bears a superficial resemblance to Friedreich ataxia when the onset is in childhood but lacks dysarthria and Babinski signs. A form of spinocerebellar degeneration related to human T-cell lymphotropic virus type I (HTLV-I), causing so-called tropical spastic paraparesis as well as the vacuolar myopathy of AIDS, must also be included in the differential diagnosis of late-onset cases.

Treatment Not much can be said on this subject since there is little effective therapy. A double-blind crossover study by Trouillas and associates found that the administration of oral 5-hydroxytryptophan modified the cerebellar symptoms. This drug is serotoninergic and is known to suppresses posthypoxic action myoclonus. Apart from this form of treatment, with which we have had no experience, no therapeutic measures are known to alter the course of the neurologic disease. Idebenone, an antioxidant (the short-chain analogue of coenzyme Q₁₀) has been shown in several small trials to reduce the progression of left ventricular hypertrophy, a substantial risk factor for arrhythmias and sudden death in these patients, but it does not affect the ataxia. These results are summarized in an article by Filla and Moss. Heart failure, arrhythmias, and diabetes mellitus are treated by the usual medical measures. Surgery for scoliosis and foot deformities may be helpful in selected cases.

Predominantly Cerebellar (Cortical, Holmes Type) Forms of Hereditary and Sporadic Ataxia

Soon after the publication of Friedreich's descriptions of a spinal type of hereditary ataxia, reports began to appear of somewhat different diseases in which the ataxia was related to degenerative changes in the cerebellum and brainstem rather than the spinal cord. Claims of their independence from the spinal type were based largely on a later age of onset, a more definite hereditary transmission (usually of autosomal dominant type), the persistence or hyperactivity of tendon reflexes, and the more frequent concurrence of ophthalmoplegia, retinal degeneration, and optic atrophy. Several of these clinical features, particularly briskness of tendon reflexes, are alien to the classic form of Friedreich ataxia.

By 1893 Pierre Marie thought it desirable to create a new category of hereditary ataxia that would embrace all of the non-Friedreich cases. He collated the familial cases of progressive ataxia that had been described by Fraser, Nonne, Sanger Brown, and Klippel and Durante (see Greenfield and Harding for references) and proposed that all of them were examples of an entity to which he applied the name *héredo-ataxie cérébelleuse*. Marie's proposition was based almost entirely on clinical observations—not his own but those made by the aforementioned authors. Later, as members of these families died, postmortem examinations disclosed that Marie's hereditary cerebellar ataxia included not one but several disease entities. Indeed, as pointed out by Holmes

(1907) and later by Greenfield, in three of the four families the cerebellum showed no significant lesions at all. Yet there was by then no doubt of the existence of a separate class of predominantly cerebellar atrophies, some purely cortical and others associated with a variety of noncerebellar lesions.

Clinical Features Holmes in 1907 described a family of eight siblings, of whom three brothers and one sister were affected by a progressive ataxia, beginning with a reeling gait and followed by clumsiness of the hands, dysarthria, tremor of the head, and a variable nystagmus. It may be taken as the prototype of pure cerebellar cortical degeneration. The ataxia began insidiously in the fourth decade and progressed slowly over many years. The late cortical cerebellar atrophy of Marie, Foix, and Alajouanine, reported in 1922, is probably the same disease. In their patients also, the onset was in later life (average age 57 years). The onset was usually insidious, rarely abrupt, and the progress was extremely slow, allowing survival for 15 to 20 years. Ataxia of gait, instability of the trunk, tremor of the hands and head, and slightly slowed, hesitant speech conformed to the usual clinical picture of a progressive cerebellar ataxia. Nystagmus was rare. Intelligence was usually preserved. The patellar reflexes were increased in many cases, the ankle jerks were often absent, and the plantar reflexes were said to be extensor in some. The last finding, in the absence of hyperreflexia and spasticity, must be accepted with caution, since avoidance-withdrawal responses are often mistaken for Babinski signs. In our own practices, sporadic forms of pure cerebellar degeneration have been as common as inherited ones, as already mentioned, but we have not performed extensive genetic testing. The differential diagnosis in the nonfamilial cases is quite broad, as discussed at the end of this section.

Pathology Postmortem examination of the Holmes-type cases disclosed a symmetrical atrophy of the cerebellum involving mainly the anterior lobe and vermis, the latter being more affected than the hemispheres. The Purkinje cells were absent in the lingula, centralis, and pyramis of the superior vermis and reduced in number in the quadrangularis, flocculus, biventral, and pyramidal lobes. The other cerebellar cortical neurons and granule cells were diminished in number, but the latter less so. The white matter was slightly pale in myelin stains. The roof and pontine nuclei were normal. There was cell loss in the dorsal and medial parts of the inferior olive nuclei. A questionable pallor was noted in the corticospinal and spinocerebellar tracts in myelin stains of the spinal cord. The vermic atrophy and that of adjacent parts of the cerebellum can be visualized with great clarity in MRIs (Fig. 39-7).

The pathologic findings in the cases of Marie, Foix, and Alajouanine were essentially the same. In further reports, both familial and sporadic cases of this type have been collected. The similarity of the pathologic (and clinical) changes to those of *alcoholic cerebellar degeneration* is at once apparent and should always raise the question of an alcoholic-nutritional cause in sporadic cases (Chap. 41).

Cerebellar Atrophy with Prominent Brainstem Features (Sporadic and Familial Olivopontocerebellar Atrophy)

A sporadically occurring instance of a disorder closely resembling the Holmes type of cortical cerebellar degeneration but with additional features of brainstem atrophy was described in 1900 by Déjerine and André-Thomas, who named it *olivopontocerebellar*

Figure 39-7. Familial cortical cerebellar atrophy. T1-weighted MRI in the sagittal plane showing marked atrophy of vermis and enlargement of fourth ventricle. The brainstem is only mildly atrophic. Compare with Fig. 39-8 in which the cerebellum and pons are atrophic.

atrophy (OPCA). The onset of symptoms was in the fifth decade of life, and the main manifestations were ataxia—first in the legs, then in the arms, hands, and bulbar musculature—a symptomatology common to all the cerebellar atrophies. As more and more cases of this type were collected (by 1943, Rosenhagen had collected 45 from the literature, to which he added 11 of his own), a *hereditary pattern* (autosomal dominant) was evident in some, and one or more long tracts in the spinal cord were found to have degenerated. About half the cases later developed the symptoms of Parkinson disease with degeneration of nigral cells and, in a few, of striatal cells as well, thereby linking the disease to striatonigral degeneration and what is now called *multiple system atrophy* (MSA) (see earlier discussion of this entity and below).

Notable findings in both the sporadic (Menzel and Déjerine-Thomas types) and the familial forms of OPCA are the extensive degeneration of the middle cerebellar peduncles, the cerebellar white matter, and the pontine, olivary, and arcuate nuclei; loss of Purkinje cells has been variable. Most likely this degeneration represents a terminal “dying back” of axons of the pontine and olivary nuclei with secondary myelin degeneration. The extreme atrophy of the medullary olivary nuclei virtually identifies the process and is evident on MRIs (Fig. 39-8).

In addition to the linkage in some cases with striatonigral degeneration, the boundaries of the entity of hereditary OPCA have gradually been extended; Konigsmark and Weiner subdivided them into the following types: (1) hereditary (dominant) type of Menzel; (2) hereditary (recessive) type of Fickler-Winkler; (3) hereditary (dominant) type with retinal degeneration; (4) hereditary (dominant) type of Shut-Haymaker, with spastic paraparesis and areflexia; and (5) hereditary (dominant) type with dementia, ophthalmoplegia, and extrapyramidal signs. But even this classification does not do justice to the variable presentations. To these can be added two additional types: (6) inherited cases of OPCA with neuropathy and slowed eye movements described by Wadia, of which we have seen two cases, and (7) cases with dystonia and a variety of other clinical findings, most of them in single cases or single families (hemiballismus, athetosis, contractures of the legs, fixed pupils, ophthalmoplegia, ptosis, gaze palsy, deafness, retinal degeneration, mental

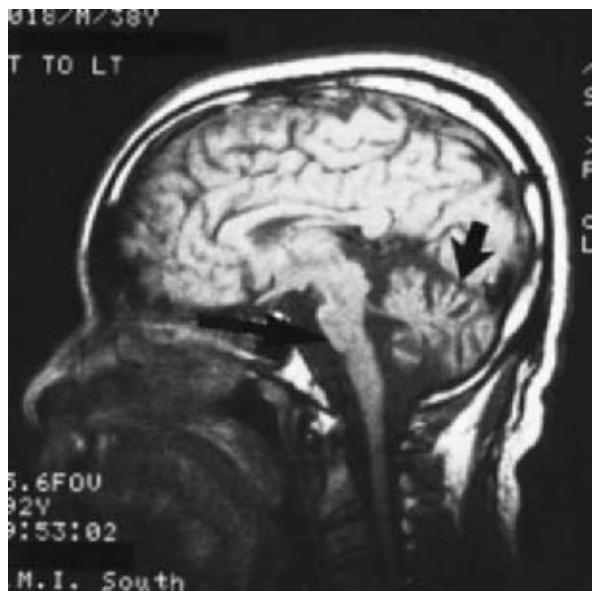

Figure 39-8. Olivopontocerebellar atrophy. MRI in the sagittal plane demonstrating both vermian atrophy (short arrow) and smallness of the pons (long arrow). (Reproduced by permission from Bisese JH: *Cranial MRI*. New York, McGraw-Hill, 1991.)

retardation and epilepsy, claw foot and scoliosis, incontinence, parkinsonian symptoms and signs, dementia). Even a neonatal type is known. Some are detailed further on, under “Other Complicated Hereditary Cerebellar Ataxias.”

Cases of *sporadic olivopontocerebellar atrophy* are more common than the familial variety and tend to occur at an older age than the familial ones; nystagmus, optic atrophy, retinal degeneration, ophthalmoplegia, and urinary incontinence are generally not observed. However, there are numerous cases that include mild extrapyramidal and neuropathic signs, slow eye movements, dystonia, impairment of vertical saccadic eye movements (thus simulating progressive supranuclear palsy), a vocal cord paralysis that is typical of MSA, and deafness. We have observed examples of each of these, particularly those with ophthalmoplegia (the so-called Wadia type). The relationship of olivopontocerebellar atrophy to MSA has already been discussed (page 925), but we would emphasize again that OPCA occurs most often independent of extrapyramidal degeneration for which reason we have chosen to accord it a separate designation.

Cerebellar Atrophy with Prominent Basal Ganglionic Features

Machado-Joseph-Azorean Disease A special form of hereditary ataxia with brainstem and extrapyramidal signs has been described in patients mainly but not exclusively of Portuguese-Azorean origin. One such case was described by Woods and Schaumburg under the name *nigrospinodentatal degeneration with nuclear ophthalmoplegia*. The disorder was characterized by an autosomal dominant pattern of inheritance and by a slowly progressive ataxia beginning in adolescence or early adult life in association with hyperreflexia, extrapyramidal (parkinsonian) rigidity, dystonia, bulbar signs, distal motor weakness, and ophthalmoplegia. There was no impairment of intellect, and in the examples the authors have seen, the extrapyramidal symptoms were mainly rigidity and

slowness of movement. There were no signs of corticospinal involvement. The conjunction of a Parkinson syndrome with cerebellar ataxia is also reminiscent of MSA except for an earlier age of onset and the prominence of dystonia, amyotrophy, and ophthalmoplegia. Postmortem examination disclosed a degeneration of the dentate nuclei and spinocerebellar tracts and a loss of anterior horn cells and neurons of the pons, substantia nigra, and oculomotor nuclei. The heredoataxia was unaccompanied by signs of polyneuropathy, which was an important feature of the disease in Portuguese emigrants, described earlier by Nakano and colleagues as Machado disease, this being the name of the progenitor of the afflicted family.

A similarly affected Azorean family named Joseph was described by Rosenberg and colleagues (1976) under the name of *autosomal dominant striatonigral degeneration*. The disease had its onset in early adult life and was characterized by progressive ataxia of gait, followed by dysarthria, nystagmus, slowness of eye movements, reduced facial mobility, slow lingual movements, fasciculations of face and tongue, dystonic postures, rigidity of the limbs, cerebellar tremor, hyperreflexia, and Babinski signs.

Under the name *Azorean disease of the nervous system* (now better known as *Machado-Joseph disease*), Romanul and colleagues described yet another family of Portuguese-Azorean descent, many members of which were affected by a syndrome comprising a progressive ataxia of gait, parkinsonian features, limitation of conjugate gaze, fasciculations, areflexia, nystagmus, ataxic tremor, and extensor plantar responses; the pathologic changes closely resembled those described by Woods and Schaumburg. Romanul and coworkers compared the genetic, clinical, and pathologic features of their cases with those described in other Portuguese-Azorean families and concluded that all of them represent a single genetic entity with variable expression. This concept of the disease has been corroborated by the further observations of Rosenberg and of Fowler, who studied 20 patients with the Machado-Joseph-Azorean disease over a 10-year period.

This disease is not limited to Azoreans. Cases conforming to the above descriptions have now been observed among African-American, Indian, and Japanese families (Sakai et al, Yuasa et al, Bharucha et al). Cancel and colleagues have found an unstable number of CAG repeating sequences in a novel gene, ataxin-3, and named the disorder, which corresponds to Machado-Joseph disease, type 3 spinocerebellar ataxia (SCA 3).

There is no treatment of proven value. Early diagnosis of patients at risk is possible by the examination of ocular movements. In asymptomatic patients, Hotson and associates found dysmetric horizontal and vertical saccades similar to those in symptomatic individuals. In fully developed cases, the MRI findings are characteristic—reduced width of the superior and middle cerebellar peduncles, atrophy of the frontal and temporal lobes, and smallness of the pons and globus pallidus (Murata et al).

Multiple System Atrophy with Predominant Ataxia (See page 925) This entity has been discussed with the degenerative disorders of the basal ganglia earlier in the chapter. Here it is only pointed out again that a number of cases of sporadic progressive ataxia in mid- and late-life are attributable to this process and have been termed MSA-C to signify the predominant cerebellar feature. The extrapyramidal, corticospinal, or autonomic aspects of the illness become evident only with continued follow-up or by pathologic examination. Some guidance as to the frequency of MSA as the cause of otherwise undifferentiated sporadic ataxia is given in

the study by Abele and colleagues who found it to account for almost one-third of cases, but the precise number is open to question, since pathologic examinations were not made.

Dentatorubropallidolysian Atrophy (DRPLA) This is a rare familial disorder, described mostly in Japan and in small European pockets, in which symptoms of cerebellar ataxia are coupled with those of choreoathetosis and dystonia and, in isolated instances, myoclonus, parkinsonism, epilepsy, or dementia. Pathologically there is degeneration of the dentatorubral and pallidolysian systems (Smith; Iizuka et al). The main consideration when chorea is prominent is the separation of this disorder from Huntington disease (Warner et al). The gene defect is an unstable CAG trinucleotide repeat on chromosome 12 that codes for polyglutamine in the gene and expresses the protein atrophin. This same mutation has been defined in families from throughout the world (e.g., Warner et al). As with Huntington chorea (where the expanded polyglutamine tract is in huntingtin), this disease is inherited as an autosomal dominant trait and shows an inverse correlation between the age of onset and the size of the gene expansion. Diagnosis can be confirmed by means of DNA analysis.

Other Complicated Hereditary Cerebellar Ataxias

Dentatorubral Degeneration This is a rare and still somewhat nebulous entity, but it is probably distinct from the condition described above, under "Dentatorubropallidolysian Atrophy." There are, however, several instructive features. In 1921, Ramsay Hunt published an account of 6 patients (2 of whom were twin brothers) in whom myoclonus was combined with progressive cerebellar ataxia. The age of onset in the 4 nonfamilial cases was between 7 and 17 years, and the cerebellar ataxia followed the myoclonus by an interval of 1 to 20 years. Hunt named this disorder *dyssynergia cerebellaris myoclonica*. In the twin brothers there were signs of Friedreich ataxia; postmortem examination of one showed a degeneration of the posterior columns and spinocerebellar tracts but not of the corticospinal tracts. The only lesion in the cerebellum was an atrophy and sclerosis of the dentate nuclei with degeneration of the superior cerebellar peduncles. Louis-Bar and van Bogaert in 1947 reported a similar case, and they noted, in addition to the above findings, degeneration of the corticospinal tracts and loss of fibers in the posterior roots. Thus the pathology was identical to that of Friedreich ataxia except for the more severe atrophy of the dentate nuclei.

Earlier (1914), under the title of *dyssynergia cerebellaris progressiva*, Hunt had drawn attention to a progressive disease in young individuals manifest by what he considered to be a pure cerebellar syndrome. One of the three patients described in this paper died 13 years after the onset of her illness. Necropsy disclosed cavitary lesions in the lenticular nuclei, cerebellum, and pons and a diffuse increase of Alzheimer (type 2) glial cells, associated with asymptomatic nodular cirrhosis of the liver—i.e., findings typical of progressive lenticular degeneration (Wilson disease). Hunt's reports emphasize the hazard of classifying cerebellar ataxias on the basis of clinical findings alone, a point made effectively by Holmes in relation to the hereditary cerebellar ataxia of Marie (see earlier).

Cerebellar Ataxia with Selective Degeneration of Other Systems In addition to those enumerated earlier on page 185,

briefly mentioned here are the hereditary ataxias, all rare, with sensory peripheral neuropathy (Biemond type with degeneration of dorsal root ganglia and posterior columns, of which we have seen two instances; see Nachmanoff et al); with optic atrophy; an autosomal recessive syndrome of cerebellar ataxia with pigmentary retinal degeneration and congenital deafness; an autosomal dominant hereditary ataxia with muscular atrophy, retinal degeneration, and diabetes mellitus; Friedreich ataxia with juvenile parkinsonism; an autosomal recessive ataxia with total albinism; the autosomal recessive ataxia with cataracts, oligophrenia, pyramidal signs, and stunting of growth; and an essential (familial) tremor complicated in later years by cerebellar ataxia. Pollock and Kies have described yet another late-life form of hereditary cerebellar ataxia with near global loss of pain and temperature sensation (due to loss of primary sensory afferents). Details regarding these rare ataxias and appropriate references can be found in the monograph on the inherited ataxias edited by Kark et al.

Paroxysmal Ataxias Two adult forms of hereditary cerebellar ataxia are paroxysmal in nature (see Chap. 5). In one type (EA-2 for episodic ataxia, type 2), the episodes occur without explanation and last several hours; vertigo is usually a prominent feature of the attacks. Between attacks the patient is normal or has only minimal ataxia and nystagmus (Griggs et al). These ataxic episodes respond strikingly to oral acetazolamide. The disorder has been found to be a disorder of the calcium channel on chromosome 19. A similar but physiologically and genetically unrelated paroxysmal ataxia (EA-1) is characterized by episodes that may be precipitated by exercise and by muscle myokymia (rippling) between attacks. Vertigo does not occur and acetazolamide is less effective or not effective at all. The disorder is due to an abnormality of the potassium channel gene on chromosome 12. Both of these episodic ataxias are therefore "channelopathies" (see Chap. 54). Also of interest is spinocerebellar atrophy type 6, a progressive condition in which a mutation has been traced to same gene implicated in the EA-2 acetazolamide-responsive paroxysmal ataxia, but this disorder is not paroxysmal and results in progressive ataxia, dysarthria, and loss of proprioception.

Genetics of the Heredodegenerative Ataxias (Table 39-5)

The many familial degenerative ataxic disorders described in the preceding pages are genetically distinct. As indicated, *autosomal recessive* Friedreich ataxia is due to an expanded GAA repeat in the frataxin gene (Campuzano et al). The direct molecular test for the GAA expansion is useful for diagnosis, particularly for atypical cases with late onset (Dürr et al). The rarer recessive type associated with vitamin E deficiency arises from mutations in the gene that encodes an alpha tocopherol (vitamin E) transport protein, as mentioned above.

Among the *autosomal dominant* cerebellar ataxias of later onset, molecular and gene studies have identified mutant genes at 14 chromosomal loci, including three associated with episodic ataxia. Of these 14 forms of autosomal dominant ataxia, 8 are known to be caused by expanded CAG-trinucleotide repeats (SCA types 1, 3, 6, and 7, 12, 17, as well as dentatorubropallidolysian atrophy, or DRPLA). Undoubtedly others will be discovered. However, as has been affirmed, the precise mechanisms by which the expanded polyglutamine molecule leads to neuronal cell death remain uncertain. It is likely that differences in the clinical manifestations of

these disorders will reflect differences in the patterns of expression of the affected proteins; i.e., each is expressed in different subpopulations of neurons and at different stages in development. This raises the possibility that the cascade of events that triggers neuronal degeneration is similar in each of the diseases with a CAG expansion and that a therapy might be discovered that is effective in all of them.

Table 39-5 summarizes the chromosomal loci, genetic terminology, related neural abnormalities, and clinical features of the CAG-dependent (and other) cerebellar atrophies.

The main types are summarized again here with some clinical comments:

- SCA 1: 6p; ophthalmoparesis, pyramidal and extrapyramidal signs; included in this group are most of the olivopontocerebellar atrophies.
- SCA 2: 12q; slowed eye movements and saccades (Wadia type). Dentatorubropallidolysian atrophy (DRPLA): 12p.
- SCA 3: 14q; the Machado-Joseph phenotype with several allelic variants.
- SCA 4: 16q; sensory neuropathy and pyramidal signs.
- SCA 7: 3p; retinal degeneration.
- SCA 6: 19p; related to the alpha subunit of a voltage-dependent calcium channel; a different mutation at the same locus causes the acetazolamide-responsive episodic ataxia (EA-2).
- EA-1: (episodic ataxia) 12p; potassium channelopathy.
- EA-2: (acetazolamide-responsive episodic ataxia) 19p; calcium channelopathy.

Differential Diagnosis of the Degenerative Ataxias (See Table 5.1, Page 78) Sporadic forms of cerebellar ataxia in adults are in some instances traceable to strokes involving cerebellar pathways (Safe et al). These are, of course, of acute onset. Some cases of ataxia are alcoholic-nutritional in origin, and a few are related to abuse of drugs, especially anticonvulsants, which may in a few cases cause a slowly progressive and permanent ataxia; rarely, organic mercury induces subacute cerebellar degeneration, and adulterated heroin causes a more abrupt and severe ataxic syndrome. The paraneoplastic variety of cerebellar degeneration often enters into the differential diagnosis; as a rule it occurs mostly in women with breast or ovarian cancers and evolves much more rapidly than any of the heredodegenerative forms. The more rapid onset of ataxia and the presence of anti-Purkinje cell antibodies (anti-Yo; page 583) are central to identifying the nature of this disease. From time to time one observes a similar idiopathic variety of subacute cerebellar degeneration, particularly in women who have no neoplasm and lack the specific antibodies of the paraneoplastic disease (Ropper). Rare cases of ataxia have been associated with celiac disease and Whipple disease, as noted in Chap. 5. Ataxia may also be an early and prominent manifestation of Creutzfeldt-Jakob disease caused by a transmissible prion (see Chap. 33) or of an inherited metabolic disease (Chap. 37). Of the latter, late-onset GM₂ gangliosidosis may simulate a cerebellar degeneration in adults (page 826). Rare cases of aminoacidopathy manifesting for the first time in adult life have also provoked a cerebellar syndrome.

Treatment This has been unsatisfactory and is limited largely to supportive measures such as the prevention of falling. Amantadine 200 mg daily for several months has shown limited benefit in some studies (Boetz et al). Whether thalamic electrical stimulators, or the type used for the treatment of Parkinson disease, have a role in suppressing the cerebellar tremor is not known.

Hereditary Polymyoclonus

The syndrome of quick, arrhythmic, involuntary single or repetitive twitches of a muscle or group of muscles was described in Chap. 6, where it was pointed out that the condition has many causes. Those due to hereditary metabolic diseases are presented in Chap. 37. Familial forms are known, one of which, associated with cerebellar ataxia, was discussed earlier (dyssynergia cerebellaris myoclonica of Ramsay Hunt). But there is another disease, known as *hereditary essential benign myoclonus*, that occurs in relatively pure form unaccompanied by ataxia (page 87). In the latter condition, it may at times be difficult to evaluate coordination because willed movement is interrupted by the myoclonus and may be mistaken for intention tremor. Only by slowing the voluntary movement can the myoclonus be reduced or eliminated. This myoclonic disease is inherited as an autosomal dominant trait. It becomes manifest early in life; once established, it persists with little or no change in severity throughout life, often with rather little disability. It can, by its natural course, be differentiated from some of the hereditary metabolic diseases such as the Unverricht and Lafora types of myoclonic epilepsy, the lipidoses, tuberous sclerosis, and myoclonic disorders that follow certain viral infections and anoxic encephalopathy. Of interest is the response of this form of movement disorder, as in the case of acquired postanoxic myoclonus (page 89), to certain pharmacologic agents, notably clonazepam, valproic acid, and 5-hydroxytryptophan, the amino acid precursor of serotonin, particularly when these agents are used in combination.

The main clinical distinctions to be made are from Creutzfeldt-Jakob subacute spongiform encephalopathy; drug-induced myoclonus, particularly lithium; renal failure and other acquired metabolic disorders; asterixis; and from the startle responses (page 90). Myoclonus as one component of a more complex movement disorder in corticobasal-ganglionic degeneration has already been mentioned.

SYNDROME OF MUSCULAR WEAKNESS AND WASTING WITHOUT SENSORY CHANGES

Motor System Disease

This general term is used to designate a progressive degenerative disorder of motor neurons in the spinal cord, brainstem, and motor cortex, manifest clinically by muscular weakness, atrophy, and corticospinal tract signs in varying combinations. It is a disease of middle life, for the most part, and progresses to death in a matter of 2 to 5 years or longer in exceptional cases.

Customarily, motor system disease is subdivided into several subtypes on the basis of the particular grouping of symptoms and signs. The most frequent form, in which amyotrophy and hyperreflexia are combined, is called *amyotrophic lateral sclerosis*, or *ALS* (*amyotrophy* is the term applied to denervation atrophy and weakness of muscles). Less frequent are cases in which weakness and atrophy occur alone, without evidence of corticospinal tract dysfunction; for these the term *progressive spinal muscular atrophy* is used. When the weakness and wasting predominate in muscles innervated by the motor nuclei of the lower brainstem (i.e., muscles of the jaw, face, tongue, pharynx, and larynx), it is customary to speak of *progressive bulbar palsy*). In a small proportion of patients, the clinical state is dominated by spastic weakness,

hyperreflexia, and Babinski signs, with lower motor neuron affection becoming apparent only at a later stage of the illness if at all. This is designated as *primary lateral sclerosis*, a rare form of motor system disease in which the degenerative process remains confined to the corticospinal pathways (Pringle et al). The present authors believe that the pure spastic paraplegias without amyotrophy represent a special class of disease, hence they are described separately. There is also a relatively common familial form of spastic paraplegia in which the disease process is confined to the corticospinal tracts or, in some cases, combined with posterior column or other neurologic signs.

In addition, a special type of spinal muscular atrophy disease occurs in infancy and childhood. Indeed, this condition is the leading cause of heritable infant mortality and, after cystic fibrosis, the most frequent form of serious autosomal recessive disease (Pearl). The best known is the Werdnig-Hoffmann type of *infantile spinal muscular atrophy* (SMA type I); but there are other familial forms beginning in later childhood, adolescence, or early adult life (SMA types II and III, or the Wohlfart-Kugelberg-Welander type). Despite the clinical heterogeneity of the heritable childhood spinal muscular atrophies, they all derive from mutations in the SMN gene (see below), i.e., they are genetically homogeneous (Gilliam et al; Brzustowicz et al). This group of early-onset spinal muscular atrophies is separated genetically from familial ALS.

History Credit for the original delineation of amyotrophic lateral sclerosis is appropriately given to Charcot. With Joffroy in 1869 and Gombault in 1871, he studied the pathologic aspects of the disease. In a series of lectures given from 1872 to 1874, he provided a lucid account of the clinical and pathologic findings. Although called Charcot disease in France, *amyotrophic lateral sclerosis* (the term recommended by Charcot) has been preferred in the English-speaking world. Duchenne had earlier (1858) described *labioglossosolaryngeal paralysis*, a term that Wachsmuth in 1864 changed to *progressive bulbar palsy*. In 1869 Charcot called attention to the nuclear origin of progressive bulbar palsy, and in 1882 Déjerine established its relationship to ALS. Most authors credit Aran and Duchenne with the earliest descriptions of progressive spinal muscular atrophy, which they believed to be of myogenic origin. This interpretation was, of course, incorrect; Cruveilhier, a few years later, noted the slender anterior roots, and soon thereafter the disease was brought into line with ALS as a myelopathic or spinal muscular atrophy.

Amyotrophic Lateral Sclerosis This is a common disease, with an annual incidence rate of 0.4 to 1.76 per 100,000 population. Men are affected nearly twice as often as women. Most patients are more than 45 years old at the onset of symptoms, and the incidence increases with each decade of life (Mulder). The disease occurs in a random pattern throughout the world except for a dramatic clustering of patients among inhabitants of the Kii peninsula in Japan and in Guam, where ALS is often combined with dementia and parkinsonism. In about 10 percent of cases, the disease is familial, being inherited as an autosomal dominant trait with age-dependent penetrance. The familial cases do not differ much in their symptoms and clinical course from nonfamilial ones, although as a group the former have a somewhat earlier age of onset, an equal distribution in men and women, and a slightly shorter survival.

In the most typical forms of disease, the onset is perceived by the patient as weakness in a distal part of one limb. This may be noted first as an unexplained tripping because of slight foot drop.

Or there may be awkwardness in tasks requiring fine finger movements (in handling buttons and automobile ignition keys), stiffness of the fingers, and slight weakness or wasting of the hand muscles. In other words, features related to upper and to lower motor neuron degeneration (or both) may appear insidiously in one limb. Cramping beyond what seems natural and fasciculations of the muscles of the forearm, upper arm, and shoulder girdle also appear. The earliest manifestation of the lower motor neuron component of this disease is often volitional cramping—for example, leg cramps as the patient turns in bed during the early morning hours. (This is never a presenting complaint, but it is quite common as an early manifestation.) As the weeks and months pass, the other hand and arm may be similarly affected. Before long, the triad of atrophic weakness of the hands and forearms, slight spasticity of the arms and legs, and generalized hyperreflexia—all in the absence of sensory change—leaves little doubt as to the diagnosis. Muscle strength and bulk diminish in parallel or there is a relative preservation of power early in the illness. Despite the amyotrophy, the tendon reflexes are notable for their liveliness. Babinski and Hoffmann signs are variably present. Surprisingly, they may not appear even as the illness progresses. Abductors, adductors, and extensors of fingers and thumb tend to become weak before the long flexors, on which the handgrip depends, and the dorsal interosseous spaces become hollowed, giving rise to the “cadaveric” or “skeletal” hand. The muscles of the upper arm and shoulder girdles are typically involved later. When an arm is the first limb affected, all this occurs while the thigh and leg muscles seem relatively normal, and there may come a time in some cases when the patient walks about with useless, dangling arms. Later the atrophic weakness spreads to the neck, tongue, pharyngeal, and laryngeal muscles, and eventually those in the trunk and lower extremities yield to the onslaught of the disease.

The affected parts may ache and feel cold, but true paresthesias, except from poor positioning and pressure on nerves, do not occur or are minor. Sphincteric control is well maintained even after both legs have become weak and spastic, but many patients acquire urinary and sometimes fecal urgency in the advanced stages of the disease. The abdominal reflexes may be elicitable even when the plantar reflexes are extensor. Extreme spasticity is rarely seen. Coarse fasciculations are usually evident in the weakened muscles but may not be noticed by the patient until the physician calls attention to them. Fasciculations are almost never the sole presenting feature of ALS—a clinical truism with which one can reassure physicians and medical students who fear, on the basis of persistent focal muscle twitching, that they are developing the disease.

The course of this illness, irrespective of its particular mode of onset and pattern of evolution, is progressive. There may be periods lasting weeks or months during which the patient observes no advance in symptoms but clinical changes can nonetheless be detected. Half the patients succumb within 3 years of onset and 90 percent within 6 years (Mulder et al). The clinical variants of motor neuron disease that occur with regularity and have distinguishing clinical features are described below.

Other Patterns of Evolution In addition to the special configurations discussed further on, there are many patterns of neuromuscular involvement other than the one just described. A leg may be affected before the hands. A foot drop with weakness and wasting of the pretibial muscles may be incorrectly attributed to peroneal nerve compression until weakness of the gastrocnemius and other muscles betrays a more widespread involvement of lumbosacral

neurons. In our experience this crural amyotrophy is somewhat less frequent than the brachial-manual type. Another variant is the early involvement of thoracic, abdominal, or posterior neck muscles, the last being one of the causes of head lolling in older individuals. Yet another pattern is of early diaphragmatic weakness; such cases come to attention because of respiratory failure. The pattern of more symmetrical proximal limb or shoulder-girdle amyotrophy with onset at an early age is also well known and simulates muscular dystrophy (Wohlfart-Kugelberg-Welander disease—page 946). On several occasions we have observed a pattern involving the arm and leg on the same side, first with spasticity and then with some degree of amyotrophy; this is sometimes called the *hemiplegic* or *Mills variant*. However, this condition more frequently turns out to be due to multiple sclerosis.

The first manifestations may be a spastic weakness of the legs, in which case a diagnosis of primary lateral sclerosis may be made (discussed further on); only after a year or two do the hand and arm muscles weaken, waste, and fasciculate. It is cases of this type that led to the inclusion of spastic paraparesis as a variant of ALS. Early on, a spastic bulbar palsy with dysarthria and dysphagia, hyperactive jaw jerk and facial reflexes, but without muscle atrophy, may be the initial phase of disease.

From time to time, as the disease advances, very mild distal sensory loss is observed in the feet without explanation, but always, if the sensory loss is a definite and early feature, the diagnosis must remain in doubt. About 5 percent of cases of ALS are observed in conjunction with a frontotemporal dementia; less commonly, there is an association with a Parkinson syndrome (page 806).

Progressive Muscular Atrophy (PMA) This clinical syndrome is more common in men than in women, in a ratio of 4 to 1. It probably encompasses several diseases of the lower motor neuron, only some of which are manifestations of ALS. In fact, the original report of familial PMA by William Osler described a family now known to have a mutation in the SOD1 gene (see below). In about half the patients, the illness takes the form of a symmetrical (sometimes asymmetrical) wasting of intrinsic hand muscles, slowly advancing to the more proximal parts of the arms; less often, the legs and thighs are the sites of the initial atrophic weakness; less often still, the proximal parts of the limbs are affected before the distal parts. Fascicular twitchings and cramping are variably present.

These purely lower motor neuron amyotrophies tend to progress at a slower pace than the usual case of ALS, some patients surviving for 15 years or longer. Chio and colleagues, who analyzed the factors affecting life expectancy in 155 patients with PMA, found that younger patients had a more benign course—the 5-year survival was 72 percent in patients with an onset before age 50 and 40 percent in patients with onset after age 50. Some of the most chronic varieties of PMA are familial. Otherwise they differ from ALS only in that the tendon reflexes are diminished or absent and signs of corticospinal tract disease cannot be detected. The main disease to be distinguished from PMA is an immune-mediated motor neuropathy that occurs with or without multifocal block of electrical conduction (page 1099) and various muscle diseases, notably, inclusion body myopathy. The presence of a paraproteinemia, specifically IgM with antibodies against the GM₁ ganglioside, or the finding of focal conduction block or sensory nerve abnormalities on the EMG implies the presence of an autoimmune neuropathy disease rather than one of motor neuron type, as discussed on page 1149.

Progressive Bulbar Palsy Here reference is made to a condition in which the first and dominant symptoms relate to weakness and laxity of muscles innervated by the motor nuclei of the lower brainstem, i.e., muscles of the jaw, face, tongue, pharynx, and larynx. This weakness gives rise to an early defect in articulation, in which there is difficulty in the pronunciation of lingual (*r, n, l*), labial (*b, m, p, f*), dental (*d, t*), and palatal (*k, g*) consonants. As the condition worsens, syllables lose their clarity and run together, until finally the patient's speech becomes unintelligible. In other patients, slurring is due to spasticity of the tongue, pharyngeal, and laryngeal muscles; the speech sounds as if the patient were eating food that is too hot. Usually the voice is modified by a combination of atrophic and spastic weakness, as indicated below. Defective modulation of the voice with variable degrees of rasping and nasality is another characteristic. The pharyngeal reflex is lost, and the palate and vocal cords move imperfectly or not at all during attempted phonation. Mastication and deglutition also become impaired; the bolus of food cannot be manipulated and may lodge between the cheek and teeth; and the pharyngeal muscles do not force it properly into the esophagus. Liquids and small particles of food find their way into the trachea or nose. The facial muscles, particularly of the lower face, weaken and sag. Fasciculations and focal loss of tissue of the tongue are usually early manifestations; eventually the tongue becomes shriveled and lies useless on the floor of the mouth. The chin may also quiver from fascicular twitchings, but diagnosis of the disease should not be made on the basis of fasciculations alone, i.e., in the absence of weakness or atrophy.

The jaw jerk may be present or exaggerated at a time when the muscles of mastication are markedly weak. In fact, spasticity of the jaw muscles may be so pronounced that the slightest tap on the chin will evoke clonus and blinking; rarely, attempts to open the mouth elicit a "bulldog" reflex (jaws snap shut involuntarily). Commonly, when a jaw jerk is present, a positive snout reflex can also be detected, both of these reflect degeneration of the posterior frontal lobe. Spastic weakness of the oropharyngeal muscles may be the initial manifestation of bulbar palsy and may at times surpass signs of atrophic weakness; pseudobulbar signs (pathologic laughter and crying) may reach extreme degrees. This is the only common clinical situation in which spastic and atrophic bulbar palsy coexist. Strangely, the ocular muscles always escape.

As with other forms of motor system disease, the course of bulbar palsy is inexorably progressive. Eventually the weakness spreads to the respiratory muscles and deglutition fails entirely; the patient dies of inanition and aspiration pneumonia, usually within 2 to 3 years of onset. About 25 percent of cases of motor system disease begin with bulbar symptoms, but rarely if ever does the sporadic form of progressive bulbar palsy run its course as an independent syndrome (pure heredofamilial forms of progressive bulbar palsy in the adult are known but rare). Practically always, after a few months or more, the other manifestations of ALS become evident. In general, the earlier the onset of the bulbar involvement, the shorter the course of the disease. Treatment is discussed below.

Primary Lateral Sclerosis (PLS) This entity, like ALS, can be a form of motor neuron disease, although we consider most cases to be examples of a separate process. Many but by no means all patients in whom the signs of corticospinal tract degeneration betray the presence of ALS will develop indications of lower motor neuron disease within 1 year, usually earlier. Approximately 20 percent of these patients, however, have a slowly progressive cor-

ticospinal tract disorder that begins with a pure spastic paraparesis; later, and to a lesser degree, the arms and oropharyngeal muscles become involved. These cases have distinctive neuropathologic features and are designated as *primary lateral sclerosis*, a term originally suggested by Erb in 1875. A historical review of the subject appears in the article by Pringle and colleagues. The features that most distinguish these cases from hereditary spastic paraparesis (HSP) is the onset during adulthood and the involvement of the arms and oropharyngeal muscles; the latter are almost universally spared in HSP.

The typical case begins insidiously in the fifth or sixth decade with a stiffness in one leg, then the other; there is a slowing of gait, with spasticity predominating over weakness as the years go on. Walking is still possible with the help of a cane for many years after the onset, but eventually this condition acquires the characteristic features of a severe spastic paraparesis. Over the years, finger movements become slower, the arms become spastic, and, if the illness persists for decades, speech takes on a pseudobulbar tone. In some patients the illness evolves over a few years. There are no sensory symptoms or signs. The legs are often found to be surprisingly strong, the difficulty in locomotion being attributable mainly to rigid spasticity. About half the patients acquire spasticity of the bladder. Pringle and associates suggest that an important diagnostic criterion of the disease is progression for 3 years without evidence of lower motor neuron dysfunction. A rare type begins in the oropharyngeal muscles, as mentioned above, but almost always, atrophy and fasciculations in this same region are evident within months.

Laboratory studies are seldom helpful. In a few instances we have been able to detect changes in the spinal course of the corticospinal tract on FLAIR MR images, but the majority of our other cases showed no such changes. Several authors have emphasized prolonged motor evoked potentials and conspicuous precentral atrophy on MRI (see Kuipers-Upmeijer et al). The spinal fluid and CK level are normal and the EMG reveals no indications of neurogenic denervation unless the spasticity is simply the initial feature of ALS.

Pathologic studies in a limited number of cases have disclosed a relatively stereotyped pattern of reduced numbers of Betz cells in the frontal and prefrontal motor cortex, degeneration of the corticospinal tracts, and preservation of motor neurons in the spinal cord and brainstem (Beal and Richardson, Fisher, Pringle et al). The corticospinal tract lesions are identical to those in typical ALS, described further on. Whether some of these cases are examples of late-onset familial spastic paraparesia (see further on) has not been explored with molecular techniques.

Differential Diagnosis of PLS Some patients who have only restricted bilateral signs of upper motor neuron disease prove to have multiple sclerosis, a slow compression of the spinal cord by spondylosis or meningioma, or the myelopathic form of adrenoleukodystrophy (affected males or female carriers). In a few, tropical spastic paraparesia, HIV myelopathy, or a family history of spastic paraparesia (Strümpell-Lorrain disease, described further on) has been uncovered. Almost unique among cases of this type have been a few linked to an adult onset of phenylketonuria or other aminoacidopathies, or to vitamin B₁₂ deficiency.

Laboratory Features of Motor Neuron Disease Laboratory investigation provides useful confirmatory evidence even in the typical clinical syndrome. The EMG, as expected, displays widespread fibrillations (evidence of active denervation) and fasciculations and

enlarged motor units (denoting reinnervation), and motor nerve conduction studies reveal only a slight slowing, without focal motor conduction block. If the atrophic paresis is restricted to an arm or hand, raising the question of cervical spondylosis, evidence of denervation over many widely separated somatic segments favors the diagnosis of ALS. In questionable cases, it is good practice to insist that denervation be demonstrated in at least three limbs before concluding that the process is ALS. (The currently favored criteria used for the purposes of clinical research mandate that this finding be present.) Widespread denervation of the paraspinal muscles and genioglossus or facial muscles is also strongly indicative of the disease, but testing of these muscles demands considerable experience. A muscle biopsy is sometimes helpful in corroborating neurogenic denervation. Sensory nerve action potentials should be normal; tests of motor nerve conduction have a normal velocity, but the amplitudes become progressively lower as the disease progresses—in the earliest stages, they too may be normal. When in a typical case the amplitudes of sensory nerve action potentials are reduced, there is usually an underlying entrapment neuropathy, diabetes, or late-life neuropathy. Sensory evoked potentials are mildly abnormal in a proportion of patients, but the explanation for this finding is obscure. (Sensory complaints and minimal sensory loss have been commented on above.) The CSF protein is usually normal or marginally elevated. Serum creatine kinase is moderately elevated in patients with rapidly progressive atrophy and weakness, but it is just as often normal. Motor evoked potentials elicited from the cortex are also prolonged in patients with prominent corticospinal signs. In this group, the MRI may show slight atrophy of the motor cortices and wallerian degeneration of the motor tracts (Fig. 39-9). These changes may be diagnostically useful and appear as increased FLAIR and T2 signal intensity in the posterior limb of the internal capsule, descending motor tracts of the brainstem, and spinal cord, all of which are subtle and may be missed.

Pathology The principal finding in ALS is a loss of nerve cells in the anterior horns of the spinal cord and motor nuclei of the lower brainstem. Large alpha motor neurons tend to be affected before small ones. In addition to neuronal loss, there is evidence of slight gliosis and proliferation of microglial cells. Many of the surviving nerve cells are small, shrunken, and filled with lipofuscin. It is not uncommon to also detect ubiquitin inclusions in threads, skeins, or dense aggregates within the affected neurons by special stains. Occasionally, there is another ill-defined cytoplasmic inclusion body. According to some reports, swelling of the proximal axon is an early finding, presumably antedating visible changes in the cell body itself. The anterior roots are thin, and there is a disproportionate loss of large myelinated fibers in motor nerves (Bradley et al). The muscles show typical denervation atrophy of different ages. Whitehouse and coworkers found a depletion of muscarinic, cholinergic, glycinergic, and benzodiazepine receptors in regions of the spinal cord where motor neurons had disappeared.

The corticospinal tract degeneration is most evident in the lower parts of the spinal cord, but it can be traced up through the brainstem to the posterior limb of the internal capsule and corona radiata by means of fat stains, which show the macrophages that accumulate in response to myelin degeneration. There is a loss of Betz cells in the motor cortex; this is manifest as a slight frontal lobe atrophy on the MRI, but it is not a prominent finding in most cases of ALS (Kiernan and Hudson). Other fibers in the ventral and lateral funiculi are depleted, imparting a characteristic pallor in myelin stains. Some pathologists have interpreted this as evi-

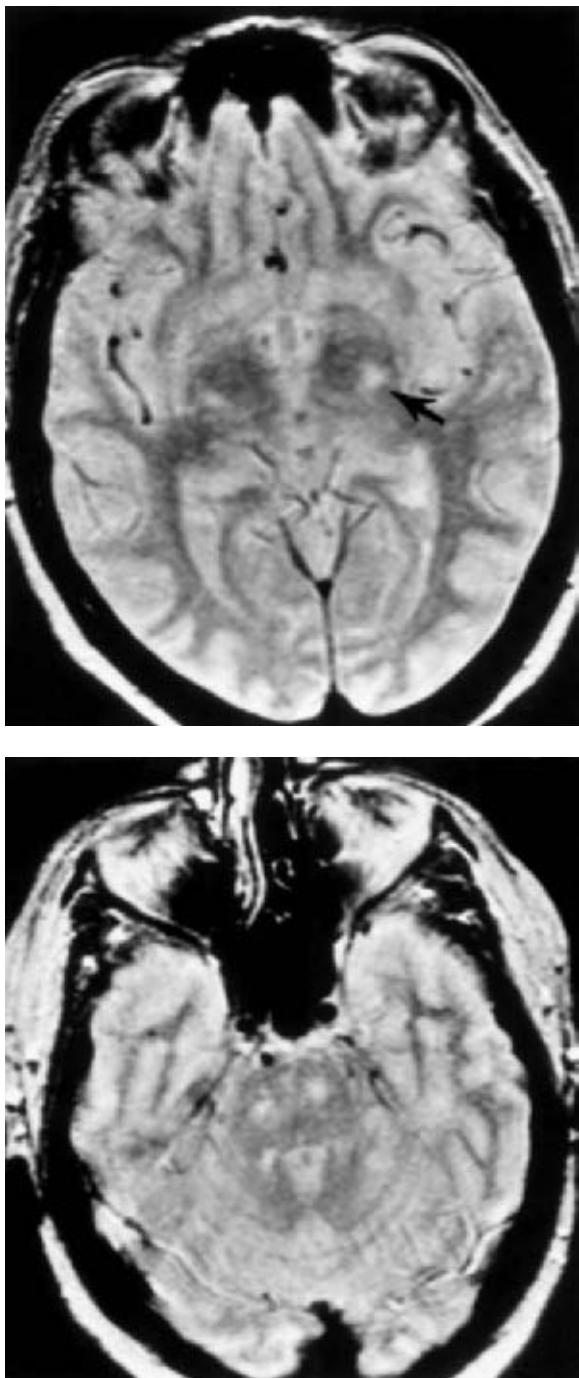

Figure 39-9. T2-weighted MRI showing signal changes that reflect Wallerian change in the corticospinal tracts at the level of the internal capsule (top, arrow) and the pons (bottom) in a case of ALS.

dence of involvement of nonmotor neurons and hence object to the term *motor system disease*. However, we regard this condition of more diffuse pallor as due to a loss of collaterals of motor neurons that contribute to the lamina propria. One observes the same effect in severe, long-standing poliomyelitis. In cases of familial ALS resulting from mutations in the SOD1 gene, the nonmotor systems seem to be more affected (Cudkowicz).

Neuropathologic studies of cases of ALS with dementia are few in number. In addition to the usual loss of motor neurons, these

cases have shown an extensive neuronal loss, gliosis, and vacuolation involving the frontal premotor area, particularly the superior frontal gyri and the inferolateral cortex of the temporal lobes. The histologic changes of Alzheimer or Pick disease have not been seen in our cases; neurofibrillary degeneration has been observed but is inconsequential in comparison to that seen in the Guamanian Parkinson-dementia-ALS complex (Finlayson et al; Mitsuyama). Attempts to transmit this ALS-dementia syndrome to subhuman primates have been unsuccessful.

Differential Diagnosis of ALS The clinical picture of motor system disease may be simulated by a central spondylotic bar or ruptured cervical disc, but with these conditions there is usually pain in the neck and shoulders, limitation of neck movements, and sensory changes, and the lower motor neuron changes in spondylosis are restricted to one or two spinal segments. The EMG is helpful if not decisive in differentiating these disorders. A mild hemiparesis or monoparesis due to multiple sclerosis may for a time be difficult to distinguish from early ALS. Progressive spinal muscular atrophy may be differentiated from peroneal muscular atrophy (Charcot-Marie-Tooth neuropathy) by the lack of family history, the complete lack of sensory change, and different EMG patterns. Motor system disease beginning in the proximal limb muscles may be misdiagnosed as a limb-girdle type of muscular dystrophy. The main considerations in relation to progressive bulbar palsy are myasthenia gravis and, less often, polymyositis, muscular dystrophy, and especially the inherited (Kennedy) type of bulbospinal atrophy, which is discussed further on. The spastic form of bulbar palsy may suggest the pseudobulbar palsy of lacunar disease. A crural form of PMA may be confused with diabetic polyradiculopathy or polymyositis.

As already mentioned, a major consideration is the differentiation of PMA from a chronic motor polyneuropathy, particularly the form that displays multifocal conduction block. Extensive nerve conduction studies and needle EMG examinations are necessary to distinguish the two; these neuropathic processes are discussed with the peripheral neuropathies in Chap. 46. The presence of an IgM monoclonal paraproteinemia or of specific antibodies directed against GM₁ are indicative of the immune motor neuropathy, but in half of the cases the tests are negative. There is also a rare form of subacute poliomyelitis (possibly viral) in patients with lymphoma or carcinoma; it leads to an amyotrophy that progresses to death over a period of several months. For further discussion of the paraneoplastic variety of motor system disease, see page 585.

Because it may produce a motor-predominant radiculopathy, chronic Lyme infection is sometimes considered in the differential diagnosis of ALS. Some clinics screen for Lyme antibodies using both an enzyme-linked immunosorbent assay (ELISA) and the more sensitive and specific Western immunoblot, but we have never detected such a case. Infrequently, we have seen myelopathic motor findings and motor radiculopathy with vitamin B₁₂ deficiency, and there are exceptional reports of myeloradiculopathy with lead poisoning; we sometimes include tests for these conditions. Another entity that may simulate ALS is inclusion body myositis (IBM)—an atypical myopathy that begins asymmetrically and involves distal muscles, usually without much elevation of serum CPK levels. In a recent series of 70 patients with this condition, 13 percent were initially diagnosed as having ALS (Dabby et al). Features distinguishing the IBM cases included normal corticospinal signs, preservation of deep tendon reflexes in weak mus-

cles, and finger flexor weakness. One concludes from this series that a detailed, quantitative EMG and possibly a muscle biopsy are indicated in cases that display predominantly lower motor features. Fully developed ALS is difficult to confuse with these conditions. Acid maltase deficiency may also simulate ALS in causing fatigability and early respiratory failure.

Over the years, the authors have occasionally encountered young men with localized and asymmetrical amyotrophy of the leg or arm that became arrested and did not advance over a decade or two. Several reports of such a partial spinal amyotrophy have appeared in recent years (Hirayama et al; Moreno Martinez et al). In the type described by Hirayama, young men are affected with progressive and asymmetrical amyotrophy of the forearm and hand that has been traced to ligamentous hypertrophy in the ventral spinal canal. This causes a compression of the cervical spinal cord, presumably a chronic ischemic effect (page 1077). In a familial variety of pure restricted amyotrophy, only the vocal cords became paralyzed over a period of years in adult life; only later were the hands affected.

Some patients who have recovered from paralytic poliomyelitis may develop progressive muscular weakness 30 or 40 years later; the nature of this relationship is obscure. We favor the explanation that atrophy of anterior horn cells with aging brings to light a critically depleted motor neuron population (see further on). It appears to progress little if at all.

An observation of interest is the finding of a form of progressive spinal muscular atrophy in patients with GM₂ gangliosidosis, the storage disease that presents in infancy as Tay-Sachs disease (Kolodny and Raghavan). The onset is in late adolescence and early adult life and the atrophic paralysis is progressive, so that this condition is often mistaken for Wohlfart-Kugelberg-Welander disease or ALS. A number of cases of this type have been discovered in Ashkenazi Jews by the use of lysosomal enzyme analysis.

An estimate of the frequency of all the aforementioned alternative diagnoses that have been exposed by the study of cases that were initially presumed to be PMA but turned out to represent another process is given by Visser and colleagues. In 17 of 89 patients the initial diagnosis of PMA proved in the end to be due to anti-GM₁ motor conduction block, chronic inflammatory demyelinating polyneuropathy, and various myopathies. This notwithstanding, ALS or the more discrete forms of motor system disease rarely offer any difficulty in diagnosis.

Pathogenesis The pathogenesis of the sporadic form of motor system disease is not known. Some insight has been afforded by analyses of the 10 percent of ALS cases that are inherited in an autosomal dominant pattern (see Table 39-6). Of these, about 25 percent harbor mutations in a gene that codes for the cytosolic enzyme Cu-Zn superoxide dismutase (SOD1) (Rosen et al). More than 100 different mutations have been identified in this gene. SOD1 is extremely abundant, accounting for perhaps 0.5 percent of all cytoplasmic protein. It is therefore not surprising that several aspects of neuronal function are compromised by the toxic properties of the mutant SOD1 protein. Recent studies have revealed that the demise of motor neurons is a consequence of pathology in both the motor neurons themselves and in the surrounding non-neuronal cells (Clement et al). Current evidence supports the notion that mutant SOD1 protein aggregates cause excitotoxic glutamatergic activity and mitochondrial dysfunction. Confirmation has been sought in the putative response of experimental models of

ALS to treatment with glutamate blockers (see further on). The SOD1 gene is not, however, mutated in sporadic cases.

An even rarer and recessively inherited childhood form of motor neuron disease (affecting corticospinal more than spinal motor neurons) has been attributed to mutations in a gene whose protein (alsin) is a component of the neuronal cell-signaling pathways. Yet another rare childhood-onset form of disease arises from mutations in the sentaxin gene, a DNA helicase that probably assists in chromatin folding and unfolding. (It is of interest that a recessively inherited mutation in the same gene transmits a recessive form of ataxia with oculomotor disorder.) In several families, a mutation has been detected in a protein that is involved in the transport of vesicles in neurons. A case of ALS with prominent corticospinal signs has been described in an individual with a novel mutation in the mitochondrial gene for cytochrome-c oxidase. These various genetic forms of motor neuron disease are summarized in Table 39-6. It is apparent that the cellular mechanisms that sustain motor neurons can be disrupted at several sites. Whether some derangement of the SOD1 protein that arises during aging contributes to the pathogenesis of the sporadic type is unknown, but study of this mutation, and of the rare inherited childhood forms of ALS, is providing provocative avenues for research.

Trauma, particularly traction injury of an arm, has been reported occasionally as an antecedent event in patients with ALS, but a causative relationship has not been established. Younger and coworkers have found a higher incidence of paraproteinemia in patients with motor system disease than can be accounted for by chance. Many other examples of disordered immune function have been described in patients with motor system disease, but a coherent explanation of ALS as an autoimmune disease has not emerged. It has never been proved that intoxication with heavy metals (lead, mercury, aluminum) can cause motor system disease, although there are reports of concurrent myelopathic and radicular motor signs in patients with lead intoxication. There is little evidence that such cases represent a reactivation of the virus or the presence of some other infectious agent. The progressive weakness that occurs some 30 to 40 years after recovery from polio should not be confused with PMA, as indicated above. Finally, we have had occasion to see two patients who, many years after a severe electrical injury that passed through the region of the cord, developed a progressive and severe amyotrophy of the arms; other such cases are known (see page 1056).

Treatment With the exception of riluzole, discussed below, there is no specific treatment for any of the motor neuron diseases. Supportive measures, however, are exceedingly important. In initial office visits, it has been our practice to give the patient some idea of the seriousness of the condition; but in early discussions we avoid the devastating statement that ALS is invariably fatal. Typically, patients and family members will ask explicitly about these matters in subsequent visits; such data as are appropriate to the patient's circumstances and character can be conveyed at that time, usually with the caveat that any individual may outlive the standard survival statistics.

The antiglutamate agent riluzole was shown by Bensimon and colleagues to slow the progression of ALS and improve survival in patients with disease of bulbar onset. However, it added only 3 months of life at best. This claim has been confirmed in several follow-up studies, although again the benefit has been marginal. Several additional agents are reported to have been effective in an SOD1 transgenic model of ALS. These are presently undergoing

Table 39-6

Genetic Defects Associated with ALS

NOTATION	CHROMOSOME	GENE	GENETICS	AGE OF ONSET	CLINICAL FEATURES
SOD1	21q	Superoxide dismutase	AD	Adult	Clinically and pathologically similar to sporadic ALS
DCTN	2q	Dynactin	AD	Adult	Slowly progressive with predominant bulbar features
CytoC ALS2	mtDNA 2q33	Cytochrome-c oxidase	Mitochondrial AR	Adult	Prominent spasticity
		GEF/alsin		Juvenile	Very slowly progressive, predominantly corticospinal
SETX	9q34	Sentaxin	AD	Juvenile	Very slowly progressive
VAPB	20q	Vesicle-associated membrane protein	AD	Adult	Similar to sporadic ALS

study in ALS patients. Guanidine hydrochloride and injections of cobra venom, gangliosides, interferons, high-dose intravenous cy clophosphamide, and thyrotropin-releasing hormone are but some of a long list of agents that are said to arrest the disease process, but these claims have been discredited.

An attempt can be made to reduce the spasticity with medications, such as baclofen or tizanidine, or by subarachnoid infusions of baclofen via an implanted lumbar pump. Initial intrathecal test doses are given to predict a response to the pump infusions of baclofen, but this test may fail; in severe cases it may therefore be advisable to proceed with a constant infusion for several days. Some degree of improved comfort from a reduction in the extreme rigidity is usually the most that can be expected. Some relief from spasticity may also be afforded by the use of benzodiazepines or sometimes dantrolene. These approaches are most suitable for cases of primary lateral sclerosis, which can be expected to progress slowly and for a long period.

At all stages of ALS, physical therapy is useful in maintaining mobility, but overwork of the muscles leading to fatigue and cramps should be avoided. Physical therapy is invaluable, for example, for avoiding contractures of the fingers and shoulders. Occupational therapy is likewise helpful, particularly assessments of the patient's function in the home.

Important in the management of ALS is periodic monitoring of respiratory function. We typically perform pulmonary function tests every few months after the first year or so of illness. Our experience has been that the vital capacity in cubic centimeters can be estimated by multiplying the highest number to which a patient can count with one deep breath by 100. Thus, the ability to count to 25 with a full effort in a single breath corresponds to a vital capacity of approximately 2.5 L. Significant practical advances have been made in the respiratory management of ALS. The introduction of bimodal positive airway pressure (BIPAP) has allowed patients to sleep better and reduce daytime somnolence. Many patients do not initially tolerate the device, usually because of mal-adjusted face masks or excessive applied airway pressures. Almost always, a seasoned pulmonary technologist can find solutions to these problems. It is appropriate to begin BIPAP at (or before) the earliest sign of carbon dioxide retention, a state that is heralded by disruption of sleep, nightmares, early morning headaches, and daytime drowsiness. The second device that has greatly improved respiratory care in these patients has been the "Cough Assist" machine (Emerson), essentially a device that executes an artificial cough by first insufflating the lungs and then rapidly applying negative pressure, thereby facilitating clearing of the airways. It has

been our impression that patients with weak diaphragms can reduce the frequency of pneumonia by the twice-daily use of this device.

With this type of noninvasive respiratory assistance, it may be possible to defer tracheostomy for months or years. Ultimately, as the diaphragm fails, BIPAP is needed not only at night but also during the day. As BIPAP use approaches 20 to 24 h per day, patients must usually address the difficult question of tracheostomy and mechanical ventilation. We broach this subject early enough in the course of the disease to allow ample time for discussion and reflection. Particularly with access to information on the Internet, many patients are well informed about these issues. In practice, most patients elect not to undergo tracheostomy and full ventilation.

Another important issue regards nutrition. As oropharyngeal palsy progresses, food should be cut into small pieces and dry foods, such as toast, avoided; milk shakes and preparations of the same consistency are ideal at this stage. Speech therapists are capable of teaching patients methods to adapt to declining bulbar function and at the same time minimizing aspiration. Ultimately in our experience, virtually every ALS patient will need a feeding tube to maintain normal hydration and caloric intake. While we adopt a neutral position regarding full ventilation, we tend to urge patients to undergo placement of a feeding tube. This clearly increases survival and improves quality of life by preventing dehydration and recurrent aspiration. Laparoscopic and radiologic technologies for the placement of a gastrostomy tube render the procedure swift and nearly painless. Some patients have tubes inserted as outpatients and then start gastric feeding within a day or two.

Other devices, often guided by the physical and occupational therapist, may be of great assistance to the patient and family as the disease progresses. These include a mechanized bed and structural accommodations in the home that facilitate entry of a wheelchair and the safe use of the bath or shower as well as thick-handled utensils. Ambulation aids, beginning with simple canes (first one, then two) followed by a walker (preferably with basket and seat) and then a wheelchair (manual or electric) are of value in maintaining a sense of independence and assuring safety.

As the disease enters its later stages, facile access to the neurologist and, if desired, regular visits for advice are very reassuring to the patient and family. Hospice-type care is often needed in the last weeks of illness for patients who can otherwise be cared for at home, and morphine or similar drugs as well as antianxiety agents should be used liberally to ease discomfort, respiratory distress, and anxiety in the final days.

Heredofamilial Forms of Progressive Muscular Atrophy

These diverse diseases are the concern mainly of child neurology. They are presented here because they fall within the category of system degenerations, often of heredofamilial type.

Spinal Muscular Atrophy The classic form of spinal muscular atrophy of hereditary type was first described by Werdnig in 1891 and 1894, by Hoffmann in 1893, and, at about the same time by Thomsen and Bruce. The cases described by these authors all involved infants. Further clinical analyses, however, indicated the inadequacy of this narrow grouping. Brandt, in his study of 112 Danish patients, found that in about one-third the weakness was present at birth, and in 97 the onset was in the first year of life; in 9 patients, the disease was not recognized until after the first year of life. In 1956 Walton, and later Wohlfart and colleagues and Kugelberg and Welander (see below), identified milder forms of spinal muscular atrophy in which the onset was between 2 and 17 years and walking was still possible in adult life. Byers and Bunker, in a study of 52 patients, subdivided them into three groups on the basis of age of onset; in one group the disease was recognized at birth or in the first month or two of life; in a second, between 6 and 12 months; and in a third, after the first year. In their last group, it was not unusual for the patient to survive into adolescence and adult life. In a few of the late-onset types, signs of corticospinal tract involvement are conjoined, and Bonduelle has also included some patients with areflexia, pes cavus, Babinski signs, choreiform movements, and mental retardation in this group. More recently, the designations SMA I, II, and III have been introduced, based largely on the age of onset (Table 39-7).

Genetic Aspects of Spinal Muscular Atrophies Familial spinal muscular atrophy that begins in infancy and childhood is inherited mainly as an autosomal recessive trait. All the SMA phenotypes in children have been mapped to the same chromosome: 5q11.2-13.3 (Brzustowicz et al; Gilliam et al; Munsat et al). SMA-associated mutations affect the gene at what has been termed the “survival of

motor neuron” (SMN) site. The SMN protein participates in forming protein-RNA complexes (so-called small nuclear ribonucleoproteins and RNA) that are essential for gene splicing. Within the SMN locus there are two genes: SMN1, which generates a full-length, fully functional form of SMN, and SMN2, which makes a truncated, partially functional SMN. Making matters more complex, some individuals have more than two copies of SMN2. As a result, loss of both copies of SMN1 may cause very severe SMA in some individuals (in whom only one copy of SMN2 compensates for loss of SMN1), while others with multiple copies of SMN2 have milder disease. Thus, the amount SMN1 and SMN2 protein determines the severity of disease. Affected siblings demonstrate very similar clinical patterns of disease. However, the same gene error gives rise to very different phenotypes in different families, so that modifying posttranscriptional or nongenetic attributes must be playing a role. Less often, autosomal dominant and X-linked patterns of inheritance have been found, usually in adults.

Clinical Manifestations of Early-Onset Classic Werdnig-Hoffmann Type; SMA I The most frequent form of these spinal muscular atrophies, the severe infantile type, is a common disease, occurring once in every 20,000 live births. After cystic fibrosis, it is the most frequent cause of death from a recessively inherited disease. Characteristically the infant, usually born normally, is noted from birth to be unnaturally weak and limp (“floppy”). Some mothers report that fetal movement in utero had been less than expected or lacking altogether. In severe cases, arthrogryposis at the ankles and wrists or dislocation of the hips is noted at birth (page 1244). The muscle weakness in these children is generalized from the beginning, and death comes early, usually within the first year. Other infants seem to develop normally for several months before the weakness becomes apparent. In these, the trunk, pelvic, and shoulder-girdle muscles are at first disproportionately affected, while the fingers and hands, toes and feet, and cranial muscles retain their mobility. *Hypotonia* accompanies the weakness, and since passive displacement of articulated parts in testing muscle tone is easier to judge than power of contraction at this early age, it may be singled out as the dominant clinical characteristic. As a

Table 39-7
Classification of the spinal muscular atrophies (SMA)

TYPE	INHERITANCE	AGE OF ONSET	CLINICAL FEATURES	PROGNOSIS
SMA I (infantile, Werdnig-Hoffmann)	Autosomal recessive	Preterm to 6 months	Neonatal hypotonia (floppy baby), weakness of sucking and swallowing, may have arthrogryposis, unable to sit	Few survive 1 year
SMA II (intermediate type)	Autosomal recessive	6 to 15 months	Proximal weakness, fasciculation, fine hand tremor, unable to stand	Variable; death from respiratory complications
SMA III (Wohlfart-Kugelberg-Welander)	Autosomal recessive or dominant	1 year to adolescence	Delayed motor development, proximal leg weakness	Slowly progressive, variable outcome
Kennedy syndrome (bulbospinal atrophy)	X-linked (CAG repeat expansion), less often autosomal dominant	Early adulthood	Scapuloperoneal or distal atrophy, oropharyngeal weakness, gynecomastia, oligospermia	Slowly progressive
Fazio-Londe disease	Autosomal recessive, rarely dominant	Childhood to early adolescence	Progressive bulbar and respiratory failure	Survival for years, respiratory failure

rule the tendon reflexes are unobtainable. Volume of muscle is diminished but is difficult to evaluate in the infant because of the coverings of adipose tissue. Fasciculations are seldom visible except sometimes in the tongue. Perception of tactile and painful stimuli is undiminished, and emotional and social development measure up to age.

As the months pass, the weakness and hypotonia progress gradually and spread to all of the skeletal muscles except the ocular ones. Intercostal paralysis with a degree of collapse of the chest is the rule. Respiratory movements become paradoxical (abdominal protrusion with chest retraction). The cry becomes feeble, and sucking and swallowing are less efficient. Such infants are unable to sit unless propped, and they cannot hold up their heads without support. They cannot roll over or support their weight when placed on their feet. Their posture is characteristic: arms abducted and flexed at the elbow, legs in the "frog position" with external rotation and abduction at hips and flexion at hips and knees. If the effects of gravity are removed, all muscles continue to contract; i.e., there is paresis, not paralysis. Until late in the illness, these children appear bright-eyed, alert, and responsive.

The disease runs a steadily downhill course. Infants in whom the disease becomes apparent only after several months of life have a less rapid decline than those affected in utero or at birth. Some of the former become able to sit and creep and even to walk with support; those with later onset may survive for several years and even into adolescence or early adult life, as already mentioned.

Laboratory data of confirmatory value are few. Muscle enzymes in the serum are usually normal, rarely elevated. The EMG, if performed at a late enough stage of development, displays fibrillations, proving the denervative basis of the weakness. Motor unit potentials are diminished in number and, in the more slowly evolving cases, some are larger than normal (giant or polyphasic potentials reflecting reinnervation). Motor nerve conduction velocities are normal or fall in the low-normal range (these are normally slower in infants than in adults). Early electrophysiologic studies may also give ambiguous results.

Pathologic Findings Muscle biopsy after 1 month of age reveals a typical picture of group atrophy; shortly after birth this change is difficult to discern. Aside from denervative atrophy, the essential abnormalities are in the anterior horn cells in the spinal cord and the motor nuclei in the lower brainstem. Nerve cells are greatly reduced in number, and many of the remaining ones are in varying stages of degeneration; a few are chromatolytic and contain cytoplasmic inclusions. It is not unusual to see figures of neuronophagia. There is replacement gliosis and secondary degeneration in roots and nerves. Other systems of neurons, including the corticospinal and corticobulbar systems, remain intact.

Differential Diagnosis The major problem in diagnosis is to distinguish Werdnig-Hoffmann disease from an array of other diseases that cause hypotonia and delayed motor development in the neonate and infant. The list of disorders that imitates spinal muscular atrophy constitutes a large part of the differential diagnosis of the so-called *floppy infant*. The congenital myopathies (as described in Chap. 52), the glycogenoses, and disorders of fatty acid metabolism frequently present in this way. The preservation of tendon reflexes and relative lack of progression of muscle weakness distinguish the latter disorders. Because of the gravity of the diagnosis, muscle biopsy should be performed if there is any suspicion of spinal muscular atrophy. If studied properly, the biopsy usually yields the correct diagnosis.

Clinical disorders more or less similar to the spinal muscular

atrophies may be identified occasionally in certain hereditary metabolic diseases. For example, Johnson and coworkers have described a patient who began experiencing weakness of the legs, cramping, and fasciculations during adolescence in what proved to be a variant of hexosaminidase A (GM₂) deficiency, and biopsy of rectal mucosa showed nerve cells with the typical membranous cytoplasmic bodies of Tay-Sachs disease. Others have reported similar cases. A progressive motor neuron or motor nerve disorder has also been observed in glycogen storage disease affecting anterior horn cells. Motor nerve fibers also suffer damage in metachromatic and globoid body leukoencephalopathies, and this may occur in adults, in association with paraproteinemia and multiple myeloma and as a paraneoplastic process.

Certain forms of muscular dystrophy, notably myotonic dystrophy, which is about twice as frequent as Werdnig-Hoffmann disease, may become manifest in the neonatal period and interfere with sucking and motor development (Chap. 52). As a rule, the weakness is not as severe or diffuse as that in Werdnig-Hoffmann disease. The mother, but not the child, may display myotonia, either elicitable clinically or, if more subtle, with EMG recording. Also, a number of polyneuropathies may cause a serious degree of weakness in early childhood. Unfortunately, in respect to the latter, adequate sensory testing is not possible because of the patient's age, but the CSF protein is often elevated. Again, diagnosis is greatly facilitated by nerve-muscle biopsy and measurement of nerve conduction velocities. These velocities are reduced but must be interpreted with caution because of incomplete development of axons and of myelination in the first months of life. The needle EMG examination shows subtle signs of denervation that cannot be easily distinguished from the finding in the spinal muscular atrophies. Examination of parents and siblings may disclose a clinically inapparent neuropathy. Polymyositis of childhood may also simulate both muscular dystrophy and motor neuron disease (page 1205).

Mental retardation with a flaccid rather than spastic weakness of the limbs is another major category of disease that must be distinguished. Also, certain of the polioencephalopathies and leukodystrophies may weaken muscles and abolish tendon reflexes, but usually there is evidence of cerebral involvement. The same may be said of the Down syndrome, cretinism, Prader-Willi syndrome, and achondroplasia. Finally, very sick children with celiac disease, cystic fibrosis, and other chronic diseases may be hypotonic to the point of simulating neuromuscular disease. Usually speech is not delayed and tendon reflexes are preserved in these purely medical states, and strength returns as the medical problem is corrected.

There remains, after the assiduous study of the "floppy infant," a group of cases of hypotonia and motor underdevelopment that cannot be classified. The term *amyotonia congenita* (Oppenheim) was once applied to all of this group but is now obsolete. Walton proposed the term *benign congenital hypotonia* to designate patients who manifest limp and flabby limbs in infancy and a delay in sitting up and walking but who improve gradually, some completely and others incompletely. Neither of these terms serves the purpose of precise diagnosis. It is likely that among this group there are other examples of congenital myopathy that await differentiation by application of modern histochemical, ultrastructural, and genetic techniques.

Chronic Childhood and Juvenile Proximal Spinal Muscular Atrophy (Wohlfart-Kugelberg-Welander Syndrome) This is a somewhat different form of heredofamilial spinal muscular atrophy, which, as the name indicates, involves the proximal muscles

of the limbs predominantly and is only slowly progressive. It was first clearly separated from other forms of motor system disease and from muscular dystrophy by Wohlfart and by Kugelberg and Welander in the mid-1950s. In about one-third of the cases, the onset is before 2 years of age, and in half, between 3 and 18 years. Males predominate, especially among patients with juvenile and adult onset. The usual form of transmission is by an autosomal recessive pattern; most cases result from mutations in the SMN gene. Families with dominant and sex-linked inheritance have also been described.

The disease begins insidiously, with weakness and atrophy of the pelvic girdle and proximal leg muscles, followed by involvement of the shoulder girdle and upper arm muscles. Unlike the sporadic form of spinal muscular atrophy, the Wohlfart-Kugelberg-Welander variety (also listed in other books and monographs as Kugelberg-Welander disease) is bilaterally symmetrical from the beginning, and fasciculations are observed in only half the cases. Ultimately the distal limb muscles are involved and tendon reflexes are lost. Bulbar musculature and corticospinal tracts are spared, although Babinski signs and an associated ophthalmoplegia (presumably neural) have been reported in rare instances.

The presence of fasciculations and the EMG and muscle biopsy findings—all of which show the characteristic abnormalities of neural atrophy—permit distinction from muscular dystrophy. Cases that have been examined postmortem have shown loss and degeneration of the anterior horn cells.

The disease progresses very slowly, and some patients survive to old age without serious disability. In general, the earlier the onset, the less favorable the prognosis; however, even the most severely affected patients retain the ability to walk for at least 10 years after the onset. Admittedly, it is difficult to make a sharp distinction between these cases of Wohlfart-Kugelberg-Welander disease and certain milder instances of Werdnig-Hoffmann disease with onset in late infancy and early childhood and prolonged survival (Byers and Bunker).

Kennedy Syndrome (X-Linked Bulbospinal Muscular Atrophy) An unusual pattern of *distal muscular atrophy with prominent bulbar signs* and, less often, ocular palsies was first described by Kennedy. The time of onset has varied from childhood to adult age, but most patients have been in their third decade when neurologic symptoms arose. Most cases have shown an X-linked pattern of inheritance and a lesser number an autosomal dominant pattern. The proximal shoulder and hip musculature are involved first by weakness and atrophy, followed in about half of patients by dysarthria and dysphagia. Often muscle cramps or twitching precede weakness. Facial fasciculations and mild weakness are also characteristic and may be striking. The tendon reflexes become depressed and may be absent; a mild sensory neuropathy is almost universal. In the family described by Kaeser, in which 12 members in five generations were affected, the pattern of weakness was shoulder-shank, i.e., scapuloperoneal; it may therefore be mistaken for muscular dystrophy. The muscular atrophy is associated in two-thirds of patients with gynecomastia, a feature that may first identify affected men in a kindred. Oligospermia and diabetes are frequent associations. The CK level is elevated, sometimes tenfold, and physiologic studies reveal denervation and reinnervation as well as indications of a mild sensory neuropathy.

As in Huntington disease and certain of the spinocerebellar atrophies, the genetic defect is a CAG expansion, in this case in the gene that codes for the androgen receptor on the short arm of

the X chromosome (La Spada et al; see Table 39-7). Indeed, the first reported polyglutamine disease was in Kennedy syndrome. Lengthened sequences correlate with an earlier age of onset (anticipation, as in Huntington disease) but have no relation to the severity of disease. Androgen receptors have been found on motor neurons of the spinal cord; in fact, the subpopulation of motor neurons that is susceptible to both Kennedy syndrome and ALS express abundant surface androgen receptors, but it is not clear whether this has direct pathogenic significance. Neuronal inclusions have recently been described, composed of aggregations of the abnormally long polyglutamine protein sequences that correspond to the CAG expansion. A family with the bulbospinal phenotype but without the CAG expansion has also been reported (Paradiso et al). Other features, such as optic atrophy and sensory neuronopathy, were present in some members of this kindred but are not features of typical cases. The diagnosis can be confirmed by genetic testing for the lengthened trinucleotide sequence. Prenatal diagnosis and identification of female carriers is also possible by genetic testing.

Progressive Bulbar Palsy of Childhood (Fazio-Londe Syndrome) Fazio in 1892 and Londe in 1893 described the development of a progressive bulbar palsy in children, adolescents, and young adults. There is progressive paralysis of the facial, lingual, pharyngeal, laryngeal, and sometimes ocular muscles. The illness usually presents with stridor and respiratory symptoms, followed by facial diplegia, dysarthria, dysphagia, and dysphonia. These become increasingly pronounced until the time of death some years later. In a few patients there is a late development of corticospinal signs and sometimes ocular palsies. Also jaw and oculomotor paresis appears occasionally, and in one case there was progressive deafness. The disease is rare, only 24 well-described examples having been recorded in the medical literature by 1992 (McShane et al). Inheritance may be autosomal dominant, as in Fazio's original case, and rarely X-linked, but it is more likely to be autosomal recessive. Pathologic examination has shown a loss of motor neurons in the hypoglossal, ambiguus, facial, and trigeminal motor nuclei. In a few cases, the nerve cells in the ocular motor nuclei were also diminished. This disease, the few times we have encountered it, had to be differentiated from myasthenia gravis, a pontomedullary glioma, and brainstem multiple sclerosis.

Hereditary Forms of Spastic Paraparesis

Hereditary Spastic Paraparesia (Strümpell-Lorrain Disease) This disease was described by Seeligmuller in 1874 and later by Strümpell in Germany and Lorrain in France; it has now been identified in nearly every part of the world. The pattern of inheritance is usually autosomal dominant, less often recessive (one family has shown X-linked inheritance), and the onset may be at any age from childhood to the senium. Harding divided the disease into two groups, the more common one beginning before age 35 with a very protracted course and the other with a late onset (40 to 60 years). The latter type often shows sensory loss, urinary symptoms, and action tremor.

The clinical picture is that of a gradual development of spastic weakness of the legs with increasing difficulty in walking. The tendon reflexes are hyperactive and the plantar reflexes extensor. In the pure form of the disease, sensory and other nervous functions are entirely intact. If the onset is in childhood, as many cases are, the foot arches become exaggerated, the feet are shortened, and

there is a tightening (pseudocontracture) of calf muscles, forcing the child or adolescent to “toe-walk.” This is a common orthopedic problem and may require surgical correction. In children, the legs appear to be underdeveloped, and in both children and adults they may become quite thin. Sometimes the knees are slightly flexed; at other times the legs are fully extended or hyperextended (genu recurvatum) and adducted. Weakness is variable and difficult to estimate. Sphincteric function is usually retained. Subtle sensory loss in the feet has been reported. The arms are variably involved. In some patients, the arms appear to be spared even though the tendon reflexes are lively. In others, the hands are stiff, movements are clumsy, and speech is mildly dysarthric. Conjoined findings such as nystagmus, ocular palsies, optic atrophy, pigmentary macular degeneration, ataxia (both cerebellar and sensory), sensorimotor polyneuropathy, ichthyosis, patchy skin pigmentation, epilepsy, and dementia have all been described in isolated families (see further on).

The few available pathologic studies have shown that, in addition to degeneration of the corticospinal tracts throughout the spinal cord, there is thinning of the columns of Goll, mainly in the lumbosacral regions, and of the spinocerebellar tracts, even when no sensory abnormalities had been detected during life. These were the pathologic findings described by Strümpell in his original (1880) report of two brothers with spastic paraparesis; one of them, in addition, had a cerebellar syndrome, but again there were no sensory abnormalities. A reduction in the number of Betz and anterior horn cells has also been reported.

Genetic Aspects of Hereditary Spastic Paraparesis Several genetic mutations have given rise to this disease. As of this writing, there are 23 HSP loci (10 dominant, 9 recessive, 4 X-linked) and 11 HSP genes (see Table 39-8). The common uncomplicated autosomal dominant form of disease has been linked to chromosomes 2p, 8q, 14q, and 15q, the 2p variety being most frequent; the recessive variety has been linked to 8p, 15q (the most frequent recessive type), and 16q. Some of the recessive types have the unusual feature of thinning of the corpus callosum. The common variety associated with a mutation on chromosome 2p results in great variability of clinical presentation within and among families (see Nielsen and colleagues). Rare X-linked types have been associated with mutations on the long arm of the chromosome, one of which is an allelic variant of the Pelizaeus-Merzbacher gene.

In a few of these kindreds the genes responsible for disease have been identified. For example, the most common form is caused by mutations in the *spastin* gene, which encodes a membrane protein. Rarely, the causative mutation is in the metalloprotease gene *paraplegin* on the mitochondrial membrane; it is proposed that this defect impairs oxidative phosphorylation. The genetics of the hereditary spastic paraparesis has been reviewed by Fink.

Differential Diagnosis In the diagnosis of this disorder, one should consider an indolent spinal cord or foramen magnum tumor, cervical spondylosis, a spinal form of multiple sclerosis (this was the clinical diagnosis in Strümpell's original cases), Chiari malformation, compression of the cord by a variety of congenital bony malformations at the craniocervical junction, and a number of chronic myelitides—among them, lupus erythematosus, sarcoidosis, acquired immunodeficiency syndrome (AIDS), adrenomyeloneuropathy, primary lateral sclerosis (described earlier in this chapter), and tropical spastic paraparesis (caused by HTLV-1).

Variants of Familial Spastic Paraparesis The literature contains a large number of descriptions of familial spastic paraparesis combined with other neurologic abnormalities. Some of the syndromes had developed early in life in conjunction with moderate degrees of mental retardation. In these, the rest of the neurologic picture appeared many years after birth and was progressive. Some idea of the number of these “hereditary paraparesia-plus” syndromes and the diverse combinations in which they may present is conveyed in the review by Gout and colleagues. Again, it is hardly possible to describe each of these symptoms in any degree of detail. The list below includes the best-known entities. But if the term *hereditary spastic paraparesia* is to have any neurologic significance, it should be applied only to the pure form of the progressive syndrome. The more common “atypical” or “syndromic” cases—with amyotrophy, cerebellar ataxia, tremors, dystonia, athetosis, optic atrophy, retinal degeneration, amentia, and dementia—should be put in separate categories and their identity retained for nosologic purposes until such time as additional biochemical and genetic data related to pathogenesis are forthcoming. The gene mutations found in some of the variant types have been summarized by Fink, but—as with all types of uncomplicated hereditary spastic paraparesis—the mechanisms of neuronal loss are not known. To be separated from these cases are all the congenital nonprogressive types of

Table 39-8
Genetic defects associated with hereditary spastic paraparesis (HSP)

GENETICS	NOTATION	CHROMOSOME	GENE	AGE OF ONSET	CLINICAL AND MISCELLANEOUS FEATURES
AD	3A	14q11	Atlastin	Childhood	Guanylate binding protein
AD	4	2p22	Spastin	20s	40–50% of HSP; binds to microtubules
AD	6	15q11	NIPA1	Teens	Golgi membrane protein
AD	10	12q13	KIF5A	Childhood	Kinesin heavy chain - motor protein
AD	13	2q24	Heat shock protein	Adult	Located in mitochondrial matrix
AD	17	11q13	Seipin (BSCL2)	Variable	Silver syndrome: HSP with wasting of hands, feet
AR	7	16q24	Paraplegin	Adult	Mitochondrial chaperone and metalloprotease; optic atrophy, neuropathy, myopathy
AR			Spartin		HSP with wasting of distal limbs, hands, feet
AR	21	15q22	Maspardin	Late teens	Endosomal protein involved in protein transport
XR	1	Xq28	L1 cell adhesion molecule	Infancy	Mental retardation, hydrocephalus, callosal hypoplasia, spasticity
XR	2	Xq22	Proteolipid protein XR	Infancy Childhood	Cognitive impairment, spasticity, ataxia HSP

spastic diplegia and athetosis. The following list includes the best-known entities:

1. *Hereditary spastic paraparesis with spinocerebellar and ocular symptoms (Ferguson-Critchley syndrome)*. This syndrome is characterized by a disorder of gaze, optic atrophy, cerebellar ataxia, and spastic paraparesis. Most impressive are the manifestations of spinocerebellar ataxia beginning during the fourth and fifth decades of life, accompanied by weakness of the legs, alterations of mood, pathologic crying and laughing, dysarthria and diplopia, dysesthesias of limbs, and poor bladder control. The tendon reflexes are lively, with bilateral Babinski signs. Sensation is diminished distally in the limbs. The whole picture resembles multiple sclerosis. In other cases, running through several generations of a family, the extrapyramidal features were more striking; such cases overlap with the following syndromes.
2. *Hereditary spastic paraparesis with extrapyramidal signs*. Action and static tremors, parkinsonian rigidity, dystonic tongue movement, and athetosis of the limbs have all been conjoined with spastic paraparesia. Gilman and Romanul have reviewed the literature on this subject. In the authors' experience, the picture of parkinsonism with spastic weakness and other corticospinal signs has been the most frequent combination.
3. *Hereditary spastic paraparesis with optic atrophy*. This is known as *Behr syndrome* or *optic atrophy-ataxia syndrome*, since cerebellar signs are usually conjoined. Some of the members of the large family reported by Bruyn and Went also had athetosis. The syndrome is transmitted as an autosomal recessive trait, with onset in infancy and slow progression.
4. *Hereditary spastic paraparesis with macular degeneration (Kjellin syndrome)*. Spastic paraparesia with amyotrophy, oligophrenia, and central retinal degeneration constitutes the syndrome described in 1959 by Kjellin. While the mental retardation is stationary, the spastic weakness and retinal changes are of late onset and progressive. When ophthalmoplegia is added, it is called the *Barnard-Scholz syndrome*.
5. *Hereditary spastic paraparesis with mental retardation or dementia*. Many of the children with progressive spastic paraparesia either have been mentally retarded since early life or have appeared to regress mentally as other neurologic symptoms developed. Examples of this syndrome and its variants are too numerous to be considered here but are contained in the review of Gilman and Romanul. The autosomal recessive syndrome of *Sjögren-Larsson*, with the onset in infancy of spastic weakness of the legs in association with mental retardation, stands somewhat apart because of the associated ichthyosis.
6. *Hereditary spastic paraparesis with polyneuropathy*. We have observed several patients in whom a sensorimotor polyneuropathy was combined with unmistakable signs of corticospinal disease. The age of onset was in childhood or adolescence, and the disability progressed to the point where the patient was chair-bound by early adult life. In two of the cases, a sural nerve biopsy revealed a typical hypertrophic polyneuropathy; in a third case there was only a depletion of large myelinated fibers. The syndrome resembles the myeloneuropathy of adrenoleukodystrophy.
7. *Spastic paraparesis with distal muscle wasting (Broyer syndrome)*. This disorder is transmitted as an autosomal recessive trait. Onset is in childhood with amyotrophy of the hands, followed by spasticity and contractures of the lower limbs. Cerebellar signs (mild), athetosis, and deafness may be added.

This disorder is transmitted as an autosomal recessive trait. Onset is in childhood with amyotrophy of the hands, followed by spasticity and contractures of the lower limbs. Cerebellar signs (mild), athetosis, and deafness may be added.

SYNDROME OF PROGRESSIVE BLINDNESS (See Chap. 13)

There are two main classes of progressive blindness in children, adolescents, and adults: progressive optic neuropathy and retinal degenerations (*retinitis pigmentosa* and so-called *tapetoretinal macular degeneration*). Of course, there are many congenital anomalies and retinal diseases beginning in infancy that result in blindness and microphthalmia. Some of those of neurologic interest have already been described briefly in connection with the hereditary spastic paraplegias and in Chap. 13.

Hereditary Optic Atrophy of Leber

Although familial amaurosis was known in the early eighteenth century, it was Leber in 1871 who gave the definitive description of this disease and traced it through many genealogies. The family studies of Nikoskelainen and coworkers indicate that all daughters of carrier mothers become carriers themselves, a type of transmission that is determined by inheritance of defective mitochondrial DNA from the mother (Wallace et al). In an extensive review of Leber hereditary optic atrophy by the National Hospital group in London, some of the clinical variations are described. Common to all their cases was the presence of a pathogenic mitochondrial DNA abnormality (Riordan-Eva et al), but the defect may occur at one of several sites (page 841). Thus, Leber optic atrophy has been added to the growing list of mitochondrial diseases, which, as a group, are discussed in detail in Chap. 37.

In most patients, the visual loss begins between 18 and 25 years, but the range of age of onset is much broader. Usually the visual loss has an insidious onset and a subacute evolution, but it may evolve rapidly, suggesting a retrobulbar neuritis; moreover, in these latter instances, aching in the eye or brow may accompany the visual loss, just as it does in the demyelinative variety. Subjective visual phenomena are reported by some. Usually both eyes are affected simultaneously, though in some one eye is affected first, followed by the other after an interval of several weeks or months. In practically all cases, the second eye is affected within a year of the first. In the unimpaired eye, abnormalities of visual evoked potentials may antedate impairment of visual acuity (Carroll and Mastaglia).

Once started, the visual loss progresses over a period of weeks to months. Characteristically, central vision is lost before peripheral, and there is a stage at which bilateral central scotomata are readily demonstrated. Early on, perception of blue-yellow is deficient, while that of red and green is relatively preserved. In the more advanced stages, however, the patients are totally color-blind. Constriction of the fields may be added later. At first there may be swelling and hyperemia of the discs, but soon they become atrophic. Peripapillary vasculopathy, consisting of tortuosity and arteriovenous shunting, is the primary structural change; this has been present also in asymptomatic offspring of carrier females.

As visual symptoms develop, fluorescein angiography shows shunting in the abnormal vascular bed, with reduced filling of the capillaries of the papillomacular bundle. Although patients are left

with dense central scotomata, it is of some importance that the visual impairment is seldom complete; in some patients, relative stabilization of visual function occurs. In a few, there may be a surprising improvement.

Examination of the optic nerve lesion shows the central parts of the nerves to be degenerated from papillae to the lateral geniculate bodies, i.e., the papillomacular bundles are particularly affected. Presumably axis cylinders and myelin degenerate together, as would be expected from the loss of nerve cells in the superficial layer of the retina. Both astrocytic glial and endoneurial fibroblastic connective tissue are increased. Tests for the three main mitochondrial mutations that give rise to the disorder are now available.

Congenital optic atrophy (of which recessive and dominant forms are known), retrobulbar neuritis, and nutritional optic neuropathy are the main considerations in differential diagnosis.

Retinitis Pigmentosa

This remarkable retinal abiotrophy, known to Helmholtz in 1851 soon after he invented the ophthalmoscope, usually begins in childhood and adolescence. Unlike the optic atrophy of Leber, which affects only the third neuron of the visual neuronal chain, retinitis pigmentosa affects all the retinal layers, both the neuroepithelium and pigment epithelium (see Fig. 13-1). For this combination, Leber proposed the term *tapetoretinal degeneration*, thinking it preferable to *retinitis pigmentosa*, since there is no evidence of inflammation. The incidence of this disorder is two or three times greater in males than in females. Inheritance is more often autosomal recessive than dominant; in the former, consanguinity plays an important part, increasing the likelihood of the disease by approximately 20 times. Sex-linked types are also known. It is estimated that 100,000 Americans are afflicted with this disease.

One form of retinitis pigmentosa is linked to mutations on the gene for the photosensitive rod-cell protein opsin (which, in combination with vitamin A, forms rhodopsin). When light strikes rhodopsin in the normal eye, the opsin releases vitamin A, and this initiates the sequence of changes that activate the rods. As a consequence of the gene abnormality, the quantity of opsin and rhodopsin in retinitis pigmentosa is reduced; these opsin mutations are typically single amino acid substitutions (Dryja et al).

The first symptom is usually an impairment of twilight vision (nyctalopia). Under dim light, the visual fields tend to constrict; but slowly, as the disease progresses, there is permanent visual impairment in all degrees of illumination. The perimacular zones tend to be the first and most severely involved, giving rise to partial or complete ring scotomata. Peripheral loss sets in later. Usually both eyes are affected simultaneously, but cases are on record where one eye was affected first and more severely. Color vision is lost relatively late. The electrical activity of the retina (measured by the electroretinogram) is gradually extinguished, in contrast to the Leber type of optic atrophy, in which it is retained.

Ophthalmoscopic examination shows the characteristic triad of pigmentary deposits that assume the configuration of bone corpuscles, attenuated vessels, and pallor of the optic discs. The pigment is due to clumping of epithelial cells that migrate from the pigment layer to the superficial parts of the retina as the rod cells degenerate. The pigmentary change spares only the fovea, so that eventually the world is perceived by the patient as though he were looking through narrow tubes.

The many and diverse syndromes to which retinitis pigmen-

tosa may be linked include: oligophrenia, obesity, syndactyly, and hypogonadism (Bardet-Biedl syndrome); hypogenitalism, obesity, and mental deficiency (Laurence-Moon syndrome); Friedreich and other types of spinocerebellar and cerebellar ataxia; spastic paraparesia and quadriplegia with Laurence-Moon syndrome; neurogenic amyotrophy, myopia, and color-blindness; polyneuropathy and deafness (Refsum disease); deaf mutism; Cockayne syndrome and Bassen-Kornzweig disease; and several mitochondrial diseases—particularly progressive external ophthalmoplegia and Kearns-Sayre syndromes.

The differential diagnosis includes the Batten form of cerebroretinal degeneration (ceroid lipofuscinosis), Pelizaeus-Merzbacher disease, and Gaucher disease as well as the various forms of ceroid lipofuscinosis and retinal infections such as syphilis, toxoplasmosis, and cytomegalic inclusion disease.

Virtual blindness is the outcome in many cases, but in others the visual failure stops short of that. It is doubtful whether any of the many proposed modes of therapy (sympathectomy, steroids, vitamins A and E, coenzyme Q₁₀) have any effect in halting the progress of the disease.

Stargardt Disease

This is a bilaterally symmetrical, slowly progressive macular degeneration, differentiated from retinitis pigmentosa by Stargardt in 1909. In essence it is a hereditary (usually autosomal recessive) tapetoretinal degeneration or dystrophy (the latter term being preferred by Waardenburg), with onset between 6 and 20 years, rarely later, and leading to a loss of central vision. The macular region becomes gray or yellow-brown with pigmentary spots, and the visual fields show central scotomata. Later the periphery of the retina may become dystrophic. The lesion is well visualized by fluorescein angiography, which discloses a virtually pathognomonic “dark choroid” pattern. Activity in the electroretinogram is diminished or abolished. Both dominantly inherited Stargardt disease and the closely related cone-rod dystrophy have been linked to a defect on chromosome 6p in some families and 13q in others; the less common recessive variety has been mapped to 1p. In the former type, several gene errors code for a transporter protein (termed ABCR) of the photoreceptor.

This disease, with its selective loss of cone function, is in a sense the inverse of retinitis pigmentosa. According to Cohan and associates, it may be associated with epilepsy, Refsum syndrome, Kearns-Sayre syndrome, Bassen-Kornzweig syndrome, or Sjögren-Larsson syndrome, or with spinocerebellar and other forms of cerebellar degeneration and familial paraplegia.

SYNDROME OF PROGRESSIVE DEAFNESS (See Chap. 15)

There is an impressive group of hereditary, progressive cochleovestibular atrophies that are linked to degenerations of the nervous system. These are the subject of an informative review by Konigsberg and are summarized below. Such neuro-otologic syndromes must be set alongside a group of five diseases that affect the auditory and vestibular nerves exclusively: dominant progressive nerve deafness; dominant low-frequency hearing loss; dominant midfrequency hearing loss; sex-linked, early-onset neural deafness; and hereditary episodic vertigo and hearing loss. The last of these is of special interest to neurologists because both balance and hearing are affected.

It should be pointed out that in 70 percent of cases of hereditary deafness, there are no other somatic or neurologic abnormalities. To date, three separate autosomal mutations have been identified that are associated with this pure “nonsyndromic” type of hereditary deafness, the most common of which is in the connexin gene as discussed in Chap. 15. In one such family from Costa Rica, the gene codes for a protein that regulates the polymerization of actin, the major cytoskeletal component of the hair cells of the inner ear (see review by Pennisi). More recently, a number of mitochondrial disorders have been associated with deafness alone as well as with a number of the better-characterized mitochondrial syndromes (see Chap. 37). The age of onset of hearing loss in the pure forms has been variable, extending well into adulthood.

Hereditary Hearing Loss with Retinal Diseases Konigsmark has separated this overall category into three subgroups: patients with typical retinitis pigmentosa, those with Leber optic atrophy, and those with other retinal changes.

With respect to retinitis pigmentosa, four syndromes are recognized in which retinitis pigmentosa appears in combination: with congenital hearing loss (Usher syndrome); with polyneuropathy (Refsum syndrome); with hypogonadism and obesity (Alstrom syndrome); and with dwarfism, mental retardation, premature senility, and photosensitive dermatitis (Cockayne syndrome).

Hereditary hearing loss with optic atrophy forms the core of four special syndromes: dominant optic atrophy, ataxia, muscle wasting, and progressive hearing loss (Sylvester disease); recessive optic atrophy, polyneuropathy, and neural hearing loss (Rosenberg-Chutorian syndrome); optic atrophy, hearing loss, and juvenile diabetes mellitus (Tunbridge-Paley syndrome); and optocochleodentate degeneration with optic atrophy, hearing loss, quadriplegia, and mental retardation (Nyssen–van Bogaert syndrome).

Hearing loss has also been observed with other retinal changes, two of which might be mentioned here: Norrie disease, with retinal malformation, hearing loss, and mental retardation (oculoacousticocerebral degeneration), and Small disease, with recessive hearing loss, mental retardation, narrowing of retinal vessels, and muscle atrophy. In the former, the infant is born blind, with a white vascularized retinal mass behind a clear lens; later the lens and cornea become opaque. The eyes are small and the iris is atrophied. In the latter, the optic fundi show tortuosity of vessels, telangiectases, and retinal detachment. The nature of the progressive generalized muscular weakness has not been ascertained.

Hereditary Hearing Loss with Diseases of the Nervous System There are several conditions in which hereditary deafness accompanies degenerative disease of the peripheral or central nervous

system. Those associated with mitochondrial encephalopathies have already been mentioned. The other main types with autosomal inheritance include the following:

1. *Hereditary hearing loss with epilepsy.* The seizure disorder is mainly one of myoclonus. In one dominantly inherited form, photomyoclonus is associated with mental deterioration, hearing loss, and nephropathy (Hermann disease). In May-White disease, also inherited as an autosomal dominant trait, myoclonus and ataxia accompany hearing loss. Congenital deafness and mild chronic epilepsy of recessive type have also been observed (Latham-Monro disease).
2. *Hereditary hearing loss and ataxia.* Here Konigsmark was able to delineate five syndromes, the first two of which show a dominant pattern of heredity, the last three a recessive pattern: piebaldism, ataxia, and neural hearing loss (Telfer syndrome); hearing loss, hyperuricemia, and ataxia (Rosenberg-Bergstrom syndrome); ataxia and progressive hearing loss (Lichtenstein-Knorr syndrome); ataxia, hypogonadism, mental deficiency, and hearing loss (Richards-Rundle syndrome); ataxia, mental retardation, hearing loss, and pigmentary changes in the skin (Jeune-Tommasi syndrome).
3. *Hereditary hearing loss and other neurologic syndromes* (see Table 15-1). These include dominantly inherited sensory radicular neuropathy (Denny-Brown); progressive polyneuropathy, kyphoscoliosis, skin atrophy, eye defects (myopia, cataracts, atypical retinitis pigmentosa), bone cysts, and osteoporosis (Flynn-Aird syndrome); chronic polyneuropathy and nephritis (Lemieux-Neemeh syndrome); congenital pain asymbolia and auditory imperception (Osuntokun syndrome); and bulbopontine paralysis (facial weakness, dysarthria, dysphagia, and atrophy of the tongue with fasciculations) with progressive neural hearing loss. The onset of the last syndrome occurs at 10 to 35 years of age; the pattern of inheritance is autosomal recessive. The disease progresses to death. It resembles the progressive hereditary bulbar palsy of Fazio-Londe except for the progressive deafness and loss of vestibular responses. Regrettably, in most of these syndromes, there are no data regarding labyrinthine function.

The details of these many syndromes are contained in Konigsmark's review. The main syndromes are listed in Table 15-1 (page 254) and have been summarized here in order to increase awareness of the large number of hereditary-degenerative neurologic diseases for which the clue is provided by the detection of impaired hearing and labyrinthine functions.

CHAPTER 40

THE ACQUIRED METABOLIC DISORDERS OF THE NERVOUS SYSTEM

An important segment of neurologic medicine and one that is seen with great frequency in general hospitals consists of disorders in which a global disturbance of cerebral function (encephalopathy) results from failure of some other organ system—heart and circulation, lungs and respiration, kidneys, liver, pancreas, and the endocrine glands. Unlike the diseases considered in Chap. 37, in which a genetic abnormality affects the metabolic functions of many organs and tissues, including the brain, the cerebral disorders discussed in this chapter are strictly secondary to derangements of the visceral organs themselves. They stand at the interface of internal medicine and neurology.

Relationships of this type, between an acquired disease of some thoracic, abdominal, or endocrine organ and the brain, have rather interesting implications. In the first place, recognition of the neurologic syndrome may be a guide to the diagnosis of the systemic disease; indeed, the neurologic symptoms may be more informative and significant than the symptoms referable to the organ primarily involved. Moreover, these encephalopathies are often reversible if the systemic dysfunction is brought under control. Neurologists must therefore have an understanding of the underlying medical disorder, for this may provide the means of controlling the neurologic part of the disease. In other words, the therapy for what appears to be a neurologic disease lies squarely in the field of internal medicine—a clear reason why every neurologist should be well trained in internal medicine. Of more theoretical importance, the investigation of the acquired metabolic diseases may provide new insights into the chemistry and pathology of the brain. To select a single example, the discovery of an episodic encephalopathy that is associated with advanced liver disease and portacaval shunts opened a vast new area in brain chemistry, pertaining to the effect of ammonia on glutamine metabolism, and has brought to light an intriguing histopathologic change—a relatively pure hyperplasia of protoplasmic astrocytes. Each visceral disease affects the brain in a somewhat different way, and since the pathogenic mechanism is not completely understood in any of them, the study of these metabolic diseases promises rich rewards to the scientist.

In Table 40-1 the acquired metabolic diseases of the nervous system are classified according to their most common modes of clinical expression. Not included are the diseases due to nutritional deficiencies and those due to exogenous drugs and toxins, which can be considered metabolic in the broad sense; these are presented in the following chapters.

METABOLIC DISEASES PRESENTING AS A SYNDROME OF CONFUSION, STUPOR, OR COMA

The syndrome of impaired consciousness, its general features, the terms used to describe it, and the mechanisms involved are dis-

cussed in Chap. 17, which serves as an introduction to this section. There it is pointed out that metabolic disturbances are frequent causes of impaired consciousness and that their presence must always be considered when there are no focal signs of cerebral disease and both the imaging studies and the cerebrospinal fluid (CSF) are normal. Intoxication with alcohol and other drugs figures prominently in the differential diagnosis. *The main features of the reversible metabolic encephalopathies are mental confusion, typified by disorientation and inattentiveness and accompanied in certain special instances by asterixis, tremor, and myoclonus, but usually without signs of focal cerebral disease.* This state may progress in stages to one of stupor and coma. Slowing of the background rhythms in the electroencephalogram (EEG) reflects the severity of the metabolic disturbance. With few exceptions, usually pertaining to cerebral edema, imaging studies are normal.

Laboratory examinations are highly informative in the investigation of the acquired metabolic diseases. In every patient with symptoms suggestive of a metabolic encephalopathy, the following determinations should be made: serum Na, K, Ca, glucose, BUN, NH₃, and osmolality. If there is evidence of hypoxia or the patient is known to have chronic obstructive airway disease, determination of arterial pH, PCO₂ and PO₂ are carried out as well. Serum osmolality can be measured directly or calculated from the values of Na (meq/L, K meq/L), glucose, and BUN (in mg/dL), using the following formula:

$$\text{Serum osmolality} = 2[(\text{Na}) + (\text{K})] + \text{glucose}/18 + \text{BUN}/3$$

When there is a discrepancy between the calculated and the directly measured osmolalities, it can be assumed that additional circulating ions are present. Most often they are derived from an exogenous toxin or drug such as mannitol, but renal failure, ketoacidemia, and an increase of serum lactate may also result in the accumulation of small molecules that contribute to the serum osmolality.

Where an exogenous toxin is suspected of causing an encephalopathy and in all cases where the cause is unknown, a “toxic screen” of blood and urine, using high-pressure liquid chromatography, should be obtained. A point to be remembered is that the brain may be damaged, even to an irreparable degree, by a disturbance of blood chemistry (e.g., hypoglycemia, hypoxia) that has vanished by the time the patient is examined.

Ischemic-Hypoxic (Ischemic-Anoxic) Encephalopathy

Here the basic disorder is a lack of oxygen and of blood flow to the brain, the result of failure of the heart and circulation or of the lungs and respiration. Often both mechanisms and both organ failures are responsible and one cannot say which predominates; hence the dually ambiguous allusions in medical records to “cardiores-

Table 40-1**Classification of the acquired metabolic disorders of the nervous system in adults**

- I. Metabolic diseases presenting as a syndrome of confusion, stupor, or coma
 - A. Ischemia-hypoxia
 - B. Hypercapnia
 - C. Hypoglycemia
 - D. Hyperglycemia
 - E. Hepatic failure
 - F. Reye syndrome
 - G. Azotemia
 - H. Disturbances of sodium, water balance, and osmolality
 - I. Hypercalcemia
 - J. Other metabolic encephalopathies: acidosis due to diabetes mellitus or renal failure (see also inherited forms of acidosis, in Chap. 37); Addison disease
 - K. Hashimoto disease encephalopathy
- II. Metabolic diseases presenting as a progressive extrapyramidal syndrome
 - A. Acquired hepatocerebral degeneration
 - B. Hyperbilirubinemia and kernicterus
 - C. Hypoparathyroidism
- III. Metabolic diseases presenting as cerebellar ataxia
 - A. Hypothyroidism
 - B. Hyperthermia
 - C. Celiac sprue disease
- IV. Metabolic diseases causing psychosis or dementia
 - A. Cushing disease and steroid encephalopathy
 - B. Hyperthyroid psychosis and hypothyroidism (myxedema)
 - C. Hyperparathyroidism
 - D. Pancreatic encephalopathy (?)

piratory failure" and in neurologic notations to "ischemic-hypoxic" encephalopathy.

Ischemic-hypoxic encephalopathy in various forms and degrees of severity is one of the most frequent and disastrous cerebral disorders encountered in the emergency departments and recovery rooms of every general hospital. The medical conditions that most often lead to it are as follows:

1. A reduction in cerebral blood flow as a result of myocardial infarction or ventricular arrhythmia, external or internal blood loss, and septic or traumatic shock—in all of which circumstances cardiac function fails before that of respiration
2. Hypoxia from suffocation due to drowning, strangulation, or aspiration of vomitus, food, or blood; from compression of the trachea by a mass or hemorrhage; or from tracheal obstruction by a foreign body
3. Carbon monoxide (CO) poisoning, in which respiration fails first and then the cardiovascular system
4. Diseases that paralyze the respiratory muscles (Guillain-Barré syndrome, amyotrophic lateral sclerosis, myasthenia, and, in the past, poliomyelitis) or damage the central nervous system (CNS) diffusely but the medulla specifically, again with respiratory failure being the initial factor, followed by cardiac failure
5. A general anesthesia accident during which the patient is exposed to inspired gas that is oxygen-deficient

When blood flow is stable, the most important element in the delivery of oxygen is the oxygen content of the blood. This is the product of hemoglobin concentration and the percentage of oxygen saturation of the hemoglobin molecule. At normal temperature and pH, hemoglobin is 90% saturated at an oxygen partial pressure of 60 mmHg and still 75% saturated at 40 mmHg; i.e., as is well known, the oxygen saturation curve is not linear. The product of the oxygen content and the cardiac output is the ultimate determinant of the adequacy of oxygen supply to the organs.

Reduced to the simplest formulation, a deficient supply of oxygen to the brain is due either to a failure of cerebral perfusion (ischemia) or to a reduced amount of circulating arterial oxygen, the result of diminished oxygen saturation, or insufficiency of hemoglobin (hypoxia). Although they are often combined, the neurologic effects of ischemia and hypoxia are subtly different.

Physiology of Ischemic and Hypoxic Damage A number of physiologic mechanisms of a homeostatic nature protect the brain under conditions of both ischemia and hypoxia. Through a mechanism termed *autoregulation*, there is a compensatory dilatation of resistance vessels in response to a reduction in cerebral perfusion, which maintains blood flow at a constant rate, as noted in Chap. 34. When the cerebral blood pressure falls below 60 to 70 mmHg, an additional compensation in the form of increased oxygen extraction allows normal energy metabolism to continue. In total cerebral ischemia, the tissue is depleted of its sources of energy in about 5 min, although longer periods are tolerated under conditions of hypothermia. Also, energy failure due to hypoxia is counteracted by an autoregulatory increase in cerebral blood flow; at a PO₂ of 25 mmHg, the increase in blood flow is approximately 400 percent. A similar increase in flow occurs with a decrease in hemoglobin to 20 percent of normal.

In most clinical situations in which the brain is deprived of adequate oxygen, as already commented, there is a combination of ischemia and hypoxia, with one or the other predominating. The pathologic effects of ischemic brain injury from systemic hypotension differ from those due to pure anoxia. Under conditions of ischemia, the main damage takes the form of incomplete infarctions in the border zones between major cerebral arteries. With anoxia, neurons in portions of the hippocampus and the deep folia of the cerebellum are particularly vulnerable. More severe degrees of either ischemia or hypoxia lead to selective damage to certain layers of cortical neurons, and if more profound, to generalized damage of all the cerebral cortex, deep nuclei, and cerebellum. The nuclear structures of the brainstem and spinal cord are relatively resistant to anoxia and hypotension and stop functioning only after the cortex has been badly damaged.

The cellular pathophysiology of neuronal damage under conditions of ischemia is discussed in Chap. 34. Essentially, the mechanism of injury is an arrest of the aerobic metabolic processes necessary to sustain the Krebs (tricarboxylic acid) cycle and the electron transport system. Neurons, if completely deprived of their source of energy, proceed to catabolize themselves in an attempt to maintain their activity and in so doing are damaged to a degree that does not permit their survival—i.e., they undergo necrosis. The accumulation of catabolic products (particularly lactic acid) in the interstitial tissue contributes to the parenchymal damage. Ultimately, the accumulated injury leads to cell death, probably through more than one mechanism. The most acute forms of cell death are characterized by massive swelling and necrosis of neuronal and nonneuronal cells (cytotoxic edema). Short of immediate

ischemic necrosis, a series of internally programmed cellular events may also propel the cell toward death in a delayed fashion, a process for which the term *apoptosis* has been borrowed from embryology. There is experimental evidence that certain excitatory neurotransmitters, particularly glutamate, contribute to the rapid destruction of neurons under conditions of anoxia and ischemia (Choi and Rothman); the pertinence of these effects to clinical situations is uncertain. Ultimately, this process may be affected by massive calcium influx through a number of different membrane channels, which activates various kinases that participate in the process of gradual cellular destruction. There is also a poorly understood phenomenon of delayed neurologic deterioration after anoxia; this may be due to the blockage or exhaustion of some enzymatic process during the period when brain metabolism is restored.

Clinical Features of Anoxic Encephalopathy *Mild degrees of hypoxia without loss of consciousness* induce only inattentiveness, poor judgment, and motor incoordination; in our experience there have been no lasting clinical effects in such cases, though Hornbein and colleagues found, on psychologic testing, a slight decline in visual and verbal long-term memory and mild aphasic errors in Himalayan mountaineers who had earlier ascended to altitudes of 18,000 to 29,000 ft. These observations make the point that profound anoxia may be well tolerated if arrived at gradually. For example, we have seen several patients with advanced pulmonary disease who were fully awake when their arterial oxygen pressure was in the range of 30 mmHg. This level, if it occurs abruptly, causes coma. *An important derivative rule is that degrees of hypoxia that at no time abolish consciousness rarely if ever cause permanent damage to the nervous system.*
